University of Peshawar
Khyber Pakhtunkhwa, Pakistan

Preface

Way back in 1999, one of us (M. Qasim Jan) submitted a research proposal (titled, Geological Bibliography of northern Pakistan up to AD 2002) to Pakistan Science Foundation (PSF) for funding. The members of Technical Committee, notably Dr. Khalid Mahmood Khan, the then Chairman of PSF, Dr. M. Nawaz Chaudhry, Professor of Geology at Punjab University, Lahore, and Mr. S. Hasan Gauhar, Director General of the Geological Survey of Pakistan (DG, GSP), insisted that the bibliography, instead, should be annotated. The suggestion was reluctantly accepted, without fully realizing the immensity of the task that would take us so many years, and yet be incomplete.

This document covers the Khyber Pakhtunkhwa and its adjacent Tribal territory, Potwar-Islamabad-Murree areas of Punjab, Azad Jammu and Kashmir, and Gilgit-Baltistan. Publications on the foreland basin molasse sediments of the Salt Range have been included for completing references on the Siwaliks of Pakistan. This work incorporates published and publicly available documents related to solid earth sciences and water resources. References to many of the expedition reports and local publications have been given despite our lack of access to them. We would appreciate receiving information on references which have not been annotated or not included.

In this age of fast and efficient communication and availability of so much online information, the need for publication of this manuscript can be debated. However, it can be justified on the ground that it provides ready access to a pool of large number of contributions, including local publications, many of which are not available online. It is hoped that this work would be of substantial use to the earth scientists and those engaged with natural resources, natural hazards, planning and development.

The Pakistan Science Foundation is thanked for having provided seed grant for the execution of this project. We appreciate the continued support of the National Centre of Excellence in Geology, University of Peshawar. Dr. Imran A. Khan, DG GSP and Mr. Asif Nazeer Rana, Director of the Geoscience Laboratory of the GSP, provided a large number of GSP publications, Dr. MonaLisa facilitated access to student theses submitted to Quaid-i-Azam University, Islamabad, and Mr. A. Wahab, Mrs. Malka Saimeen Ozar, Hafiz Shahid Hussain and Mr. Shahid Waheed of our Centre remained helping hands at various stages. We thank them all.

M. Qasim Jan (mqjan@yahoo.com)

A/1. Abass, S.F.A., Amin, M. & Siddiqui, F.A., 1967. Talc deposits of Jamrud, Khyber Agency. Pakistan Journal of Scientific and Industrial Research 10, 300-303.

Geology and chemical composition of the talc deposits have been investigated. Two veins, about 3km apart, contained about 40,000 tons of talc. Talc is of fairly good quality, and suitable for use in the cosmetic, pottery, paper, textiles, tile preparation, and soap industry. Improved mining methods are recommended for winning the maximum %age of talc.

Key Words: Talc, Khyber Agency, Jamrud.

A/2. Abbas, A., 1843. Journey of a tour through parts of Punjab and Afghanistan, in the year 1837. Asiatic Society of Bengal Journal 12, 564 - 621.

This is a travelogue of the area stretching from the Salt Range to Waziristan, through Peshawar, Kohat and Kurram Agency. Written in Persian, it was translated into English by Major R. Leech. It contains brief mention of the occurrence of salt at Kalabagh and Karak, antimony in Kurram, and coal and iron in Kanigurum.

Key words: Afghanistan, FATA, Salt Range, Punjab.

A/3. Abbas, S.A., 1996. Mapping of the weathered and sub-weathered layers from seismic refraction rate in Ghaghriot area, Islamabad. M.Sc. Thesis, Quaid-i-Azam University, Islamabad.

The seismic refraction data of 'Ghaghriot' village, Islamabad has been reinterpreted with a view to map the weathered and sub weathered layer and establish a relationship between the velocity and lithology of the area. The data was of 25 spreads with reverse shooting scheme. After plotting the travel time curves the velocities and depths were determined and were put in the form of Isovelocity maps of V0, V1 and V2 and Isopach maps of Z0 and Z1. An integrated study of these maps with the tubewell logs and VES columns reveal the following results.

The velocity of weather layer ranges from 333 m/sec to 620 m/sec and the thickness from 2.6m to 5.6 meters. It is composed of clay, silt and sand. The velocity of subweathered layer varies from 1358 m/sec to 1655 m/sec and its thickness varies from 18.9 to 35.1 m. It is composed of boulder and gravel with lesser amount of clay. This thick bed of boulder and gravel is saturated with water and water table varies from a depth of 4m -5m. The velocity of third layer varies from 1974 m/sec to 3096 m/sec showing the presence of interbedded clay within the gravel and boulder layer. It is also saturated with water.

A/4. Abbas, S.G., 1974. Brief report on geology of chromite deposits near Bucha Village, Mohmand Agency, Malakand Division. Geological Survey of Pakistan, Information Release 87, 7p.

Small Chromite bodies were found associated with ultramafic rocks, during a one day reconnaissance traverse near Bucha Village, Mohmand Agency, Malakand Division. The examined area appears to have some economic potential, as Chromite is believed to be of metallic grade and number of boulders indicate the presence of more Chromite bodies which could not be found out during the short time available for investigation. Boulders also show the presence of massive magnetite and haematite probably derived from the adjoining area.

Key words: Chromite, ultramafic rocks, Mohmand Agency.

A/5. Abbas, S.G., 1992. Prospects for metallic minerals in Pakistan. GSP, Information Release 520, 11p.

This report gives brief information on metallic minerals of Pakistan and includes those reported from the northern parts of the country. A generalised summary report describing present status and future prospects of Aluminium, Chromium, Copper, Lead-Zinc, Gold, Silver, Iron, Platinum, Tungsten and Lithium.

Key words: Metallic minerals, economic geology.

A/6. Abbas, S.G., & Rossman, D.L., 1969. Geology and economic potential for Chromite, Dargai Ultramafic Complex, Malakand Agency, Peshawar Division, West Pakistan. GSP and U. S. Geological Survey Project Report, PK Series, PK (IR)–51.

This report presents the geology of the area, along with information on ultramafic rocks including dunites and peridotites. There is some detail on the occurrence and economic potential of the chromite deposits. The report is accompanied by detailed maps (1:25000) and cross-sections.

Key words: Indus Suture, ultramafic rocks, chromite, Malakand Agency

A/8. Abbas, S.Q., Bhatti, M.A., Pasha, M.K. & Din, F., 1992. Structural analysis of Margala-southern Hazara fold belt. Abstracts, First South Asia Geological Congress, Islamabad, p.50.

The structural behavior inferred from the geological mapping of the Margala and southern Hazara Hills depicts that the area is fault propagated folded belt which is characterised by the sub- thrusting and isoclinal folding. On the northern margin of this belt lies the Nathiagali Thrust whereas the southern boundary is marked by the presence of the Main Boundary Thrust (MBT). It is also evident that the folding thus developed within the Jurassic-Miocene sedimentary rock sequence have been truncated as a result of subsequent thrusting and back thrusting. The ramping of the MBT has placed the Jurassic-Pliocene strata to come to abnormally in contact with the Eocene-Miocene rocks.

In the north, this belt has been overrun by the Pre-Cambrian flysch deposits of Hazara Formation while it is riding over the Eocene-Miocene rocks of the Potwar foredeep in the South. An attempt has been made to illustrate the tectonic model of the folded belt by balancing the selected cross-sections across this structural block.

Key words: Structural analyses, Margala, Hazara.

Key words: Foreland Basin, fluvial facies.

A/13. Abbasi, I.A., 1991. Large scale vertical aggradation of sandstones in the Kamlial Formation of the Kohat basin, Pakistan. Geological Bulletin, University of Peshawar 24, 33-44.

The Kamlial Formation in the Kohat fold-thrust belt is composed dominantly of thick sandstone interbedded with siltstone and intraformational conglomerate. The sandstone bodies are over 100 meter thick in the upper part and, on the average, 30 meter thick in the lower and middle part of the formation. The sandstone bodies are multistoried and their large thicknesses are due to vertical and lateral amalgamation of sand bodies deposited in a slowly subsiding foreland basin. An average thickness of 4-6 meter has been estimated for the individual sand bodies deposited by 6-8 meter deep, intermediate to high sinuosity streams. Tabular sand bodies interbedded with overbank fines were deposited by high sinuosity streams. The drainage system during the deposition of the Kamlial Formation in the Kohat foreland basin was mainly flowing to the east, which is consistent with that of the Potwar Plateau.

Key words: Siwalik Molasse, Kamlial Formation, Kohat.

A/14. Abbasi, I.A., 1992. Major patterns of fluvial facies of the Himalayan foreland-basin in the trans-Indus area, Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.1.

Molasse sediments (over 6 km thick) were accumulated in the western Himalayan foreland-basin (Kohat area) and reflect the subsidence of the basin, and approach of the Himalayan orogenic belt. The succession is composed largely of sand and silt in the lower part, and conglomerate in the upper part. The sand-bodies in the sand silt succession are mainly composed of plane bedding, low-angle plane bedding and trough cross bedding. The abundance of plane bedding and low-angle plane bedding suggest deposition from high energy flow conditions commonly associated with low-sinuosity river systems. The sand-bodies are usually 10 to 20 metres thick in the lower part, but up to 100 meters thick and many km in lateral extent in the upper part of the succession. The earliest recorded progradation of proximal conglomeratic facies over the finer grained sediments occurred in the Kohat area of the foreland-basin during Late Miocene. The coarser grained facies probably appeared in response to the northward drift of the depositional area closer to the source area, and the site became the proximal part of a large fluvial system. The thick polymict succession comprised of clast supported massive conglomerate, crudely stratified to horizontally bedded, and planar cross-bedded conglomerate assemblages suggest deposition by proximal braided streams. The early appearance of thick proximal plain facies suggests that the major palaeo-river system entered the foreland-basin through the Kohat area earlier than 10 Ma, approximately along the present day course of the Indus River.

A/16. Abbasi, I.A., 1994b. Clay minerals in the Himalayan foreland basin sediments: Implications for the progress unroofing of an orogenic belt. In: Ahmed, R. & Sheikh, A.M. (Eds.), Geology in South Asia-I. Proceedings of the First South Asia Geological Congress, Islamabad, 1992. Hydrocarbon Development Institute of Pakistan, Islamabad, 280-284.

A sequence of over 6km thick detrital sedimentary rocks is exposed in the Kohat area, western Himalayan foreland basin. These rocks are grouped into two coarsening-upward sequences: the basal Rawalpindi Group and upper Siwalik Group. Clay-mineral studies from silt and clay beds through this succession reflect a fairly consistent mineralogy, but relative abundance of different minerals varies across the succession. Chlorite content decreases upsection with a corresponding increase in the smectite content. The proportion of muscovite/illite remains constant. Muscovite/illite crystallinity increases progressively upsection, showing highest crystallinity values in the Shakardarra Formation, which makes up the upper part of the Siwalik Group. The variations in the mineral abundance and inverse trends in the muscovite/illite crystallinity are probably due to progressive unroofing of an orogenic belt in the source area exposing higher grade metamorphic and igneous rocks.

Key words: Clay Minerals, orogeny.

A/17. Abbasi, I.A., 1994c. Fluvial architecture and depositional system of the Miocene molasse sediments, Shakardarra Formation, southeastern Kohat, Pakistan. *Geological Bulletin, University of Peshawar* 27, 81-98.

The Neogene molasse sediments in southeastern Kohat area are divided into two groups, the Rawalpindi, and the Siwalik groups. The Siwalik Group in the study area, around Shakardarra town, is a coarsening upward sequence of silt dominated Chinji Formation, sand dominated Shakardarra Formation, and polymictic conglomerate dominated Indus conglomerate Formation. The Shakardarra Formation is comprised of sandstone-siltstone in the basal part, dominantly sandstone in the middle part and sandstone –conglomerate in the upper part. The major sandstone-bodies, on average, are up to 15m thick and many km in lateral extent in the lower part, whereas, upto 100m thick and tens of kilometers in lateral extent in the middle and upper parts. The sandstone-bodies are multistoried, and are characterised by inchannel lithofacies such as plane bedding, low angle plane –bedding and trough cross-bedding. A number of bar macroforms and channel features of different hierarchical order have been observed in the sandstone-bodies. A high-energy braided river system is suggested for the deposition of the sediments. The paleoriver system was flowing approximately parallel to the present day Indus River and entered the foreland basin through the study area at least since last 10 Ma.

Key Words: Siwalik Molasse, Shakardarra Formation, Kohat.

A/18. Abbasi, I.A., 1997a. Sedimentology and tectonic setting of polymictic conglomerates in a rapidly subsiding Miocene-Pliocene Foreland Basin: Kohat Plateau, Northern Pakistan. *Geological Bulletin, University of Peshawar* 30, 297-309.

More than 6km of Neogene molasse sediments of the Rawalpindi and Siwalik Groups accumulated in the western Himalayan (Kohat) foreland basin, northern Pakistan, in response to active basin subsidence and orogenic uplift. In the Kohat Plateau, the Siwalik Group consists of a coarsening upward sequence of silt in the lower part (Chinji Formation), sand in the middle part (Shakardarra Formation) and conglomerate (Janak Conglomerate Formation) in the upper part. This formation was previously named as the Indus Conglomerate Formation by Abbasi and Friend (1989), but I now propose that it should be called the Janak Conglomerate Formation. This new name is proposed because of the danger that the previous name will be confused with stratigraphic terms used in the Indus Suture Zone of Ladakh, India, where the terms Indus Group, Indus Formation, Indus Molasse and Indus Flysch have all been used in recent years (e.g. Srivastava, et al., 1979; Searle et al., 1990; Searle, 1996). The name of Janak belongs to a village located on the northwestern edge of the outcrop area of the formation, at 71°38'30"E, and 33°14'30" N (Fig. 2). The Janak Conglomerate Formation is exposed over an area of 400km², and is about 1500m thick. The conglomerate/sandstone ratio is 1:1 in the lower part and increases to 4:1 in the middle and upper parts. The formation is laterally variable but consists of three main lithofacies i.e., a) crudely stratified to horizontally bedded conglomerate (Gh), b) massive, clast supported conglomerate (Gm), and c) planar cross-stratified conglomerate (Gp). In lithofacies Gp, some of the cross-sets are up to 7m thick suggesting channels as deep as 14m or more. However, the average thicknesses of the cross-sets are 3-5m, suggesting channels 6-10 m deep. The progradation of the conglomerates over the finer grained formations is probably mainly a response to this depositional site on the Indian plate, to the progressive movement of the plate towards the uplifted Himalaya. But in the Kohat area, the late Miocene progradation of the conglomerates is distinctly earlier than elsewhere in the western Himalayan foreland basin. The conglomerates pass laterally into the finer grained facies of the Nagri and Dhok Pathan formations to the east and south of the Kohat basin, and also pass into finer

grained sediments to the west. This suggests that it was in this area that the largest river system entered the western foreland, about 10 ma, approximately along the course of the present-day Indus river.

A/19. Abbasi, I.A., 1997b. Channel pattern and range front influence on the Indus River, Punjab Plain, Pakistan. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p. 3.

The Indus River is one of the world's major river systems and is the largest in Pakistan which along with its tributaries drain most part of the Punjab plain. The river pattern is control by bed-rock structures and morphology in the higher mountains and foreland fold-thrust belt, and by its own alluvium in the Punjab plain. Data from Survey of Pakistan topo sheets, satellite images and some old maps were used to interpret the channel pattern and the influence of range fronts i.e., Suleiman Range on the lateral migration of the river system. Wada's reports (Attalla, 1970) and later, are used for water discharge and sediment load.

Average annual sediment load at Methanol (at the confluence of five Punjab Rivers called Punned) was calculated as about 600x1'09 kg (Attalla 1970). New estimates of Millikan and Meade (1983) have shown an annual sediment discharge of about 110x109 kg at the mouth of Indus River due to enormous silting in large reservoirs. The combined waters of Punned River have over 70% of their sediment load in the form of clay and silt in suspension which has a major influence on the channel pattern further downstream. The river system changes its morphology from a strongly braided in the north, to a meandering system in the south due to decrease in gradient (11cm/km) and high suspended load. The river system is multichannel, low sinuosity in the northern reaches with a 'Total Sinuosity' (Rintoul and Richards, 1993) of 3.5 and a strong braiding element. It is transitional between meandering and braided, rather more of an anastomosed type in its middle reaches with a 'Total Sinuosity' of 2.5. South of Mithankot, the river flows as a single, large sinuous system and the 'Total Sinuosity' decreases to 1.5. The Miocene and younger molasse sediments in the Kohat and Trans Indus Ranges and in Indus fan delta suggest that the Indus river occupied its present course at about 8 Ma (Abbasi and Friend, in press). Major thrust loading along the Sulaiman and other western ranges may have controlled the flow direction along their axis since then. The present day river system shows a tendency to migrate laterally towards the range front. A similar range front control is also evident for the Jhelum River due to thrust loading along the Salt Range Thrust.

Key words: Indus river, channel pattern, Punjab plain.

A/20. Abbasi, I.A., 1998. Major patterns of fluvial facies and evolution of the Himalayan foreland basin, southeastern Kohat Plateau, Pakistan. In: Ghaznavi, M.I., Raza, S.M. & Hasan, M.T. (Eds.), Siwaliks of South Asia, 59-96 Geological Survey of Pakistan, Islamabad.

Key words: Siwalik Molasse, sedimentology, Kohat.

A/22. Abbasi, I.A., 2001. Post Miocene gravel progradation in the western Himalayan foreland basins, Kohat Plateau, northern Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p. 21.

The sedimentary detritus shed by the Himalayan collision belts and accumulated in the foreland basin, allow correlation between the tectonic processes, lithologies involved in deformation and the resulting sediments. Thick coarsening upward molasse sediments deposited by major river systems characterize the Kohat foreland basin along the western fringes of the orogenic belt. Coarse-grained gravel sequences are deposited in the upper part of the

Siwalik Group as proximal alluvial plain facies. Two major polymictic conglomerate sequences are described from the southeastern and western part of the Kohat plateau.

In the southeastern part of the plateau, near Shakardarra town, the conglomerate sequence named as the “Janak Conglomerate”, is considered to be Miocene in age. The conglomerate has a transitional contact with the underlying Shakardarra Formation (Nagri Formation), and is comprised of thick gravel beds interbedded with sandstone. The formation is exposed over an area of 400 km², and is about 1500m thick. The conglomerate/sandstone ratio is 1:1 in the lower part and increases to 4:1 in the middle and upper parts. The clasts are comprised of gneisses, volcanics, schists, granites and quartzites, derived from the igneous and metamorphic belts of the higher and lower Himalayas, and deposited by a trunk river system analogous to the Indus River. In the southwestern part of the plateau, near Zarwam area, an approximately 2500m thick conglomerate sequence is named as the ‘Ahmedzai Conglomerate’. The Ahmedzai Conglomerate is considered as Pliocene-Pleistocene in age and has a transitional contact with the underlying Dhok Pathan Formation.

The conglomerate is comprised of clasts belonging to limestone, quartzite, chert, ultramafics and serpentinites - derived mainly from the western ranges of Waziristan and Parachinar. The conglomerates were deposited by the Kuram River, a major western tributary of the Indus River. The source area for these conglomerates is interpreted as the north Waziristan-Thal collision belt, dominated by the Cretaceous-Palaeocene igneous complex, and Mesozoic and younger carbonate rocks. The conglomerates of the Janak Formation represent deposition by a large trunk river system draining through the higher and lower Himalayan zones and are described as the high mountain fed conglomerates. These middle and lower Siwalik conglomerates provide information about the extent of older incision in the high mountains, and the portion in the basin of the major drainage path. The clasts of the Ahmedzai Conglomerate represent deposition by tributary streams draining the foothills, and are widespread along the mountain fronts. These upper Siwalik conglomerates provide information about relatively young frontal fault activity and growth of local river systems, such as Kuram River.

Key words: Siwalik molasse, sedimentology, Kohat.

A/23. Abbasi, I.A., Abid, I.A. & Khan, M.A., 1983. Statistical study of the Dhok Pathan Formation, Puki Gudikhel, Surghar Range, Karak. Geological Bulletin, University of Peshawar 16, 85-96.

Size analyses of a part of the Dhok Pathan Formation, Surghar Range, was carried out to study the behavior of different size fractions and to interpret the environments of deposition. The measures obtained on phi-scale reveal that the sandstone of the area is medium to fine-grained, moderately sorted, positively skewed and has platykurtic distribution. The C-M pattern for these sediments suggests suspension and tractive current deposits, and is comparable in appearance with the basic pattern IV and V of Passega (1957). There is no systematic horizontal or vertical variation in different statistical measures but present a rather zigzag pattern, which indicates that the material of variable size was brought to the basin between each cycle.

Key words: Siwalik Molasse, Dhok Pathan Formation, Surghar Range, Karak.

A/24. Abbasi, I.A. & Ali, F., 2000. Tectonic significance of Pliocene-Pleistocene polymictic conglomerates exposed along the western margin of Indian plate; Bannu-Waziristan area, North Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, p.36.

Thick molasse sediments of the Rawalpindi and Siwalik Groups are exposed over a large area around Bannu and North Waziristan, along the western margin of the Indian Plate. The base of the molasse sequence is defined by the Kamli Formation, overlain by the Chinji, Nagri and Dhok Pathan formations. The uppermost part of the sequence is comprised of over 2 km thick conglomerate interbedded with sandstone, known as Ahmedzai Formation. The best exposures of the conglomerate are along the Ahmedzai Syncline, North of Bannu town. The conglomerates of the Ahmedzai Formation are comprised of clasts derived from the Mesozoic and Tertiary carbonate sequences, quartzites, and from mélange zones. The clasts from mélange zones are represented by abundant chert, ultramafics such as serpentinites, and some volcanics. The material is contributed from within the Kunam Mélange Zone, located to the West of the study area. Isolated outcrops of ultramafic lithologies associated with the Paleocene abduction, due to collision along the western margin of the Indian Plate with Afghan block, are exposed in areas such as Kai and North Waziristan. The conglomerates were deposited by a river system analogous to present-day Kurrarn river draining through the western ranges, such as Koh-e-Sufaid and Kurram Mélange zone. Angular to

subangular clasts of ultramafics, particularly the serpentinites, indicate a close by source area and little transportation.

A/25. Abbasi, I.A. & Friend, P.F., 1989. Uplift and evolution of the Himalayan orogenic belts, as recorded in the foredeep sediments. In: Derbyshire, E. & Owen, L.A. (Eds.), *The Neogene of the Karakoram and Himalayas*. *Zeitschrift fur Geomorphologies*, Special Publication 76, 75-88.

Key words: Siwalik molasse, Sedimentology, Himalaya.

A/26. Abbasi, I.A. & Friend, P.F., 1993. Fluvial sole structures from the Siwalik Group north Pakistan. *Geological Bulletin, University of Peshawar* 26, 103-112.

The Siwalik Group consists of over 6 km of fluvial clastic sediments, fluvial cycles of thick sandstone (5-20 m) and siltstones (5-50 m) are common particularly in the Chinji Formation. Sole structures are well developed on the base of the sandstone bodies and represent an early phase of erosion of the overbank fines related to channel evulsion before deposition of major sandstone. Examples from the Chinji and Shakardarra formations include gutter casts, crescent marks, and flute marks all due to aqueous scour. Polygonal marks and pedestal structures, meters across, and locally metres in relief, may be subaqueous or sub-aerial in origin.

Key words: Sedimentology, Siwalik molasse, Chinji Formation, Shakardara Formation.

A/27. Abbasi, I.A. & Friend, P.F., 1997. The Neogene of Janak Conglomerate Formation of northern Pakistan: Stratigraphic effects of continental convergence and drainage. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. *Geological Survey of Pakistan, Records* 109, 32-33.

Over 6 km thick Neogene molasse sediments were deposited in the western Himalayan foreland basin in Kohat area in response to active deformation along the orogenic belt and its gradual migration in the foreland basin. In south eastern Kohat area, west of Indus river the sediments are characterised by two coarsening upward sequences of Rawalpindi and Siwalik groups. The Siwalik Group is comprised of an overbank fines rich the Chinji Formation, an inchannel sand rich the Shakardarra Formation and an upper coarse grained polymictic conglomerate rich the Janak Conglomerate Formation. This formation was first named the Indus Conglomerate Formation by Abbasi & Friend (1989), but we now propose that it should be called the Janak Conglomerate Formation. We propose this new name because of the danger that our previous name will be confused with stratigraphic terms used in the Indus Suture Zone of Ladakh, India, where the terms Indus Group, Indus Formation, Indus Molasse and Indus Flysch have all been used in recent years (e.g. Srivastava, Pal and Mathur, 1979; Searle, Pickering and Cooper, 1990). The name of Janak belongs to a village located on the northwestern edge of the outcrop area of the Formation, at 71°38'30"E, and 33°14'30"N.

The study of the Siwalik Group of the Potwar area by Gill (1952), was the first in which it was recognised that the mainly sandstone-dominated successions of the central Potwar are the lateral equivalents of major conglomerates further west, near the Indus River. Outcropping on both Kohat and Potwar sides of the Indus River, these form the Janak Conglomerate. The Janak Conglomerate Formation was deposited by a large (approximately 15 m deep) river draining southwards from the High-Himalayas of northernmost Pakistan. The deposition appears to have started about 8 Ma ago and lasted until Quaternary times. The formation has a thickness of about 1500 metres, and a lateral extent perpendicular to general river flow of about 25 km.

Comparison with other conglomerate occurrences along the Himalayan front shows that a distinction can be made between foothills-fed conglomerates, for which clasts came from local source areas, that were being uplifted along thrusts in the Sub-and Lower Himalayas during Upper Siwalik deposition.

High-mountain-fed conglomerates, for which clasts came from all the Himalayan lithotectonic zones. These conglomerates were formed by large rivers, involving drainage of the whole Himalayan belt, and conglomerates of this type are found in both Middle and Upper Siwalik deposits. The Janak Conglomerate Formation is of this type, and was formed by the paleo-Indus.

Key words: Janak Conglomerate Formation, Siwalik Molasse.

A/28. Abbasi, I.A. & Friend, P.F., 2000. Exotic conglomerates of the Neogene Siwalik succession and their implications for the tectonic topographic evolution of the western Himalaya. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication, 170, 455-466.

Published information on the Siwalik Group (Neogene) conglomerates in the Sub-Himalayan belt of Himachal Pradesh, India, and the Potwar Plateau, Pakistan, is used as the basis of a model that recognizes two types of conglomerates with different relationships to the linear Himalayan mountain front. The two type are: (1) foothills-fed conglomerates, widespread along the mountain front, that mark the appearance in the basinal succession of sediments derived from within the Sub-Himalayan fold-and-thrust belt or the neighboring Lower Himalaya; these Upper Siwalik conglomerates provide information about relatively young frontal activity and the growth of local river systems that transferred the sediments generated; and (2) high-mountain-fed conglomerate, with restricted lateral extent along the front, that mark the presence of large trunk rivers, draining the Lower and Higher zones of the Himalaya; these Middle and Upper Siwalik conglomerates provide information about the extent of older incision in the high mountains, and the position in the basin of the major drainage paths.

Our work on the Janak (formerly Indus) Conglomerate Formation, outcropping near the present Indus River, shows that it is a high-mountain-fed conglomerate, and was deposited by a large braided system (channels up to 15 m deep) that drained southwards from the High Himalaya of northmost Pakistan. The conglomerate was deposited between 9 and 1 Ma, and is preserved as a formation 1.5 km thick and 25 km wide, perpendicular to flow. This conglomerate marks the position of the Palaeo-Indus in this part of the foreland basin. The syntaxial position of the present Indus in the mountain front, and the remarkable route of the upper Indus, have resulted from drainage evolution during the alter stages of transpressive indentation of the western margin of the Indian block. Our interpretation of the Janak Conglomerate implies that this special role of the Indus must have already started by 9 Ma.

A/29. Abbasi, I.A. & Khan, M.A., 1990. Heavy mineral analysis of the molasse sediments, Trans Indus Ranges, Kohat, Pakistan. *Geological Bulletin, University of Peshawar* 23, 215-229.

The molasse sediments in the Kohat plateau comprise two coarsening upward sequences, the Rawalpindi and Siwalik Groups, which are further subdivided on the basis of their lithological characteristics into a number of formations. Correlation of these formations across different areas becomes very difficult due to their time transgressive nature. Heavy minerals area a useful tool for such correlations, as each formation is characterized by a particular heavy mineral suit. The Murree Formation of the Rawalpindi Group contains a simple association of heavy minerals, and epidote constitutes bulk of the heavy mineral suite. The epidote decreases upsection with a corresponding increase in the contents of other minerals and also by the appearance of new minerals. The Kamliyal Formation is characteristically rich in tourmaline and garnet. The Siwalik Group, particularly the Shakardarra Formation of the Miocene age, is marked by the introduction of high-grade metamorphic and igneous minerals such as amphibole, staurolite and kyanite. Amphibole constitutes the bulk of heavy minerals in the Indus Conglomerate Formation (Miocene-Pliocene age) besides pyroxene, kyanite and staurolite.

The mineral chemistry of amphibole and garnet shows that the amphibole was derived mainly from the igneous and metamorphic belts of the Kohistan island arc. The major source of garnet in the molasse sediments is interpreted as the metamorphic belts of the Indian plate exposed along its northern margin. Some garnet in the Indus Conglomerate Formation may have been derived from the Kohistan island arc terrain.

A/31. Abbasi, I.A., Khan, M.A., & Hadi, S., 2000b. Mass movement and landslide hazard, Murree area, North Pakistan. *Earth Science Frontiers* 7, Abstract Volume, 15th Himalaya-Karakoram-Tibet Workshop, Chengdu, China, P.43.

The summer resort of Murree and adjoining areas is characterized by high degree of erosivity and erodibility due to both natural and man induced factors. This area is part of a young orogenic belt that is experiencing one of the world's most rapid uplift rates, and is located in near vicinity of major thrust faults. Shear zones associated with still active faults, such as Murree Thrust and also the folding generated due to thrusting induce an inherited weakness and natural instability potential in the rocks of the Murree Hills. Ever increasing population pressure, deforestation, large-scale construction works including a new township and a road network have further aggravated the problem.

In order to study the landslides and other mass movement related problems in Murree, an area around the main town is selected for detailed analysis of the problem as it has been focus of major development and road construction work; this study is an attempt to prepare a preliminary hazard/landslide map along major road network, around Murree town to identify the unstable areas. Data collection during the fieldwork and analysis were carried out on Geographic Information System (GIS) based ILWIS format of the ITC, the Netherlands. Detailed study of few selected landslides has also been conducted to understand the mechanism of failure and extent of damage. The landslide distribution map shows that the western slopes of the Murree ridge are worst affected by the land sliding. Major landslides such as Shifang Hotel and MIT, located on the upslopes of the Jhika Gali-Lawrence College Bypass road are caused by an inadequate drainage system from the city center (Murree ridge). Beside the Bypass road section, the MIT Housing Scheme is also adversely affected by the mass movement. In most part of the area around the Murree ridge, creep is a common phenomenon in thick colluvium cover due to obvious loss of vegetation. Most of the landslides initiated at the colluvium-bedrock interface, but once initiated the tension cracks spread into the bedrock and therefore causing the failure in it. Major landslides in the area, such as Kashmir Bazar, Chitta Mor, MIT etc. exhibits a complex array of joint/fracture pattern both parallel and perpendicular to the bedding, and in various ways contribute to the mass movement.

Key words: Hazard, mass movement, landslide, Murree.

A/33. Abbasi, I.A., Khan, M.A., Hadi, S., Ishfaq, M. & Mool, P.K., 2001. Geological controls on slope failure and landslide hazards, Main Boundary Thrust Zone, Murree Hills, North Pakistan. *Journal of Asian Earth Sciences* 19, p.1.

Consult the preceding account for further information.

Key words: Hazards, landslide, MBT, Murree.

A/34. Abbasi, I.A., Khan, M.A., Ishfaq, M. & Mool, P.K. 2002. Slope failure and landslide mechanism, Murree area, north Pakistan. *Geological Bulletin University of Peshawar*, 35, 125-137.

The area around Murree town is inherently vulnerable to mass movement processes, most commonly due to land sliding. It is characterized by high degree of erosivity and erodibility due to both natural and man induced factors. The area is part of a young orogenic belt that is experiencing one of the world's most rapid uplift rates, and is located in the near vicinity of major thrust faults. Shear zones associated with still active faults, such as Murree Thrust and also the folding generated due to thrusting induce an inherited weakness and natural instability in the rocks of the area. This compounded with ever increasing population pressure, deforestation, large-scale construction work in the form of residential and commercial buildings and road network have further aggravated the problem. Lithologically the area is comprised of shale, siltstone and sandstone belonging to the Oligocene-Miocene Murree and Kuldana formations. In order to study the landslides and other mass movement problems in Murree, an area around the main town and along the Murree-Kashmir Highway is selected for detailed analysis of the problem. The eastern slopes of the Murree ridge, and the road section between Jhika Gali and Aliot village are worst affected by the landsliding. Around Murree town, major landslides such as Shijang Hotel, Midway and MIT landslides, located on the upslopes of the Jhika Gali-Lawrence College Bypass road are caused by inadequate drainage system from the city centre (Murree ridge). In most part of the area around Murree ridge, creep is a common phenomenon in thick colluvium cover due to obvious loss of vegetation. The area between Jhika Gali and Aliot village is also affected by landsliding, and some of the largest landslides such as Aliot, Birgran and Kasserri landslides have inflicted great damage to farm and forest land. This area is located in the footwall of the MBT and is deformed by folding and termination splays associated with it. Most of the landslides initiated at the colluvium-bedrock interface, but once initiated the tension cracks spread into the bedrock and therefore causing the failure in it. Major landslides in the area exhibits complex array of joint fracture pattern both parallel and perpendicular to the bedding, and in various ways contribute to the mass movement.

Key words: Slope failure, landslide, MBT, Murree.

A/35. Abbasi, I.A. & McElroy, R., 1991. Thrust kinematics of the Kohat Plateau, Trans Indus Salt Range, Pakistan. *Journal of Structural Geology* 13, 319-327.

The Kohat Plateau consists of a heavily deformed and structurally elevated thrust sheet. Pop-ups, broad synclines and narrow fault- and evaporite-cored anticlines record high-level translation of a large thrust mass along Eocene evaporites. A lower detachment level is also inferred, located at the base of the Mesozoic-Palaeozoic section. This lower detachment is common to both the Kohat and the adjacent Potwar Plateaus whereas the upper level is restricted to the Kohat. Beneath the Kohat, a blind imbricate stack of pre-Tertiary rocks is developed. Above their roof thrust, the foreland basin-fill of Kohat records greater internal deformation compared to that of the adjacent Potwar Plateau. In contrast, the Potwar thrust belt displays a greater amount of overthrusting on its basal surface, this displacement emerging in the Salt Range. Total shortening across the two plateau is comparable, but is accommodated in an areally smaller thrust belt with a higher structural relief in the Kohat as compared to the Potwar structural province. The resultant geographical offset of the thrust front is denoted by the Hukni-Kalabagh lateral ramp. The differences in the thrust kinematics are tentatively suggested to be caused by the mechanical response of the orogenic wedge to different imposed geometries of the wedge laterally within the basin. The Kohat Plateau appears to have a lower basal dip than does the western Potwar, and thus shows greater internal deformation.

A/37. Abbasi, K.M., 1982-84. Geotechnical Studies of landslides along Karakoram Highway from Shetan Pari to Aliabad. M.Sc. Thesis, Punjab University, Lahore, 122p.

This thesis is mainly composed of the study of about land sliding along Karakoram Highway from Shetan Pari to Aliabad. A brief description of other geological features is also included in the thesis. The geological map shows the different types of rocks present in the project area. Detailed study has been made in the project area to collect the data about discontinuities as joints, which plays the dominant role in case of sliding in hard rocks. This data has been plotted on equal-area stereonet to check the stability of the slopes. In case of sliding in soft material like alluvial fan, samples were collected and tested for detailed analysis. Finally on the basis of this analysis the road is classified into stable, potentially unstable and unstable regions.

A/39. Abbasi, M.H., 1973. General geological mapping of Chalt area and report on feasibility of dam site near Chalt. M.Sc. Thesis, Punjab University, Lahore, 52p.

The Chalt area is located in the south central part of the Hunza valley. The area contains volcanic and low grade metasediments. The Hunza river has a rather narrow span at Chalt, making the locality appropriate for the construction of a hydroelectric dam. Rocks abutting on both banks of the river appear to be hard and compact.

A/44. Abdus-Sattar, 2000. Some geochemical attributes of Higher Himalayan granites from Upper Kaghan valley, NW Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, p.114.

Higher Himalayan crystalline unit in the Upper Kaghan Valley is comprised of granitoids, pelites, psammites migmatites, turbidites and associated minor marble horizons recognized as basement, covered with thin pelites-psammites and intercalated marbles having amphibolite at the base and a thick sequence of calc-pelites and marbles at the top, intruded by sheet granites. This sequence is bound by the MCT in the south and MMT in the north. The whole block is metamorphosed to upper amphibolite facies. Granitoids of H.H.C in Upper Kaghan valley are mainly concordant with the regional structure and are deformed along with enclosing metasediments and associated amphibolites with minor discordance and interfingering. The geochemical analysis for major and trace elements of twenty three samples of the H.H granites has been carried out with the aim of their geochemical characterization and determining their origin. Colour index ranges from leuco to mesocratic. Analyses are plotted on various diagrams and plots including variation diagram for major/trace elements, major/minor elements, triangular diagrams, discrimination diagrams, trace element spidergrams and indexes & ratios are determined for complete overview of the granites of the Upper Kaghan valley. The analyses confirm that these granites are peraluminous, S-type, and plot in within plate granite and calc-granite field. Fractionation ratios suggest fractional crystallization.

A/47. Abers, G., Bryan, C., Roecker, S., & McCaffrey, R., 1988. Thrusting of the Hindu Kush over the southeastern Tadjik basin, Afghanistan: Evidence from two large earthquakes. *Tectonics*, 7, 41–52.

We infer from the mechanisms and depths of two large earthquakes that the Hindu Kush is actively thrusting northwest over the Tadjik basin and that the basin is closing rather than being displaced to the west. Teleseismic body waves were used to determine focal mechanisms and depths for the two largest shallow earthquakes on the southern edge of the basin. The two earthquakes, on June 24, 1972 (mb=6.0), and December 16, 1982 (mb=6.2),

have seismic moments of 2×10^{18} N-m and 6×10^{18} N-m, respectively. Focal mechanisms of both events indicate almost pure thrust faulting with nodal planes striking northeast-southwest. The inferred fault planes dip southeast, at 20° for the first event and 50° for the second. The P axes for both events are oblique to the direction of relative motion between India and Asia, suggesting that the Pamir is overthrusting the basin to the west. Depths for both earthquakes are between 20 and 25 km and place them well below the Tadjik basin sediments. The depths and steep fault planes suggest that these earthquakes represent a down dip extension within the basement of shallow folding and thrusting seen in the sediments northwest of the events. Thus convergence in Afghanistan between India and Eurasia is taken up along southeast dipping thrust faults north of the Hindu Kush as well as by northward subduction under the southern part of the range.

A/48. Abid, I.A. & Abbasi, I.A., 1983. Stratigraphy, petrography and statistical studies of Siwalik group, Surghar Range, Kohat, N.W.F.P. M.Sc. Thesis, University of Peshawar, 128p.

The late orogenic sediments i.e. Siwalik molasses of post Eocene age, exposed along the western limb of Makarwal Anticline (Surghar Range) are objective of this report. Brief petrographic and statistical studies are carried out to determine characteristics of sandstone to establish a possible provenance. Sandstone comprises of quartz, feldspar mica, calcite, hornblend, rock fragments, and minor amount of epidote, garnet, zircon, apatite chlorite, and ore. Kyanite, staurolite, sphene, orthopyroxene and rutile are the other rare minerals. According to the scheme of Folk (1958) the sandstones are lithic arkose to feldspathic litharenite. From bottom to top feldspar, rock fragments and medium to high grade metamorphic minerals increase while calcite decreases. It may indicate unroofing of granite, granodiorite, and medium to high grade metamorphic belts with the passage of time.

Sieve analyses of 40 samples indicate that dominant clastic fraction is medium to fine (0.25 to 0.125 mm), moderately sorted, positively skewed and steeply peaked. Average values of various statistical measures obtained are

Sorting	skewness	kurtosis	Mean
0.90	0.70	0.86	2.37

All the parameters plotted graphically show that there is a zig-zag pattern rather than a vertical one, which suggests a cyclic repetition of the size factor.

Stratigraphic sections measured at two localities are analysed in term of fluvial stratigraphy. The stratigraphy indicates a fluvial system of laterally migrating stream, leaving behind fining upward cycles of lateral and vertical accretion deposits. The origin of uranium mineralization is not clear. It may be either due to mechanical concentration in old paleochannels (O.W.Chase, 1976) or by percolation of mineralized solution through impervious beds (M.Masoor et. al., 1980)

A/49. Abid, I.A. & Abbasi, I.A., 1984. Preliminary petrography of the Hangu Sandstone, Hangu, Kohat. Geological Bulletin, University of Peshawar 17, 109-112.

The quartzitic sandstone of the Hangu formation is mature both texturally and mineralogically. The detritus is diagenetically cemented by secondary silica giving rise to interlocking texture. The petrography and stratigraphic position of the sandstone suggests shallow marine environments of deposition where feldspar, lithic fragments and other softer material were completely destroyed as a result of repeated winnowing by long shore currents, while quartz and a resistant suite of heavy minerals were retained.

A/50. Abid, I.A., Abbasi, I.A., Khan, M.A. & Shah, M.T., 1983. Petrography and geochemistry of the Siwalik sandstone and its relationship to the Himalayan orogeny. Geological Bulletin, University of Peshawar 16, 65-83.

The Siwalik molasse of post Eocene age, exposed along the western limb of the Makarwal Anticline (Surghar Range), has direct relationship with uplifting episodes of the Himalayan Mountains present to their north. Detailed petrography of the sandstones together with chemical analyses of a few selected samples indicate varied mineral

assemblages and major oxide proportions for Lower, Middle and Upper Siwalik. Thus the Siwalik molasse, which is hitherto classified on the basis of sandstone and shale proportions and the variations in their color, may also be divided into different units on the basis of mineral assemblages and major oxide geochemistry, or at least these aspects can be used for subsurface correlation in limited domains of the Siwalik belt.

Regarding the source rocks, carbonates were major contributor along with other rocks during the deposition of the Lower Siwalik. The presence of igneous and metamorphic rock fragments along with medium to high-grade metamorphic minerals suggest crystalline rocks as the source of the Middle Siwalik. Such a mineral assemblage has also been reported from the Middle Siwalik of India, indicating unroofing of crystallines on a regional scale in the source area. Common occurrence of zircon in the Middle Siwalik seems to have some relationship with recently reported radioactive mineralization. The Upper Siwalik seems to have been derived from the foredeep sediments (Lower and Middle Siwalik), which were involved in the southward prograding orogenic activity by the Pleistocene period.

A/53. Abubakr, M., 1965. Geology of parts of Trans-Himalayan region in Gilgit and Baltistan, West Pakistan. Geological Survey of Pakistan records, 11 (3).

Reconnaissance geological mapping at a scale 1 inch to 4 miles was carried out in the Trans-Himalayan region of Gilgit and Baltistan. The region contains three major mountain ranges, namely, the Kailas Range, the Karakoram Range, and the Hinduraj Range. They are arcuate and parallel to each other with convexity northward. The region is underlain by a sequence of metasedimentary and sedimentary rocks, and several types and ages of igneous rocks. Metasedimentary and sedimentary sequence includes slate, quartzite, limestone, and gneiss of Permo-Carboniferous age. They are intruded or intercalated by a group of rocks called Greenstone complex. All these rocks have been intruded by granodiorite and hornblende which are probably of Tertiary age. The salient structural features are the swinging of the strikes of rocks sequence on that of ranges; and isoclinal folding of the Permo-carboniferous rocks, in places, tending to recumbent folds. This swinging nature can be explained as due to the bending of all rock components around the syntaxis of the northwest Himalayas. Metamorphism of the Greenstone complex and carboniferous rocks is widespread.

A/55. Achache, J., Courtillot, V. & Besse, J., 1983. Paleomagnetic constraints on the late Cretaceous and Cenozoic tectonics of Southeast Asia. *Earth and Planetary Science letters* 63, 123-136.

Many features of the Cenozoic tectonic history of central and southeastern Asia can be understood as direct consequences of the thrust and penetration of India into Asia. Recent indentation experiments with plasticine (Tapponnier et al.) have extended this idea and have led to the prediction of a pattern of large rotations and displacements of continental blocks that can be tested by paleomagnetism. The available Cretaceous and Cenozoic paleomagnetic data from this part of the world have been reviewed and a new APWP for Eurasia has been constructed for reference. The negligible rotation of South China and large clockwise rotation of Indochina are consistent with the model, i.e., with a history of large-scale left-lateral strike-slip motion along the Altyn Tagh and Red River faults. Data from Malaya and Borneo can be reconciled with the model, although in a less straightforward fashion. The large counter clockwise rotation of South Tibet implies that it rotated in sympathy with India during the collision and suggests that future indentation experiments should include this feature. Finally a middle Cretaceous reconstruction of the south margin of Asia is proposed. One interesting result is the restored continuity of geological features in Tibet and Indochina, with active subduction of oceanic (Indian plate) crust taking place to the south at subtropical latitudes.

A/57. Afridi, A.G., 1992. Lithogeochemical studies of the Chitral area, Hindukush Range, Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, 1-2.

Lithogeochemical studies were carried out in the Chitral area, Pakistan to delineate the potential gold mineralization. The Chitral area lies in the central part of the Hindu Kush Mountains, which constitute the northwestern extension of the greater Himalayas. The area is underlain by a wide variety of metamorphic and sedimentary rocks, which are intruded by granites, pegmatites, quartz veins, and basic dikes.

One hundred and twenty samples of a variety of rocks were analyzed for Au, Ag, As, Sb, Cu, Mo, Pb, Zn, K, Rb, and Tl. The concentration of the trace elements is generally low in most of the rocks with the exception of altered carbonates and some quartz veins associated with granites and slates. The altered carbonate rocks have a significantly high concentration of Au, Ag, As, Sb, Cu, Mo, Pb, Zn, Tl. Several samples contain up to 1 ppm Au and more than 1% As. Some of the quartz veins in granitic rocks and in slates contain high contents of Au, Ag, As, Sb, and Tl, but the enrichment of these elements is not high enough to mine them profitably. A high grade vein sample containing boulangerite, however, contains extremely high enough concentrations of Au (30 ppm) and (1350 ppm). Thallium is significantly higher in hydrothermally altered carbonate rocks compared to the unaltered rocks. The enrichment of Tl over K and Rb in hydrothermally altered rocks is demonstrated in Tl-K-Rb ternary diagram. The mineralized rocks fall close to the Tl apex, and the unmineralized rock samples plot near the K apex.

The abundance of Ag, As, Sb, Cu, Mo, Pb, and Zn in altered carbonate rocks is more or less similar to the sediments hosted good deposits of western United States. The enrichment of Au and Tl, however, is not as high as in some of these deposits. The preliminary study suggests that Chitral area probably contains economically important gold deposits. Detailed lithogeochemical and pedogeochemical surveys of certain areas may prove to be useful in locating sediment hosted gold deposits.

Key words: Indus Suture, Kohistan Arc, amphibolites, mélange, Shangla, Swat.

A/59. Afridi, A.G., Khan, R.N., Shah, H. & Walliullah, 1995. Charbagh. US Geological Survey, Geological Map Series 1072, old sheet no. 58(43 B/5, 1:50000).

This map and the following show the geology of the Indus Suture zone. The southern part of the area is occupied by the southern Amphibolite belt of the Kohistan Arc. The northern part, Shangla area, is occupied by a tectonic mélange containing ultramafic blocks and blue schists in a sedimentary mélange.

A/61. Afridi, A.G.K., Shah, H. & Rahim, S., 1980. Magnetite occurrences in the Kohistan Area, Hazara Division, NWFP, Pakistan. GSP. Information Release 124, 20p.

Minor lenses of magnetite occurs in a complex metamorphic belt in the Kohistan region of the North West Frontier Province, Pakistan. Preliminary field studies carried out by the Geological Survey of Pakistan during 1977-79 have shown that all the known magnetite bodies are of limited extent and show considerable variation in mineralogical content and chemical composition. Reserves of individual lenses do not exceed a few tens of thousand tonnes in each case and the total iron content of an average ore sample is always less than 50 percent. As such these occurrences are not considered to be of economic significance for the foreseeable future.

The small scale mineralization of magnetite in the investigated area owes its origin to partial metasomatic replacement of the erratically distributed marble/ crystalline limestone lenses in the Paleozoic (?) schistose group, in contact with the latter granite.

Key words: Magnetite, Kohistan, Hazara.

A/62. Afridi, A.G.K., Khan, R.N. & Shah, H., 1983. Regional geology of Mingora and Charbagh Quadrangle, NWFP, Pakistan, with the geological map on 1:50,000 Scale. GSP Information Release 132.

This paper, with a nicely produced geological map, covers the rock assemblages on the two sides of the Indus suture. The southern part is represented by metamorphic rocks and granitoids of the Indian plate, and the northern by metabasites of the Kohistan arc. The suture mélange occurs as a sandwich between the two.

A/63. Afridi, A.Z.K., Anwar, J., & Hashmat, S.M., 1976. Fluorite deposits of Chakdara area, District Dir: Internal report of the Pakistan Mineral development Corporation, 57pp.

The fluorite deposits of Chakdara area in Dir District are found near the villages of Chatpat and Tsapparuna. Both the occurrences are about 4 miles apart. Chemical tests of both the deposits have classified them as of metallurgical grade. The Chatpat deposit is of better quality and colour. The fluorite mineralization at Chatpat is occurring in the form of thin multiple veins in granitic gneiss. Major zone of mineralization is 30 to 38 feet thick and 60 to 80 feet long. The fluorite veins which range in thickness from 1/8th of an inch to 4-1/2 feet, and are distributed alternatively with barren granitic gneiss. Some minor dissemination of fluorite is also observed in the intervening gneiss layers. Pinching and swelling is typical character of these lenticular fluorite deposits. Chemical analysis revealed in a xinu content of 51.3% CaO and 33.9% F. The fluorite deposits of Tsapparuna also occur in gneissic rocks which are northeastern extension of the Chatpat outcrops. Three main fluorite veins have been located in Tsapparuna area, which strictly follow the foliation joints. The veins range in thickness from 6 inches to 11 -1/2 inches. The fluorite in

this area is violet to dark violet in colour and is associated with quartz. Chemical analyses indicate 51.2% to 44.9% CaO and 33.7% to 29.2% F. Lead, Vanadium, Titanium, Molybdenum and strontium have also been found in Chatpat deposit. The reserves assessment has revealed that the proved reserves are 3544 tonnes whereas inferred reserves are about 7552 tonnes.

A/64. Afridi, M.I., Badshah, M.S. & Ihsanullah, M., 1991. Copper occurrence in Waziristan. Proceedings First SEGMITE Symposium, Peshawar, Pakistan, March 1991, 70–73.

The geology of the Shinkai area, North Waziristan is described, with a help of a geological map. Copper mineralization exists in the form of stock works, stringers, and cavity/vesical/void fillings, and as dissemination of primary sulphides including pyrite, chalcopyrite and bornite associated with hypogene secondary sulphides and oxides of iron and copper including malachite, azurite, cuprite, tenorite, limonite, jerosite and goethite etc. the copper is of volcanogenic and syngenetic origin. The deposits are genetically similar to Cyprus type. Average copper content is about 0.386 %.

Key words: Copper Mineralization, Waziristan.

A/65. Afzaal, P.A., Din, N., Rashid, C.M. & Majid, A.A., 1995. Influence of basement Tectonic on the structural trends of Himalayas, A case study in Potwar Plateau. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich), Switzerland.

Potwar Plateau (PP) of Pakistan lies in the western Sub-Himalayan tectonic zone and is bounded (a) to the north and south by north dipping Main Boundary Thrust (MBT) and Salt Range Thrust (SRT) respectively (b) to the east and west by Jhelum and Kalabagh wrench faults with associated syntaxial bends respectively (Fig. 1). These bounding structures are different from one another in timing, intensity and causes of deformation, structural styles and their impact on the tectonics of PP.

The present tectonic setting of PP has resulted from the northward underthrusting of Indian Plate under its own sedimentary cover. Major structures of the Sub-Himalayas are the result of reactivation of the preexisting tectonic features of the Indian Shield, in Neogene time, due to flexural bending caused by loading of the basement from southward advancing thrust sheets. The tectonics of the Pre-Cambrian crystalline basement has largely controlled the structural styles of PP in particular and higher Himalayan Ranges in general. The controlling factors are;

- i. Pre-Himalayan tectonic features/directions of the Basement.
- ii. Dip of the Basement.
- iii. Grain of the Basement.
- iv. Segmentation of the Basement resulting from partial docking with Afghan Plate in the north-west.

There are two main tectonic directions, i.e. NW & NE in the Indian Shield rocks exposed at Kirana Hills (surface expression of Sargodha Basement High) and Aravalli Ranges. These directions are reflected in the major tectonic trends of the PP and higher Himalayan Ranges (Fig. 2). In PP, east of 73° - O' Longitude the major structures like Riwat, Adhi-Ghungrilla, Pamal - Domeli, Rohtas and seismically interpreted basement offsets are aligned in a NE-SW direction. West of 73° Longitude the Kallar Kahar fault with its inferred extension, Kalabagh fault, Dhadumbur anticline, Joyamair structure show a NW-SE trend.

Internally PP can be divided into 3 parts on the basis of intensity, type and trend of deformation. These are (i) North Potwar Deformed Zone (NPDZ) (ii) East PP (iii) Southwest PP.

NPDZ represents severest and oldest phase of deformation within PP. It is marked by imbricate stack of thrust faults, tight isoclinal folding, vertical dips and thrust bound ridges. The Eastern PP is characterized by NE-SW trending tight anticlines and intervening broad synclines. In southwest PP there are a series of gentle folds, incipient in nature. A variation in dip of the basement is responsible for the difference in structural style and frequency of structures from east to west of the PP. In the eastern PP dip is <1°, so the structures in eastern PP are viewed as response to a too narrowly tapered wedge in order to increase the taper. In southwestern PP higher dip of the basement i.e. 3.6° allow the thrust sheet to slide without undergoing internal deformation. In NPDZ inspite of higher dip of the basement (3.6°) the area is strongly deformed. This zone is probably an allochthonous block, thrust southwards to its present position.

Seismic data across PP show presence of north facing basement normal faults, some of which have been noted to exist beneath the Chak Beli Khan, Chak Naurang, Qazian and south of Bhaun structures. These faults were pre-

existing weaker zones, reactivated due to loading of the basement, and influenced the deformation of east PP. Fault propagation folds in this area are produced by the movement on these faults. Similarly ramping of eastern Salt Range has been controlled by the basement normal fault south of Bhaun.

Many areas of the PP show evidence of counter clockwise rotation which was more intense in SE PP (maximum 35°) and did not occur simultaneously in all parts of the PP. This indicate the segmented nature of the basement. Taking the example of south PP where data shows differential rotation, both in time and space, of south-east, south-central and south-west PP. These blocks are separated from each other by Domeli -Diljabba and Kallar Kahar faults. The two faults are aligned in NE and NW direction respectively, which are the main tectonic directions of Indian Shield and Himalayas. These faults are interpreted as the surface expressions of deep seated basement fractures which have divided the south PP into three segments each showing differential rotation due to tectonic movement along Jhelum fault, Salt Range Thrust (SRT) and Hazara Kashmir Syntaxis (HKS). East of 730 Longitude, magnitude of SRT appear to diminish near Jalalpur. This is due to the transfer of deformation from SRT to NE-SW trending Domeli - Diljabba thrust which is the resultant of basement fault at Qazian - Bhubar structure. The Domeli-Dabba thrust ultimately merges into Jhelum fault.

The north-south trending left lateral Jhelum fault has been a long lived active feature of the Indian Shield. Synsedimentary movement on this fault may have affected the Siwalik sedimentation and later movement have cause the counter clockwise rotation in east PP. The structures in east PP were originally formed in E-W direction due to movement on the basement normal faults, and rotation have changed their direction to NE-SW. Formation of HKS is due to movement on Jhelum fault and thrusting along MBT and SRT.

Kalabagh right lateral fault is also a basement fault affecting the formation of Kalabagh Syntaxis (KS), which is considered as northwestern spur of Sargodha basement high.

Finally it is concluded that the tectonic features of the Indian shield have been duplicated in the deformation of cover rocks of the Himalayas. The basement normal/reverse faults have been reactivated to cause major thrusting, while the movement on the wrench faults due to segmentation of the Indian Plate, have produced various syntaxial bends.

A/66. Afzal, M.S., 1983-85. Geology and tectonics of Burawai Area, Upper Kaghan valley, District Mansehra, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 125p.

Nearly 114 sq. km. in the vicinity of Burawai, upper Kaghan valley has been geologically mapped, at the first time. This thesis presents first time accounts of geomorphology, lithostratigraphy, petrography and economic geology of the area. The area constitutes rocks representing old Indo-Pak basement rocks, comprising pelites, calc-pelites and marbles have been metamorphosed to kyanite and sillimanite grades. These are intruded by para-autochthonous sheet granites also metamorphosed.

Major structure comprises an open synform possibly part of a larger structural basin. The western part comprises the nose of a larger antiform.

Marble, biotite mica and kyanite are important mineral deposits which deem further exploration and evaluation. This thesis also includes petrogenesis of the rock units as well as numerous sketch sections and photographs, illustrating the geology of the area.

A/67. Afzal, S., 1990-92. Geological study for petrography and geology of Atia Qala (District Swat). M.Sc. Thesis, Punjab University, Lahore, 57p.

Rocks of Atia Qala (Distt. Swat) are part of metamorphic hornblend complex. The area lies within the southern portion of Swat. These rocks are probably the extentions of rocks of Dir in the form of a belt running approximately in East-West direction. The area given for field work comprises thirty kilometers in the North-West of Mangora. The area mainly comprises the main rock units are Norite, Diorite, Quartz-O-Feldspar and Pegamatite veins. But at some places patches of Amphibolite are also found but can be considered negligible. As the field evidences, and the laboratory study shows that the Diorite and Norite were formed from basic magma, which have under gone regional metamorphism under the intense orogenic conditions.

Quartz-O-Feldspathic and pegmatite veins are extensively distributed all over the area, indicating the evidence of Diorite magma. Major minerals are Plagioclase, Hornblend, Epidote and Quartz with accessories as Sphene and Magnetite. These are products of regionally metamorphosed igneous rocks.

A/71. Ahmad, A., 1979-81. Detailed mapping, petrology and structure of Gulpato-Banda Saoni area, Tehsil Kohistan, District Dir, NWFP. M.Sc. Thesis, Punjab University, Lahore, 78p.

Gulpato banda-Saoni area is a part of Hindu Kush range. The total investigated area is about 30 miles². The rocks in the area are composed of metasedimentary complexes with igneous intrusions. The main units in the area are calcareous quartzite, chlorite schist and biotite schist.

It is believed that chlorite schist and biotite schistose are the product of regional metamorphism on argillaceous and calcareous rocks. The contact of calcareous quartzites with schist is gradational. After this the granodiorite magma intruded in the area. In the second phase the intrusion on the magma was siliceous and of granitic composition. It formed small patch schist.

There are extensive quartzo-feldspathic and pegmatitic veins and dykes in granodiorite and schist indicating late residuals of granodiorite magma.

Fossils of larger foraminifera (Assilina, Nummulites, and Alveolina) were collected in calcareous quartzites. They are of lower Eocene age.

A/73. Ahmad, A., 2000. Thermal maturity modeling of Kohat-Potwar Basin, Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, p.1.

One - dimensional maturity modeling of three wells, Tolanj-1, Meyal-10 and Pandori-1 was carried out. All available geological, geochemical and geophysical concepts and data were integrated for making this model. Using this model, the timing and amount of hydrocarbons generated from different potential source rocks were evaluated. Vitrinite reflectance measurements of whole of the stratigraphic sequences in Tolanj-1 and Pandori-1 were carried out and used for maturity modeling, while for Meyal-10 only 2 measurements of Jurassic Formations were used. Results of maturity modeling of individual wells and their correlation with other wells indicate that maturity

increases from East and southeast to West and northwest. Salt Range Formation is not mature in eastern Potwar (Khewra gorge) and lies in gas window in central Potwar (Meyal-lo), and is late mature for gas in Kohat (Tolanj-1) area. The time of hydrocarbon generation is also different at different locations e.g., Salt Range Formation was in the peak oil generation phase in middle Eocene time in Tolanj-1 (Kohat area) and it reached at this stage in Late Miocene in Meyal-10 (central Potwar).

Key words: Thermal Modelling, Hydrocarbons, Kohat-Potwar basin.

A/74. Ahmad, A., Jamal, T., Yusaf, S. & Younis, R., 1986. Geology and structure of a part of Kohat Quadrangle, Kohat. M.Sc. Thesis, University of Peshawar, 54p.

The present work describes the stratigraphy and structure of a part of Kohat Quadrangle bounded by lat. 33. 15. 33. 25 N and long 71. 30. 71. 40 E. This part lies in the western corner of Pakistan Survey topographic sheet No. 38-O/11.

The area under investigation is composed of sedimentary rocks ranging in the age from Early Eocene to Pliocene.

The Following formations are exposed in the mapped area.

(8) Dhok Pathan Formation Middle Pliocene.

(7) Nayri Formation Early Pliocene.

(6) Chinji Formation of Siwalik group Late Miocene
. Late Tortonian age.

(5) Kamlial Formation Middle Late Miocene.

(4) Murree Formation of Rawalpindi group Miocene.

(3) Kohat Formation Eocene.

(2) Kuldana Formation..... Early-Early Middle Eocene.

(1) Jatta Gypsum Early Eocene.

The area shows moderate folding and faulting, the folds are mostly open. The faults reveal the significant movement that has taken place on the regional scale. Folds are moderately plunging East or West. The limestone is highly effected by weathering and fracturing. Doubly plunging nature of folds, fracturing and downward slipping of mass of rock or unconsolidated material of any size of limestone are the direct result of the plastic behavior of the gypsum.

Structurally the area under investigation is suitable for Oil and Gas accumulation. It has potential for non-metallic minerals i.e. limestone, common salt and gypsum.

A/77. Ahmad, D., 1995. Tectonics analyses of the southern Kohat plateau, NWFP, Pakistan. M.Phil. Thesis, University of Peshawar, 52p.

The studied area constitutes part of the southern Kohat plateau and exposes a suit of sedimentary rocks which includes evaporates, shelf sediments and a thick sequence of mollase sediments. The rocks in the area belong to the Eocene age and consists of Panoba shale, Bahaderkhel salt and Jatta Gypsum, followed by Kuldana and Kohat Formation. These units are overlain by mollase sediments of Miocene to Pleistocene age which comprises Kamlial Formation of Rawalpindi group overlain by the complete stratigraphic sequence of the Siwalik group.

The studies area constitutes the western half of the southern structural boundary of the Kohat Plateau, herein named as "Kohat Plateau Boundary Zone". It is about 120 km long with width ranging from 5-10 km and trends east-west. The studies area is characterized by the large scale east-west trending open, synclinal and tight anticlinal trends.

These compressional structures are superimposed by a Plio-Pleistocene phase of strike-slip deformation. This deformation is displayed on the surface of the formation of two large scale strike-slip faults with apparent dip-slip movements. The Zarwam fault is the northern most structural discontinuity and is believed to be a strike-slip fault with left lateral movement. The bannu-surgad fault lies south of Zarwam fault and is also characterized by strike-slip movement with the sense of movement being right lateral. Both these faults are Rheidal shears which emanates from the Kurram fault.

A/83. Ahmad, I., 1980. Petrography of Ambela Syenite, Buner Area. M.Sc. Thesis, University of Peshawar, 44p.

This work presents petrographic details of a part of the Ambela Syenite, occupying 12 sq. miles of area in the Bunair. The rocks of the thesis area, occupy north central portion of the Ambela complex, which is considered to be a part of the Peshawar Paline Alkaline Igneous province.

The intrusive rocks of this area comprises dominantly of alkali quartz Syenite with subordinate occurrence of quartz syenite and granite. Texturally the alkali quartz syenites are coarse-grained, hypidiomorphic and sub-inequigranular. Major primary minerals of these rocks are alkali feldspar, quartz and plagioclase, with varying proportions of biotite, sphene, apatite, zircon, muscovite and opaque minerals. Epidote and chlorite are rarely found as secondary minerals.

Key words: Petrography, Ambela complex, Buner.

A/84. Ahmad, I., 1986. Petrochemistry of the Shewa Shahbazgarhi Complex, Mardan. M.Phil. Thesis, University of Peshawar, 130p.

The Shewa-Shahbazgarhi complex is an isolated triangular outcrop, occurring about 12 km north-east of Mardan. The complex consists of acidic rocks, intruded by basic rocks such as metagabbro, metadolerite and local quartz monzonite dykes and sills. The acidic rocks, in order of decreasing relative ages, are microporphyry, porphyritic granite, riebeckite gneiss and aegirine riebeckite porphyry.

The common minerals in basic rocks include hastingsite, clinopyroxene, orthopyroxene (in meta-dolerite), magnetite, biotite, epidote, apatite and leucosene. The acidic rocks contain perthitized orthoclase, orthoclase, perthite, plagioclase, with riebeckite and aegirine as the common ferromagnesian minerals. (Specially in riebeckite porphyry) and the presence of the alkali amphibole and alkali pyroxene is indicative of their alkaline character. Chemical analyses of the amphibole grains obtained with electron probe closely correspond to riebeckite composition. The rocks show considerable degree of deformation and alteration (cataclasis and/or mylonitization). Two types of metamorphism (a) an amphibolite facies metamorphism and (b) retrogressive epidote amphibolite facies metamorphism has been

Noticed. Assessment of the chemical data on conventional two dimension plots and CMAS model, suggest the control of fractional crystallization over the major and trace element distribution in both the rock types. Fractional control of olivine, clinopyroxene and plagioclase is conspicuous in the basic rocks and plagioclase fractionation in the acidic rocks. Major and trace element data suggest that the basic and the acidic rocks are not comagmatic. These are derivative from two different parent liquids. A magma of subalkaline character is proposed for the basic rocks and alkaline to peralkaline for the acidic rocks, both, however, being emplaced in continental rift environments. A rift valley origin is proposed for the complex with the generation of felsic magma, probably as the result of partial melting in the lower crust. The rocks so formed were later intruded by basic dykes of continental flood basalt type.

A/85. Ahmad, I., 1987. Geology of Jowar area, Karakar Pass, Swat District, N.W.F.P., Pakistan. M.Phil. Thesis, University of Peshawar, 144p.

The Jowar area, Karakar pass in the Swat District marks the northern edge of the Indo-Pakistan plate. It is predominantly composed of highly deformed and metamorphosed, Precambrian to Cambrian granitic rocks and Paleozoic metasediments. The granitic rocks are distinguished into augen gneisses and tourmaline granites, each belonging to distinct chemical variety. The metasediments are grouped into Alpurai schist, and Nikanai Ghar marble, which are separated by the "Nikanai Ghar Fault".

Both the granitic rocks and the metasediments have undergone at least two phases of deformation and metamorphism. The first phase of deformation (D1) and the associated metamorphism (M1) produced regional foliation (S1), mineral lineation (L1) and small scale, tight to isoclinal folds (F1), throughout the Lower Swat-Buner region. During M1, the rocks are regionally metamorphosed, and the Hbl+Plag+Grt assemblages in amphibolites suggest an almandine-amphibolite facies metamorphism. The second phase of deformation (D2) is associated with retrograde metamorphism (M2), and folded S1 into mesoscopic to macroscopic scale F2 folds. It also produced crenulation lineation (L2), and locally S2 foliations.

Regional studies in the Lower Swat-Buner region suggest that the Alpurai schist and Granitic rocks formed a large recumbent fold, due to which the stratigraphic sequence in the study area is upside down. The geochemical study suggest that the amphibolite from study area are derivative from a basic igneous parent of continental tholeiitic affinity.

Key words: Geology, Karakar pass, Swat.

A/86. Ahmad, I., 1999. Structure and metamorphism south of the Malakand and adjoining area, North Pakistan. Ph.D. Thesis, University of Peshawar, 151p.

Detailed field, structure and petrographic data show that the stratigraphy in Swat extends into the northern fringe of the Peshawar basin. Two major faults, the Kishora thrust and a back thrust, dominate the structure of the studied area. The Kishora thrust divides the area into two tectonic terranes, the Indus mélanges, and the Indian shelf terrane. Located within the latter, the back thrust brings higher-grade almandine zone rocks in contact with low-grade chlorite zone rocks near Bar Bazdara and Zormandai villages.

Four deformation phases, D1, D2, D3, and D4 are recorded from north to south, each characterized by distinct fabric and folding. In the north Domains 1 and 2, D1 formed S1. The earliest recognizable fabric S1 occurs as relict intrafolial in the S2 fabric, pressure shadows and porphyroblasts. No macroscopic folding event related to S1 has been recognized. This event occurred under greenschist facies metamorphism. During D2, F2, folds (large and small

scale) were formed. F1 and F2 are coaxial and coplanar with isoclinal, recumbent axial surfaces and fold axes, which plunge gently toward the NNW, and are associated with movement on the Kishora thrust. The dominant S2 foliation developed following the interkinematic phase.

The grade of metamorphism varies from greenschist facies in the south to amphibolite facies in the north. Fractures and brittle shearing in the schists and annealing recrystallization in the granite gneiss and marbles dominate the post S2 phase. During D3 crenulation of S2 garnet growth and the formation of the S3 occurred. F3 folds are upright, open and plunge gently, but variably towards north or less commonly the south or southeast. This event occurred under amphibolite facies, and was followed by the retrograde phase (where garnet and biotite altered to chlorite) and development of east-west trending, south vergent F, folds. F, is related to the change of forces from westward to southward in the lower Swat when Kohistan was thrust southward to its present position. The superposition of the E-W trending F, folds on the generally N-S trending F, folds resulted in a dome and basin structure near Mora Kanda. In the south, Domain 3 preserves the last two deformation phases. During D, S, developed. During D, S, was transposed and also involved the growth of the magnetite porphyroblasts. The minerals chlorite, actinolite, biotite and muscovite indicate metamorphism of greenschist facies. F, and F, folds are best preserved. The large-scale F, folds are mainly E-W, but at Rustam and Budal I they are deflected into a broad arc near the Ambela complex. This is related to the back thrust in that the Ambela complex acts as buttress that deflects the later folds towards north. Matrix schist records two periods of metamorphism. During the D, deformation, which produced a transposed foliation, is also involved with the formation of greenschist facies minerals chlorite, plagioclase, and muscovite. During D, the early S, was folded. During D, the S, was folded to produce local - S, space crenulation cleavage. The Dargai ultramafic complex has been emplaced along the Kishora thrust with the ophiolitic mélange. Greenschist facies metamorphism of blocks in the mélange reached its maximum during D, and phased out by the end of D, Low P-T minerals chlorite, albite, and epidote developed during D, and early D, D, related F, folds are not present. The ultramafic blocks show prograde overprinting on greenschist facies assemblage, evident from the formation of fresh olivine in bastite.

A/87. Ahmad, I. & Ahmad, S., 1975-76. The study of pebble features orientation and petrography of Tanaki conglomerate in Hazara N.W.F.P. M.Sc. Thesis, University of Peshawar, 123p.

Tanakki Conglomerate which is exposed at several localities in Hazara district is a heterogeneous mixture of fragments of different shapes, sizes and rock types, embedded in a coarse sandy matrix. It is almost a structureless rock unit with very poorly developed bedding. The thickness varies from a few feet to a maximum of 40 feet in the area of investigation. Tanakki Conglomerate has disconformable contact with underlying Hazara slate formation (Precambrian) or at places with Tanawal formation (early Paleozoic). The upper contact is conformable with Infra Triassic group of Middlemiss (1896).

The age of Tanakki Conglomerate has been regarded by all the workers as Permian on the basis of its so-called close similarity with the Tobra Formation of Salt Range. However, the present study revealed that this correlation cannot be justified. Besides the discovery of some conodont fossils in the Sirban formation has changed the entire ages of Paleozoic rocks in Hazara. The rocks which were regarded as Permian, now fall below in Cambrian and as such Tanakki Conglomerate must belong to Precambrian - Cambrian age.

The external appearance of rock fragments constituting Tanakki Conglomerate has contrasting features. Some rock fragments have entirely smooth surface and lack any surface feature whatsoever. A considerable number of the surfaces are irregular and rough. Grooves, striations, and facets on pebble surfaces pointing towards their glacial origin are also observed.

The dominant size of rock fragments falls in the category of pebbles. Cobbles and occasional boulder size fragments are also present. There is a variety of shapes exhibited by the pebbles but more often they are of irregular shape. The average roundness and sphericity of the pebble is 0.401 and 0.703 respectively.

The bearings of long axes of pebbles show entirely random orientation but the orientation are essentially subhorizontal. Tanakki Conglomerate is composed of sedimentary rocks only. The most dominant lithology is sand stone.

Following are the different rock types met in Tanakki Conglomerate:

- (a) Sandstone
- (b) Slate/Argillite
- (c) Limestone

- (d) Quartzite
- (e) Quartz
- (f) Siltstone

Key words: Petrography, Tanakki Formation, Hazara.

A/88. Ahmad, I. & DiPietro, J.A., 2000. Analysis of folds south of Malakand and adjoining areas, North Pakistan. *Earth Science Frontiers 7 Abstract Volume*, 15th Himalaya-Karakoram-Tibet Workshop, Chengdu, China, 72-73.

North of the study area in Lower Swat, the rocks have been found to have undergone multiple deformations with at least four periods of folding during a single Paleogene metamorphism (DiPietro and Lawrence, 1991). The earliest folds are composite W-SW vergent, syn-metamorphism F1/F2 folds associated with the formation of the regional foliation. Late-metamorphic, N-S trending open upright F3 folds are associated with local foliation development, and E-W trending open F4 folds are associated with retrograde metamorphism. These interfere with each other to produce dome/basin structure.

The northern part of the study area preserves all the four superposed small-scale folds (F1 through F4). F1 and F2 are coaxial and coplanar with isoclinal, recumbent axial surfaces and fold axes that plunge gently toward the NNW. Where they are superposed, the F1 folds, they deform bedding but not foliation, whereas F2 folds deforms a bedding parallel foliation. The similar geometry and orientation suggests that F1 and F2 developed at about the same time during progressive deformation. F3 and F4 are the same as described above. They determine the map pattern of the area. In the south the earlier folds F1 and F2 fold phases are not preserved. Only the large scale F3 and F4 fold phases are well developed. Large-scale F3 folds are closed to tight with variably dipping axial surfaces, whereas large-scale F3 axes plunge gently but variably towards north or, less commonly, the south or southeast.

Large-scale F4 folds are best developed near Thakht-i-Bahai and Mian Khan where they have broadly have broadly folded the Marghazar (Duma), Kashala and the Saidu formations. F4 folds are open and E-W trending. The F4 folds are asymmetric. They have a different vergence in the different domains. In northern and southern part they are south vergent whereas they are north vergent north of Rustam. These large-scale F4 folds trend mainly E-W, but near Rustam they trend NE and near Budal they trend WNW. Thus they appear deflected into a broad arc near the Ambela complex (Fig. 1). North of Rustam, F4 folds gently deflect the northerly trending structures. South of the Rustam, they are the most obvious folds present and become south vergent. The superposition of the east-west trending F4 folds on the generally north-south trending earlier F3 folds has created the dome and basin structure in the Mora area.

The fold sequence implies an early period of E-W compression prior to the development of south verging structures. The small-scale F1 and F2 folds represent a progressive F1/F2 deformation that is associated with a single set of west-southwest vergent large-scale folds (F2). The large-scale F3 folds may have developed in intense localized shear strain related to ophiolite emplacement on the Kishora Thrust. F4 folds are upright and open with east-west axial trends. They may correlate with early doming of the lower Swat sequence and with strike slip displacement in the northern part of the MMT, north of the Swat (DiPietro and Lawrence, 1991).

The reverse vergence of the F4 folds north of Rustam may be better explained by a back thrust. Back thrust is interpreted from the structural profile AA-across Rustam to Mora area. The fault appears on the north edge of the map. This fault is also supported by the abrupt change in the metamorphic grade across the fault. Rocks north of the village of Bar Bazdara and Zormandai are in epidote amphibolite facies whereas those immediately in the south are lower greenschist. In addition, the sheared contact relationship is intrusive, but on the NW margin of the Ambela Complex the base of the Marghazar is strongly sheared. We interpret this to be related to the back thrust. F4 folds are deflected into a north convex arc from Rustam to Budal (Fig. 1). This is probably related to the back thrust in that the Ambela Complex acts as a buttress that deflects the later folds towards north. In effect, the high-grade metamorphics are underthrusting the Ambela Complex.

Key word: Structure, Folds, Malakand.

A/89. Ahmad, I., DiPietro, J.A., & Jan, M.Q., 1999. Structure and metamorphism south of the Malakand and adjoining areas, Northern Pakistan. *Terra Nostra 99. Abstract Volume*, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 1-2.

Four deformation phases (D1, D2, D3, D4), three fabrics (S1, S2, S3), and four folding events (F1, F2, F3, F4) are recorded from north to south (Figure 1). Near Malakand, D1 formed S1. The earliest recognizable fabric S1 is preserved in the S2 fabric as pressure shadows against garnet porphyroblasts and as inclusion trails in garnet and amphibole porphyroblasts within the calc-mica-garnet schist and graphitic schist. Inclusion trails are straight or rotated within garnets and are oblique to the external S2 fabric. No macroscopic folding event related to the S1 fabric has been recognized. This event probably occurred under greenschist facies metamorphism. During D2, F2 folds (large and small scale) were formed. F1 and F2 are coaxial and coplanar with isoclinal, recumbent axial surfaces and fold axes that plunge gently toward the NNW. S2 is defined by calcite, muscovite, plagioclase, quartz, and garnet. The grade of metamorphism varies from greenschist facies in the south to amphibolite facies in the north. During D3 crenulation of S2, garnet growth, and the formation of the S3 occurred. This event occurred under amphibolite facies. This event was followed by a retrograde phase where garnet and biotite were altered to chlorite. In the south, near Rustam and Takht-i-Bahai, the last two deformation phases are preserved. S1 developed during the D3 deformation. During D4, S1 was transposed and also involved with the growth of magnetite porphyroblasts. The minerals, chlorite, actinolite, biotite and muscovite indicate metamorphism of greenschist facies.

Greenschist facies metamorphism of blocks in the mélange and Dargai ultramafics reached its maximum during D2 and was phased out by the end of D3. Low P/T minerals, chlorite, plagioclase, and epidote developed during D2 and early during D3. F2 folds of the D2 deformational phase are not present. The temperature of metamorphism was in the range of 250°C to 350°C and pressures probably up to 3.5 kbar. Evidence of retrograde metamorphism overprinting D2 and D3 minerals is not observed.

Matrix schist within the mélange record two periods of metamorphism. The D2 deformation, which produced a transposed foliation, is also involved with the formation of the greenschist facies minerals, chlorite, plagioclase, and muscovite. During D3, the early S1 was folded and garnets were developed. During D4, the S2 foliation was folded to produce a local S3 spaced crenulation cleavage. This probably occurred during the greenschist facies metamorphism.

Vein mineral assemblages in both blocks and matrix rocks of the mélange provide evidence of P/T uplift paths and conditions, perhaps during emplacement of the Dargai ultramafics and the various blocks in the mélange. Vein minerals common in the talc-carbonate blocks include fuchsite, calcite, quartz and feldspar. The mineral assemblages are indicative of greenschist facies metamorphic conditions. Vein mineral assemblages common in the matrix rocks include calcite and quartz, and are also characteristic of low-grade metamorphism or hydrothermal alteration.

In the north of the study area the earliest superposed small scale folds (F1 and F2), are co-axial and co-planar with isoclinal, recumbent axial surfaces and fold axes that plunge gently toward east. F1 and F2 folds, with localized shear strain, are related to movement on the Kishora thrust. The Kishora thrust is folded by F3 folds. F4 is related to the change of forces from westward to southward in Lower Swat after the Kohistan arc was in its present position. The features described above were noticed during the present study. The Kohora Thrust is folded north of Chakdarra and near Dargai.

Key words: Structure, metamorphism, Malakand

A/90. Ahmad, I., DiPietro, J.A., Lawrence, C.P. & Jehan, N., 2001. Stratigraphy of schistose rocks near Rustam and surrounding area, district, Mardan, North Pakistan. *Journal of Asian Earth Sciences* 19, p.1.

Rustam is located about 24 km northeast of Mardan. The area comprises of low-grade greenschist facies rocks (schists, marbles) of the Indian shelf. The rocks have been grouped from base upward as Jafar Kandao, Duma, Kashala, Saidu and Nikanai Ghar formations (DiPietro et al., 1993, 1999; Pogue et al., 1992), and assigned Late Paleozoic (Carboniferous) to Mesozoic (at least Triassic) ages. Present study reports two more Conodont ages north of Rustam from the lower part of the Kashala formation (348 260 29.400N 728 110 16.300E) and the upper part of the Marghazar formation (348 230 5600N 728 130 5100E). The age of the Kashala is confirmed as Triassic whereas the Marghazar has the upper Famennian age (Late Devonian). Pogue et al. (1992) reported Carboniferous age for the Jafar Kandao formation below the Marghazar. The upper Famennian age for the Marghazar compared to the Conodont age (Carboniferous) from the Jafar Kandao formation equivalent to Marghazar formation (DiPietro et al., 1993) confirm that the stratigraphy near Rustam is inverted. Work is in progress to locate

Permo-Carboniferous boundary. Important aspect of the recent radiometric ages on Mora and Ilam gneisses (Ahmed et al., 1997), and Chakdarra gneiss (DiPietro pers. com.) placed them in Early Permian, and thus provides better control on the stratigraphy. The overlying unconformable relationship of Marghazar formation with Mora and Ilam

gneisses and the intrusive relationship of Chakdara gneiss with Marghazar put it in Late Permian or Early Triassic. The overlying Kashala and stratigraphic equivalent Saidu and Nikanai Ghar may be placed as late Triassic or younger. We interpret the major structure to be north-south trending F4 folds of the Indian plate. The grade of metamorphism increases from south to north. The Karapa greenschist previously considered a single stratigraphic horizon below the Kashala formation (Pogue et al., 1992), Duma formation (DiPietro et al., 1993, 1999) and Jafar Kandao formation (Pogue et al., 1992) are grouped as Marghazar formation (equivalent to higher grade, amphibolites facies in Swat) representing the lower limb of the F4 fold. The core is occupied by the Nikanai Ghar formation (calcic and dolomitic marbles) the youngest unit in the area. The Marghazar formation (psammitic schist, greenschist, graphitic phyllite) is overlain by calcareous schists and marbles of Kashala formation, and followed by stratigraphic equivalent Saidu graphitic phyllite and Nikanai Ghar marbles.

A/91. Ahmad, I., Hamidullah, S. & Jehan, N., 1990a. Petrology and petrochemistry of the Shewa Shahbaz Garhi complex, Mardan, north Pakistan. Abstract, 2nd Pakistan Geological Congress, University of Peshawar, p.46.

The Shewa Shahbaz Garhi Complex occurs as an isolated triangular outcrop about 12 km north-east of Mardan. It consists of a group of acidic rocks intruded by basic rocks, including metagabbro, metadolerite and local quartz monzonite and sills. In order of decreasing relative ages, the acidic rocks are microporphyry, porphyritic granite, riebeckite granite gneiss and aegirine riebeckite porphyry.

The basic rocks are generally composed of hastingsite, clinopyroxene, orthopyroxene (in metadolerite), magnetite, biotite, epidote, apatite and leucocrane. The acidic types contain potash feldspar, plagioclase with riebeckite and aegirine as the common ferromagnesian mineral, indicating alkaline character. The mineralogy of the rocks indicates an amphibolite facies and a retrogressive epidote amphibolite facies metamorphism.

The major and trace element chemistry of both the basic and acidic types are indicative of their primary development as a result of fractional crystallization with olivine, clinopyroxene and plagioclase as the dominant crystallizing phases in basic rocks and plagioclase as the dominant crystallizing phase in acidic rocks.

The chemistry also indicates the derivation of the basic rocks from a sub-alkaline magma and of the acidic rocks from magma with characters in between alkaline and per-alkaline, both types emplaced in continental rift environment followed by the emplacement of basic dykes of continental flood basalt type.

Key words: Petrology, petrochemistry, basic rocks, acidic rocks, alkaline rocks, Mardan.

A/92. Ahmad, I., Hamidullah, S. & Jehan, N., 1990b. Petrology of the Shewa-Shahbazgarhi complex Mardan, north Pakistan. Geological Bulletin, University of Peshawar 23, 135-159.

The Shewa-Shahbazgarhi complex is an isolated triangular outcrop, occurring about 12 km northeast of Mardan. The complex resides 60 km south of Main Mantle Thrust as part of the Indo-Pak plate and consists of basic and acidic rocks including microporphyry, metagabbro, metadolerite and local quartz monzonite, riebeckite gneiss, aegirine riebeckite porphyry and porphyritic microgranite, together with basic and acidic dykes and sills.

The common minerals in basic rocks include hornblende, clinopyroxene, magnetite, biotite, epidote and apatite. The acidic rocks contain orthoclase, perthite and plagioclase together with riebeckite and aegirine, indicating alkaline characters. The mineralogy reflects amphibolite facies metamorphism followed by retrogression down to at least the upper greenschist facies environment in basic as well as in acidic rocks. Following metamorphism a considerable degree of deformation (cataclasis and/or mylonisation) is indicated in the acidic rocks.

Assessment of the chemical data suggest two different parent magmas; a rift-related tholeiitic type for the basic rocks and an alkaline to peralkaline type for the acidic rocks; both being emplaced in continental environments. The chemistry also suggests the control of fractional crystallization on the initial distribution of elements among the minerals of the two groups. A plagioclase-magnetite-clinopyroxene dominant assemblage on the liquidus in basic rocks and a plagioclase-hornblende dominant assemblage on the liquidus in acidic rocks, during fractionation, are suggested. A rift valley origin proposed by previous workers is supported.

A/94. Ahmad, I., Jan, M.Q. & LeFort, P., 1999. Unusual Ti, Fe, Mn and Ba silicates in alkaline granites from Mardan, Northern Pakistan. Geological Bulletin University of Peshawar 33, 57-62.

The Shewa Shahbazgarhi complex is a late Paleozoic intrusion covering 80² km area. It consists predominantly of silicic rocks (reibikite ± aegirine gneisses, aegirine-reibikite porphyry, porphyritic microgranite and local quartz monzonite) that have been intruded locally by metadolerite. One variety of granitic rocks contains unusual barium-, titanium- and manganese-bearing phases resembling bafertisite from mangolia. The mineral occurs in trace amount as fibre (up to 0.7 mm in length) in feldspar, biotite and rarely groundmass. It is faintly pleochroic from pale yellow to golden yellow. This mineral may be a product of hydrothermal process or autometasomatism related to residual fluids in the granitic magma. Six microprobe analyses are compared with bafertisite from Mangolia.

A/95. Ahmad, I. & Lawrence, R.D., 1992. Structure and metamorphism of the Chakdara area, NW of Swat River, Pakistan. Geological Bulletin, University of Peshawar 25, 95-112.

Two major faults, the Kohistan and Kishora thrust, divide the study area into three tectonic terranes, the Indian shelf, Garai mélange, and Kohistan arc. Stratigraphy, deformation, and metamorphism within each of these terranes developed independently until they were juxtaposed during Eocene-Oligocene collision. An important aspect of this study is the documentation of youngest deformation phases related with Himalayan orogen.

Three deformation phases (D_1 , D_2 , D_3) are recorded in the Indian shelf and the mélange matrix, each characterized by distinct fabrics and folding. S_1 occurs as relict intrafolial in the S_2 fabric as well as in the porphyroblasts and pressure shadows, in the Indian shelf rocks. F_1 are locally preserved and are found associated with movement on the Kishora thrust. S_2 is defined by the orientation of platy or elongated minerals and axial planes of F_2 folds. F_2 folds are strongly developed and strike NNE and SSW. These are associated with southeastward movement on the Kishora thrust. S_3 developed as minor crenulation cleavage when S_2 was folded during later deformation D_3 . F_3 strikes NNW and NS. It may probably be associated with the Kohistan thrust during the development of the Indus syntaxis. These deformation phases took place under conditions of amphibolite facies in the Indian shelf and greenschist facies in the mélange matrix.

The mélange blocks and the Kohistan rocks record different deformation events. Apparently they preserve pre-emplacement structures. Two deformation phases are recorded. During D_1 , S_1 and F_1 developed. S_1 occurs as relicts in the S_2 foliation. D_1 occurred independently in the mélange blocks and Kohistan arc. During D_2 , the S_1 foliation was folded. D_2 in the blocks is associated with the Kishora thrust while that in the Kohistan rocks is consistent with the D_2 of the mélange matrix and the Indian Shelf. D_1 and D_2 took place under conditions of greenschist facies in the mélange blocks and of amphibolite facies in the Kohistan arc.

Key words: Structure, stratigraphy, deformation, metamorphism, Malakand.

A/96. Ahmad, I., Lawrence, R.D. & DiPietro, J.A., 1998. Olistostromal blocks in metamorphosed Saidu mélange, Malakand Agency, north Pakistan. Geological Bulletin, University of Peshawar 31. Abstract Volume, 13th Himalaya-Karakoram-Tibet International Workshop. 1-3.

In Swat, the Indus suture zone contains mélanges of diverse origins. [1] distinguished the Shangla blueschist mélange, Charbagh greenschist mélange, and the Mingora ophiolitic mélange. The subduction-related Shangla blueschist mélange contains blocks of blueschist, serpentinite, piemontite schist, greenschist, metadolerite,

metagreywacke and metachert in a sedimentary matrix. The Charbagh greenschist *mélange* is mainly greenschist which is best interpreted as a very large block in the Shangla *mélange*. The obduction-related Mingora ophiolitic *mélange* is composed of tectonized blocks and clasts of serpentinite, emerald-bearing talc-carbonate, greenstone, metapyroclastic, metagabbro, metachert and metasedimentary rock in a talc-carbonate matrix. The structurally underlying Indian shelf rocks are Precambrian Manglaur schist (mostly quartz-mica-garnet schist), Carboniferous to Triassic Alpurai group (calc-mica-garnet schist), and Triassic Saidu formation (graphitic phyllite and marbles). These units along with the *mélange* units were metamorphosed between the latest Cretaceous and late Eocene.

New field work in the area southeast of Malakand Pass (Fig. 1), where the Saidu formation is widely exposed structurally beneath the Dargai ultramafic complex, suggests that this unit contains large olistostromal marble blocks and is in whole or in part a sedimentary matrix *mélange*. Immediately under the Dargai complex ultramafic fragments are sheared into graphitic schists of the Saidu. However to the east near Kharkai village the Saidu is composed of 2 members. The lower member is the graphitic schist previously described as the only unit of the Saidu; the upper member is mainly a quartz-muscovite-talc schist with minor quartz-biotite schists with lensoid inclusions of gray to black marble (Fig. 2). Block dimensions up to 500 m by 50 m are present. The contact between the members is gradational over more than 10 meters. The marble is equigranular, coarse-grained and sugary textured. Much of it is internally brecciated in fragments with the same composition as their matrix. A few fragments contain some mica. These fragments are slightly flattened, but not dramatically strained. Massive, unbrecciated marble layers extend into the marble bodies in various orientations, commonly not parallel to the contact between the marble and the adjacent schists. The quartz-muscovite-talc schists contain small amphibolite layers that may be metavolcanic and a few horizons that look like possible meta-tuffaceous material. This upper member of the Saidu does not resemble any of the units previously mapped in the region.

The Saidu, including the marble lenses, is multiply folded. The several blocks are the noses of tight asymmetric folds overturned toward the SSW. The best documented fold west of Palai has an axis trending S70°E, plunging 30° and an axial plane dipping about 45° to the north. Another lens is made up of 4 boudin shaped fragments. No connection, such as attenuated limbs have been observed between blocks, although several blocks appear to occupy the same horizon in at least one case. Contacts between the marble blocks and the enclosing schists are mostly sheared.

Our best interpretation of this upper member of the Saidu is that it is a slope/rise sedimentary accumulation with olistostromal limestone blocks derived from reefal limestone bodies on the outer edge of the adjacent Gondwana shelf. Much of the internal brecciation may be derived from debris deposits on the reef. Lack of major strain of these features suggests that the folds in which the bodies are found developed under conditions in which the limestone was a competent unit relative to the enclosing clastic materials.

We suggest that the Saidu formation is a metamorphosed olistostromal (sedimentary type) *mélange* analogous to the "Oman Exotics" of Hawasina complex of Oman Mountains. The "Oman Exotics" form isolated masses from boulder size to 1000 m thick Middle to Upper Permian and Upper Triassic fossiliferous limestones that crop out within imbricated thrust slices beneath the Semail ophiolite in the Oman mountains. They are commonly associated with a substrate of alkalic and transitional tholeiitic basalts and are interpreted as a series of reef-associated carbonate buildups deposited in part on oceanic islands or seamounts close to the site of initial rifting of the Oman continental margin. These blocks slid into the deep sea sediments being deposited to the north. Most of these features are present in the Saidu, but obscured by metamorphism.

A/97. Ahmad, I., Rosenberg, P.S., Lawrence, R.D., Ghauri, A.A.K. & Majid, M., 1987. Lithostratigraphy of the Karakar Pass section, south of the Main Mantle Thrust, Swat, N. W. Pakistan. Geological Bulletin, University of Peshawar 20, 199-208.

The Karakar Pass section marks the northern edge of Indo-Pakistan plate. It is predominantly composed of highly deformed and metamorphosed Cambrian and Tertiary (?) granitic rocks and Paleozoic (?) metasediments. The granitic rocks of the area are divided into augen gneisses and tourmaline granites, each belonging to a different age group. The metasedimentary rocks are grouped into Alpurai schists and Nikanai Ghar Marbles.

The augen gneisses are unconformably overlain by the Alpurai schists and tourmaline granites occur as an intrusive sill-like body into the augen gneisses and the surrounding quartzose metasediments. The Alpurai schists include three members: 1) quartz-mica schist and amphibolites, 2) calc-schists and schistose marbles, and 3) graphitic schist. The whole sequence is terminated in the southeast by the Nikanai Ghar fault, which juxtaposes these units against the Nikanai Ghar Marbles.

Key words: Metamorphic rocks, granites, Precambrian, Cambrian, metasediments, Karakar pass, Swat.

A/98. Ahmad, I., Rosenberg, P.S., Lawrence, R.D., Majid, M. & Ghauri, A.A.K., 1987. Evidence of multiple deformation in the rocks of Karakar pass area, Swat, NW Pakistan. Geological Bulletin, University of Peshawar 20, 189-198.

Lithologically the Karakar Pass area is divided into Swat granitic rocks, Alpuri schists, and Nikanai Ghar Marbles. These rocks units have undergone at least three different phases of deformation (D1, D2, D3).

D1 produced a pervasive regional foliation S1, mineral lineation L1, and tight to isoclinal, NW-SE oriented F1 folds. S1 is generally parallel to original layering (So) and axial-plane to F1 folds. D2 folded S1 into open, upright F2 folds, with north-south axes. It locally caused the development of an S2 crenulation cleavage. D3 resulted into small to large scale, east west oriented, cross folds (F3).

In the Karakar Pass area the Swat granitic rocks and the Alpuri schists from the hinge and the southern limb of the east west oriented large recumbent F3 fold. To the south, the Nikanai Ghar Marbles are interpreted to form a large fault-and-fold nappe, herein named as the Nikanai Ghar Nappe.

Key words: Structure, deformation, Swat.

A/99. Ahmad, J., 1993-95. Electrical Resistivity Survey for groundwater exploration in Zulmkot Area, District Malakand, NWFP, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 82p.

The electrical technique is the most powerful tool to explore groundwater, the buried channels and the bedrock in the subsurface.

This technique was applied to explore the ground water potential in Zulmkot area District Malakand, NWFP Pakistan. Eighteen VES stations were selected for said purpose where Schlumberger and Wenner electrode configurations were used for vertical electrical sounding. The Wenner profiling was also carried out at different locations to detect buried channels of the main stream as well as to observe the lateral variations of the subsurface materials.

In order to have first hand information of material distribution in the subsurface, iso-resistivity maps for different L/2 spacing were prepared by using WINSURF computer program. These maps were used to identify the locations of high and low resistive material in the subsurface.

Later, the field data was processed in order to have the true resistivities and true depths of the subsurface formations by four different methods of interpretation.

Firstly, the field data was processed using quantitative methods such as a complete curve matching and partial curve matching using auxiliary point method. The true depths and true resistivities of the subsurface layers were obtained by using RESIST-87 computer program. The field data was also interpreted by the iterative interpretation technique using A.A.R. ZHODY'S program. Based on the results obtained from these methods of interpretation five different resistivity zones were established such as very high, high, medium, low and very low.

On the basis of true resistivities and true depths of the subsurface layers, geoelectric sections as well as profiles of transverse resistance 'T' and longitudinal conductance 'S' were constructed which helped to interpret the subsurface geology of the Zulmkot area along different lines.

Different aquifer zones have been identified in different geoelectric sections, which were constructed along different lines. There identified aquifer zones generally fall within the medium and high resistive zones, which were further confirmed by the lithologic logs of test wells at different locations. The test well data of project area reveals that the water table, generally, varies from 10 m to 25 m. On the identification of aquifer zones in the project area, different locations have been recommended for test drilling to confirm the results of the survey carried out in the Zulmkot area. In order to get more detailed information of the subsurface geology in Zulmkot area, integrated geophysical survey has also been recommended.

A/100. Ahmad, J., Ahmad, I. & Abid, A., 1980. Geology of the area between Manglaur Kishora (Malam Jabba), Swat. M.Sc. Thesis, University of Peshawar, 99p.

This report represents a comprehensive geological study of about 210 square kilometer area which lies 8 kilometer northwest of Mingora (Swat).

The area has been mapped and detailed petrography is presented. The area is occupied mainly by regional metamorphic rocks which represent the extreme northern edge of the lower Swat Buner schistose group and consists of a succession of silicious schist, amphibolite schist, calcareous schist with abundant marbles, phyllite schist and green schist.

The acidic rocks are represented by granitic gneiss and augen gneiss which mainly occupy the area under investigation and towards north have a tectonic contact with the ultramafic rocks of the Shangla Ophiolites.

The structure of the area is complex. The rocks are highly jointed and folded. Plunging folds as well as recumbent folds are commonly seen in the calcareous schist which are produced mainly due to the tectonic relationship of lower Swat Buner Schistose Group (Indian Mass) with the Hornblende Group (Asian Mass). Besides these folds, the rocks are well foliated and lineated. Graphitic schist and phyllitic schist horizons are highly jointed as compared to the other units. The area investigated does not have much economical potentials, however, kyanite, Granite and building stone is of some importance.

A/101. Ahmad, J., Khaliq, A. & Khan, T.M., 2001. Uranium potential of graphitic metapelites of Gandghar Range N.W. Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 12-13.

The graphitic metapelite belonging to Manki Formation of Gandghar Range, due to its radioactive nature, was investigated in detail including surface and subsurface exploration through drilling and aditing. The surface and subsurface data revealed that the metapelites are highly anomalous in uranium and contain an average of 40 ppm uranium compared to the uraniferous black shales in the world, which generally contain 5-11 ppm uranium. Chemical analysis of water samples collected from springs and streams located within the graphitic metapelites of Gandghar Range include highly anomalous concentration of uranium at certain localities with evidence of active leaching of uranium. This leaching process is favourable for supergene concentration of uranium within suitable structural traps formed due to intraformational deformation in metapelites and below water table.

The U-Pb isotopes have been successfully used in China to locate blind ore deposits in black shales. The same method was employed and a total of 39 rock samples from metapelites were collected and analysed in China. The results indicated radiogenic lead anomalies at five localities.

The R.O.A.C. survey at selected sites revealed strong anomalous halos at certain places along a linear zone indicating uranium concentration at depth. The chemical composition of rocks of metapelites of Gandghar Range indicate that they are more siliceous and contain high organic carbon content compared to other metapelites in the region. Moreover, these rocks are also enriched in U, Y, Ba, and Pb. The enrichment of some of the elements took place in association with detrital fraction of the rock while the rest of the enriched elements were concentrated from normal seawater in oxygenated transitional environment close to the continent. The graphitic metapelites were probably deposited in a basin fed by various source materials.

Unlike typical black shales deposit uranium does not indicate any correlation with organic carbon. The absence of relationship is primarily caused by dissolution of some elements in ground water circulating freely in otherwise impermeable rocks, made permeable by structure movement in the region. The data collected from metapelites of Gandghar Range show high potential for uranium like other black shale uranium deposits elsewhere in the world.

Key words: Gandghar Range, Uranium mineralization.

A/102. Ahmad, J., Syed, S.A. & Khaliq, A., 2000. Geological appraisal of uranium-thorium occurrences in Ambela granitic complex, NW Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, p.133.

U-Th anomalies (orthomagmatic, pegmatitic/applectic, hydrothermal) related to granitic rocks have been described. It is proposed that primary Uranium in the complex has been fractionated and remobilized in latter differentiates during cataclastic deformation. The Uranium bearing solution followed the channels so produced.

A/108. Ahmad, M., 1981-83. Lithostructural mapping of Mansehra Susal and Matial Area, District Mansehra. M.Sc. Thesis, Punjab University, Lahore, 84p.

Lithostructural mapping with preliminary structural studies have been made of Mansehra, Khaki, Rihar area district Mansehra at a scale of 1:1000. An attempt has been made to delineate the boundaries of igneous and metamorphic rocks precisely. Physiographic/stratigraphic studies and various structural contour diagrams have been drawn to determine axis of minor folds. Orientation has been determined with the help of Rose diagram. Thin section has been studied to determine different phases of deformation. Attempt has been made to analysis the strain with Flinn's and Ramsay's plots.

On the basis of microscopic and mesoscopic analysis it has been tried to interpret the structural and macroscopic scale. On the basis of Kinematics Study, structure of the area is interpreted.

Key words: Structure, Mapping, Mansehra.

A/109. Ahmad, M., 1983-85. Report on geology and structure of Balakot-Kummi Area. M.Sc. Thesis, Punjab University, Lahore, 100p.

The present work constitutes a comprehensive report on the geology of Balakot -Kummi area and is submitted in partial fulfillment of the requirements for the degree of M.Sc. at the University of the Punjab. The report includes a detailed geological map at 1:6,000 of about 65 km. sq. area along with a number of geologic sections and sketches. The various chapters include geomorphology, stratigraphy, structure and tectonics. Stratigraphically, the Balakot-Kummi area includes a number of diverse sedimentary and metamorphic elements ranging in age from Precambrian to Miocene with a fairly large gap in the Mesozoic period. Structurally, the area incorporates part of the core and western limb of the Hazara-Kashmir syntaxis and through it pass the major Murree and Panjal Faults. The Balakot-Muzaffarabad anticline is the major fold overturned and overthrust to the southwest. No major economic mineral

deposit was found within the project area, although a lot of material is available as rock crush, aggregate components and building stones.

Key words: Geology, structure, Balakot.

A/111. Ahmad, M., 1985-87. The geology and petrography of volcanic and carbonate rocks of upper Haveli (District Bagh) and Balgiran-Manjhoter, District Muzaffarabad with special emphasis on lead-zinc mineralization. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 110p.

The project area covers about 417 square kilometers located in District Bagh and Muzaffarabad, Azad Kashmir. The work has involved geological mapping of the area on a scale of 1:25,000 and 1:15,000 respectively.

This thesis deals with the geology and petrography of Panjal Volcanics and carbonate rocks of the area. The geological sequence of the area consists of sedimentary, volcanics and metamorphic rocks. Lithologically metamorphic rocks present in the area are Schist, Slates, Phyllites, Quartzite and marble while sedimentary rocks comprise Sand stone, shales, silt stone, lime stone. Volcanic rocks belong to two distinct ages. Dogra trap are of Precambrian age and occur within the Dogra Slates. Panjal volcanics or Panjal trap flows are of Upper Carboniferous age and basaltic to andesitic in composition, while mineralogical studies of Dogra trap shows that they are of basaltic composition. Petrographic analysis of Panjal volcanics, Agglomeratic slates, limestone and marble have been carried out. The mineral assemblage in volcanics is plagioclase + chlorite + epidote + Quartz + Calcite, while of agglomeratic slates is Quartz + epidote + chlorite + Calcite + plagioclase the mineralogical assemblage of lime stone and marble is calcite + quartz + muscovite + magnetite. Pb-Zn mineralization in carbonate rocks of Khetar-Treri areas has been interpreted. The evidences are strongly supporting that Pb-Zn mineralization is the result of hydrothermal solution.

Petrogenesis of Panjal Volcanics has been carried out. The evidences reveal shallow water or submarine origin of the Panjal Volcanics. Tectonically the area is highly disturbed, being involved in Himalayan orogeny.

Key words: Geology, petrography, lead-zinc, Muzaffarabad.

A/112. Ahmad, M., 1985-87. Electrical resistivity survey for groundwater potentials in Masal Talao, Amir Khan Talao, Khachar Talao and Haji Talao, District Peshawar. M.Sc. Thesis, Punjab University, Lahore, 60p.

Electrical resistivity survey in Masal Talao, Amir Khan Talao, Khachar Talao and Haji Talao (District Peshawar) was carried out in collaboration with Hydrogeology Directorate WAPDA Peshawar. The main purpose of the survey was to determine hydrogeological features such as depth to the bed rock, nature and thickness of aquifers, the quality of groundwater, and to select suitable sites for tubewell installation in the project area.

According to resistivity survey and drilling data the entire area is underlain by low resistive clay with occasional gravels. The overlying alluvium is composed of alternating layers of gravels and clays. Ground water appears to be quite fresh in the entire project area. Water table depth varies from 13m to 40m in the area under investigation.

In the project area, twenty seven probes were carried out. After interpreting the data, the V.E.S. No. 95, 93, 51, 40, 15 and 17 have been selected for the test drilling, however other probe sites also indicate the presence of aquifers in the area but of varying thickness.

The entire area appears to be favourable for tubewell installation, however the yield of water depends upon the nature of aquifers, may range from half cusec to one and half cusec project area.

Key words: Resistivity, groundwater, Peshawar.

A/113. Ahmad, M., 1986-88. Electrical resistivity survey for ground water potentials in Khesghi Area (N.W.F.P.). M.Sc. Thesis, Punjab University, Lahore, 70p.

Electrical resistivity survey in the project area includes prominent villages Khashgi Bala, Goddu kili, Mala Kili (N.W.F.P) was carried out in collaboration with Hydrogeology directorate WAPDA, Peshawar. The main purpose of the survey was to determine hydrogeological features such as nature and thickness of aquifers, the quality of groundwater, and to select suitable sites for tubewell installations in the project area.

According to resistivity survey and drilling data the entire area is underlain by low resistive clay, with occasional gravels. The overlying alluvium is composed of alternating layers of clays and sand with gravels. Ground water appears to be quite fresh in the entire project area. Water table depth varies from 11 ft to 75 ft. in the area under investigation. In the project area 32 probes were carried out. After interpreting the data, the V.E.S No. 5 has been selected for the test drilling, however other probe sites also indicate the presence of aquifer in the area but of varying thickness. The area appears to be favourable for tubewell installation; however the yield of water depends upon the nature of aquifer.

A/115. Ahmad, M., Ali, K.S.S., Khan, B., Shah, M.A. & Ullah, I., 1969. The geology of the Warsak area, Peshawar, West Pakistan. Geological Bulletin, University of Peshawar 4, 44-78.

The Warsak Area, Peshawar, West Pakistan, has been geologically mapped and the petrography of the rocks described in detail. The area consists of a series of metasediments of the greenschist facies (slates, phyllites, mica schists, garnet schists, hornblende schists, calcareous schists and marbles), which have been divided into a Lower, Middle and Upper Series. On the eastern side the metasediments disappear under the alluvium of the Peshawar plain. They range from Siluro-Devonian to Upper Palaeozoic in age, and are intruded by sills of metagabbro and metadolerite (? Cretaceous), porphyritic microgranite (?Upper Cretaceous to Lower Tertiary) and the Warsak alkaline granite (?Lower Tertiary).

The chemistry and alkaline nature of the granites (which contain aegirine, riebeckite and astrophyllite) is briefly discussed. The structure of the area is shown to be a northwards plunging syncline faulted on the east on the northern side of the Kabul River. The joint patterns and other structural features are described, and the economic geology of the area discussed.

Key words: Geology, Warsak, Peshawar.

A/116. Ahmad, M. & Ali, L., 1979. The geology of the right abutment of Terbella Dam area, reference to porosity and permeability. M.Sc. Thesis, University of Peshawar, 40p.

The Terbella Dam has been constructed on the river Indus in the Terbella quadrangle. The right bank or right abutment from the right side of the Terbella Dam area. It occurs towards the Topi, in Mardan Distt.

The Topi Terbella and Gandaf roads are two accessible routes to this area. The right abutment is originally a sedimentary unit which is later metamorphosed and intruded by some basic igneous rocks. Hence it consists of all the three major types of rock, which are sedimentary, igneous and metamorphic rock. Of the sedimentary rocks limestone is common. Metamorphic rocks dominates the area and the main representatives are quartzites, chlorite schist and phyllites. Basic igneous rocks are found in the form of intrusions. The area is folded and foliated to various extent. The oldest fault occurs beyond the tunnel outlet one trends east-west.

A series of small and compressed folds occur at the power house. The area where these folds occur is occupied by limestone, gypsum and carbonaceous schist.

Key words: Porosity, permeability, Terbella Dam.

A/118. Ahmad, M., & Rehman, A., 2000. Understanding tectonic movements within Pakistan Northern region. Abstracts, Third South Asia Geological Congress, Lahore, 142-143.

The regional movements caused by continuous complex movements along numerous faults need to be understood. This study will lead to the analysis of the processes and sources which cause major earthquakes in this region. The region is characterized by dramatic changes in the azimuth of structural trends involving thrust faults, graben, strike slip faults and folding, and is obviously under continuing severe distortions. In the recent past, magnitude 7 earthquakes have occurred in this region. Larger events (Chatkal 1946, Alai 1974) and magnitude 8 (Kashgar 1902) have been experienced. Cambridge Expedition of 1980, resurveyed the original survey network of triangles and polygons in 1913 by Mason. Armbruster, Seeber & Jacob (1978) estimated activity from micro earthquakes of the order of 37 mm per year of the northward movement of the Indian Plate relative to Eurasian Plate.

Although 1913 survey was not accurate enough as the noise level of survey should be less than 4 cm/year to confirm the movements. The 1980 survey results can be used as datum. The movements are clearly not uniform and then there is the factor of larger earthquakes. Also much of the plate tectonics convergence is definitely being absorbed as sporadic slip on extensive thrust faults and strike slip faults. There will be some locations where strains will be several times the accuracy of survey results can be used as datum. The movements are clearly not uniform and then there is the factor of larger earthquakes. Also much of the plate tectonics convergence is definitely being absorbed as sporadic slip on extensive thrust faults and strike slip faults. There will be some locations where strains will be several times the accuracy of survey observations. With the revolution in survey techniques (GPS), it is now possible not only to have the level of accuracy required but also the observations can be much quicker enough to have repeat observation. Cambridge Expedition recommended that observation be repeated after about 10 years. It will be invaluable to geologists, geophysicists and geodesists to know the deformation pattern and history.

This is a study that relates the development and composition of soils with time in the Punjab plains. Studies of the soils since the late Pleistocene give an estimate of the time required for the formation of semiarid soils. The authors found secondary accumulations of calcium carbonate in the subsurface of 10,000 to 20,000 year old soils, while 23,000 year old soils had none. The older soils also exhibited clay illuviation and low organic matter.

A/122. Ahmad, M.A., 1973. Seismic refraction investigations at Tarbela dam site and Pihur area of Hazara and Mardan districts, Peshawar division, NWFP, Pakistan. Geological Survey of Pakistan Records, 21(2), 7.

Seismic refraction survey was carried out during October- November 1970 at Tarbela damsite and Pihur-Topi Gap, Hazara and Mardan districts. The objective of the study was to determine if concealed Indus fault precisely delineated at the damsite maintains its southerly trend along the river course in Pihur-Topi area. Four refraction traverse in Pihur-Topi Gap area and one at the damsite were observed. The subsurface configuration of the bed-rock has been determined and shown in the form of sections.

It is concluded that the main Indus fault extends southwards from the Damsite towards profile AB about 9500 feet down stream from the central axis, under the gravels. Further downstream from profile AB it was not possible to trace the trend of the concealed fault as there was no positive indication on the profile CD, EF & GH which were located west and southward of profile AB in Pihur-Topi Gap.

A/125. Ahmad, M.K. 1988-90. Petrology and mineralogy of the area (Gokdara-Ghaligai), District Swat. M.Sc. Thesis.

The detailed geological map of the project area has been prepared. The project area has been mapped on a scale 1" = 12500" = 12,500'

This thesis consists of two sections. Section No.1 deals with the general geology of the project area. Introduction, Physiography, Structural Geology & Tectonics and the lithologic units of the project area have been discussed in this part. In Section No.2, Petrography, Chemical analysis, Petrogenesis, Discussion on Petrogenesis, Economic Geology and some thing, new one (Dolomite/Wollastonite Skarn) in the project area is discussed.

The project area is consisting upon the metasedimentary and metamorphic rocks which lie in the Higher Himalaya Crystallines of the MMT Zone. The rock units belong to Lower Swat Buner Schistose Group and are of Lower Palaeozoic age.

Key words: Petrology, petrography, Swat.

A/126. Ahmad, M.N., 1995. Magnetic mineralogy of Khunjerab batholith in Hunza area, northern Pakistan, with special reference to its paleomagnetic reliability. In: Khadim, I.M. & Yoshida, M. (Eds.), Rock Magnetism and Paleomagnetism. Recent Progress in Pakistan, Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad, 13, 23-41.

Rock and mineral magnetic properties are examined for altered granites collected from Khunjerab Batholith, Hunza area, Northern Pakistan. The major magnetic carriers in the granites are determined ilmenite-hematite intergrowth, goethite, maghemite, and trace amount of pyrite on the basis of results of optical microscopy, thermomagnetic analysis, magnetic hysteresis analysis, and IRM measurement. The contents of ferromagnetic minerals are very small but the grain size is rather multidomain state, and the distribution is not homogeneous even in hand sample. All the samples are strongly overprinted by recent local geomagnetic field, but neither thermal nor alternating demagnetization is effective to separate the characteristic component (CgRM) from the NRM because of its magnetic phase transition in heating experiments and high coercivity, respectively. The magnetic phase transition is generally observed at above 350°C in non-oxygen environment, which may be derived from inversion of α -phase maghemite to β -phase magnetite and/or fmm decomposition of pyrite. Therefore, paleomagnetic data of the Khunjerab Batholith, especially the direction of ancient magnetic field during the formation of the granite body can hardly be obtained.

Key words: Magnetism, paleomagnetism, Khunjerab.

A/127. Ahmad, M.N., Fujiwara, Y. & Paudel, L.P., 2000. Paleomagnetic study of igneous rocks of Gupis-Shamran area, Kohistan arc, Pakistan, NW Pakistan. *Earth Science Frontiers* 7, Abstract Volume, 15th Himalaya-Karakoram-Tibet Workshop, Chengdu China, 120-121.

Kohistan Sequence has been considered as island arc formed during the subduction of oceanic lithosphere at the leading edge of northward moving Indian Continent. Sedimentary sequences indicate that formation of the intra-oceanic Kohistan arc began in early Cretaceous time. The isotopic data demonstrate the involvement of enriched, DUPAL type mantle, suggesting that Kohistan arc was formed at or south of the present equator (Khan et al., 1997). The Intra-oceanic phase of Kohistan lasted until sometime between 102 and 85 Ma, when Kohistan collided with Asia. From this time until collision with India about 50 Ma ago, Kohistan existed as Andean-type margin.

This paleomagnetic study is from the volcanic and plutonic rocks exposed in Gupis-Shamran area (west of Gilgit) in northern part of the Kohistan arc. According to geochronological data these rocks were formed 61~55 Ma ago (Treloar et al., 1989), when Kohistan was existing as Andean-type margin. Seven to nine samples were collected from nine sites of Shamran volcanics (58 ± 1) Ma and from five sites of Pingal, Gupis, and Yasin plutons (Ar-Ar hornblende ages ranges from 61~52 Ma). On the basis of one Rb-Sr age (59 ± 2) Ma from these plutons, the above-mentioned Ar/Ar ages may be regarded as reasonable intrusion ages of these plutons (Searle, 1991).

Magnetic mineralogical study i.e. IRM analysis followed by stepwise thermal demagnetization and microscopic study reveal that magnetite is major magnetic remanent carrier in these rocks. The other opaque minerals observed are ilmenite and pyrite. Opaque minerals occur as both primary magmatic product and secondary product of mafic minerals in all the samples. The primary magnetite is found as irregular grains in interstices of other minerals. Sometimes it is also occurred as inclusions in hornblende and biotite. Secondary magnetite is alteration product of pyroxene, hornblende and biotite. In general in mafic rocks (diorite, andesite, and tuff) secondary opaques are common as compared to felsic rocks (granodiorite and granite). Slight deformation and low-grade metamorphism have affected all rocks. The mafic minerals like pyroxene, hornblende, and biotite have been partially or completely altered to chlorite, epidote, calcite and opaques. The mineralogical evidences show retrograde type metamorphism at relatively higher fluid pressure and low temperature conditions.

In most of cases two magnetic remanent components are revealed from Zijderveld diagrams of progressive thermal demagnetization. First component is a low temperature component having unblocking temperature ranging from 400~500°C, yielding remanent magnetization directions parallel to present earth's magnetic field in geographic coordinates. This remanent direction is interpreted as viscous remanent magnetizations of recent origin, carried by multidomain magnetite grains. In samples of 11 sites (8 from volcanics and 3 from plutonic rocks) characteristic remanent magnetization component with NNW and SSE pointing directions of moderate inclinations of normal and reverse polarity in geographic coordinates is obtained. The unblocking temperature in all of these cases is 570~580°C. This magnetic remanent component may not be of primary origin as mean directions are scattered after the application of the structure correction. This post-folding component may be carried by secondary magnetite, which was formed by the flow of fluids at low temperatures as observed in microscopic study. Hence this secondary remanent magnetization is chemical remanent magnetization (CRM) or thermochemical remanent magnetizations (TCRM). All the plutonic activity in the area is pre-tilting of the volcanics; therefore the secondary magnetite giving post folding remanent magnetizations cannot be produced at the time of intrusion of any pluton. The K-Ar biotite age of Gupis pluton is about 40 Ma. This is giving the evidence that at 40 Ma the area is still hot at about 300°C (closure temperature of biotite). We interpret the formation of this secondary magnetite by hydrothermal processes; due to release of water from water saturated solidus magma, during the uplift of the area. The mean direction for this secondary component along with Fisherian statistics is as follows:

Dec=339.5 Inc=43.6 k=24 Alpha-95=9.5

The calculated mean paleolatitude is about 25°N, which is 10°C south of the present position. Hence the area moved 10°C northward after the acquisition of remanent magnetization. The comparison of calculated paleolatitude of the area with Indian apparent polar wander path (APWP) indicates the acquisition age of these magnetizations is 40~35 Ma. In this comparison 470-km north south shortening south of the Kohistan arc is also taken in account to assign age of magnetizations correctly.

In samples of only three sites pre-tilt characteristic remanent magnetization is obtained. The calculated paleolatitude (6.6°N) for this pre-tilt component is well in agreement with pre-tilt remanent magnetizations of red beds of Kohistan arc. The Ar-Ar hornblende age of the volcanics is about (58 ± 1) Ma. This component may be acquired during the original cooling of the rocks before the tilting of the studied volcanics. Comparing paleolatitude with

present latitude of the area, it can be inferred that area has moved northward about 300-km since the acquisition (about 58 Ma) of remanent magnetization.

Key words: Paleomagnetism, Igneous rocks, Kohistan arc.

A/128. Ahmad, M.N., Fujiwara, Y., & Paudel, L.P. 2001. Remagnetization of igneous rocks in Gupis area of Kohistan arc, northern Pakistan. *Earth Planets Space*, 53, 373–384.

The Kohistan arc was formed due to subduction of neo-Tethyan oceanic crust beneath Asia. The arc is comprised of volcanic, plutonic and sedimentary rocks of Mesozoic to Tertiary age, formed prior and after the suturing of the Indian and Asian continents. Paleomagnetic investigations have been carried out on Paleocene volcanic and plutonic rocks exposed in the northern part of the arc. A total of 110 samples from 16 sites were drilled. According to rock-magnetic studies the main magnetic carrier is magnetite. Optical microscopy study reveals that low-grade metamorphism have effected all rocks. Magnetite is found as both a primary magmatic mineral and secondary alteration product in all samples. Samples of volcanics yield post tilting characteristic remanent magnetizations (ChRM). The in situ mean direction of the ChRMs of the intrusives is similar to the in situ mean direction of volcanics. The presence of secondary magnetite in plutons, the similarity of in situ mean ChRM of plutons with that of post-tilting ChRMs of similar age volcanics and dissimilarity of the mean ChRM of plutons from expected directions at the time of formation of plutons support a secondary origin for the ChRM of plutons. As the ChRM directions of the volcanics and intrusives are the same, it implies that both ChRMs were acquired during the same remagnetization event. Comparing the mean paleolatitude ($25 \pm 6^\circ$ N) from Gupis area with those from Indian APWP and considering the fact that there was prevailing heating event in Lower Tertiary in the area, the acquisition age of this secondary remanent magnetization can be bracketed between 50 and 35 Ma.

A/129. Ahmad, M.N. & Yoshida, M., 1995a. Paleomagnetic studies of Paleogene pyroclastic flow deposits of Utror Volcanic Formation, Kohistan arc, northern Pakistan. In: Khadim, I.M. & Yoshida, M. (Eds.), *Rock Magnetism and Paleomagnetism. Recent Progress in Pakistan*, Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad, 13, 149-168.

Calc-alkaline volcanic rocks are distributed in the Kohistan arc, the northwestern margin of the Himalayan range. The sequence of Kohistan arc has been interpreted as a mature island arc formed by subduction during Mesozoic time between the Indo-Pakistan Subcontinent and Asian Continent and obducted onto Indian plate in Eocene time. The Utror volcanics Formation is probably the upper most part of the island arc sequence. Total 23 oriented samples (5 sites) from altered plagioclase-rhyolitic pyroclastic flow deposits of this formation to the southwest of Kalam village, upper Swat valley. According to the results of progressive thermal demagnetization (THD), almost all samples possess mainly three components of remnant magnetization; the components 1, 2, and 3. The component 1 is generally unstable remanence and it can be observed in the steps less than THD 300 C. the component 2 is identified in the THD interval between 300 C and 540 C. the component 3 is detected in the final THD steps above 540 C. on the basis of results of optical ore-microscopy, thermomagnetic analysis, and coercivity spectrum analysis, origins of these magnetic components can be interpreted as follows: the component 1 is a recent magnetization of the goethite-magnetite assemblages formed by hydration and low-temperature oxidation processes.

Key words: Paleomagnetism, Cretaceous, Granites, Volcanics, Kalam, Swat.

A/133. Ahmad, M.N. & Yoshida, M., 1997b. Paleomagnetic study of Upper Cretaceous and Paleogene igneous rocks in Kalam area, Kohistan arc, North Western Himalaya. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 67-68.

The Himalayan mountain belt was formed by a crustal deformation caused by the collision of the Indo-Pakistan subcontinent with the Eurasian continent during the early Tertiary. In the northwestern part of the Himalayan belt, this collision is not simple because Ladakh-Kohistan arc was captured between the two colliding continental blocks. Different types of igneous rocks such as calc-alkaline volcanic rocks and granites are distributed in Kalam area, Pakistan, west centre part of Kohistan arc, northwestern margin of Himalayan Range. Two types of igneous rocks were selected for paleomagnetic study i.e. from altered plagioclase-rhyolitic pyroclastic flow deposits of Utror volcanics and Stage-1 granitic (Sullivan, 1993). Total 23 samples (5 sites) of the Utror volcanics and 10 samples of the granite were selected for the paleomagnetic study. Ar-Ar dates of the Utror volcanics and the granite are 55 Ma and 78 Ma respectively (Zeitler, 1985, and Treloar et al., 1989). Magnetic mineralogical studies such as optical microscopy, thermomagnetic analysis, IRM acquisition analysis reveals that goethite, titanomagnetite, and hematite are the major ferro magnetic carrier of natural remnant magnetization (NRM) in pyroclastic flow deposits of Utror volcanics while in the granite magnetite is the major carrier of NRM. Progressive thermal demagnetization (THD) analysis was carried out in 13-16 steps up to 675°C for the Utror volcanics while for the granite thermal demagnetization analysis was carried out up to 575°C in 14 steps. Zijderveld diagrams for the Utror volcanics are indicating three components of remnant magnetization; the Component-1, -2, -3. The Component-1 is generally unstable remanance and it can be observed up to THD 300°C. The Component-2 is from 300-540°C, and the Component-3 is above 549°C. On the basis of magnetic mineralogical studies, the Component-1 is recent magnetization due to the presence of goethite-maghemite assemblages which might be formed because of low temperature oxidation. The Component-2 is the magnetization of Ti-poor titanomagnetite in anatase-magnetite assemblages produced from a hydrothermal alteration. The Component-3 is remnant magnetization of hematite in ilmenite-hematite intergrowth, which might be developed because of thermal activity. In the granitic samples there is one component in Zijderveld diagrams it is stable up to 300°C then there is drastic decrease in the NRM intensity up to the 575°C. In the case of Utror volcanics negative fold test as well as optical study reveal that the nature of the remnant magnetization (Comp-2 and 3) is secondary and the mean direction are Declination=139°, Inclination=34° and Declination=138°, Inclination=-30 for the Component-2 and -3. The Paleolatitude of the Component-2 and 3 are 19°N and 16°N. The acquisition of these remanences might be due to the obduction of Kohistan arc on to the Indian continent. By comparing with the present day latitude of the study area it is estimated that there is about 2000-km crustal shortening after the collision. The ChRM in the case of granite is considered to be of primary nature and tilted corrected direction are Declination=114° and Inclination=-14°, therefore the formation of the granite was at lower latitudes i.e., 7°N in 75-78 Ma. The comparison of paleolatitudes of the granitic rocks and Utror volcanics shows that there is about 900-km northward movement after the formation of the granite till the Indian-Kohistan collision. The declination data indicate that there is a counter clockwise rotation after the formation of the granite and the collision.

A/134. Ahmad, M.N., Yoshida, M., Ali, M., Khadim, I.M., Kaneda, H., Karim, T. & Aslam, A., 1993. Geomagnetic and VLF-EM survey of some mineralized zones in Chitral District. *Proceedings of Geoscience Colloquium*, Geoscience Lab, GSP, Islamabad, 7, 44-71.

The above interpretation can be concluded in following points:

The magnetic method is useful for the exploration of copper deposits as copper is associated with magnetic minerals. The dimensions of the magnetic body associating copper mineralization can be calculated with the help of magnetic anomaly. In Kaldam Gol site estimated reserves are 3400 tons. Siderite ore deposits in limestone are also detectable by geomagnetic method, but modeling is not possible due to weak susceptibility contrast. Geomagnetic method is useful to explore the suture and faulted zones when some serpentinization develops along them.

In case of VLF-EM data there is a strong anomaly of QUAD and PHASE over siderite deposit. However there is little positive response over other ores either because of shallow depth of penetration of VLF waves because of high frequency (23.4 KHz) or some transmitter problem.

A/135. Ahmad, M.N., Yoshida, M. & Fujiwara, Y., 1999. Paleomagnetic study of Utror Volcanic Formation and Deosai volcanics of Kohistan-Ladakh arc, Pakistan, North Western Himalaya. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 2-3.

The Kohistan-Ladakh sequence has been considered as an island arc formed during the subduction of oceanic lithosphere at the leading edge of the northward moving Indian plate. The northward movement after collision of Indian plate and the arc led to the formation of the western Himalayan syntaxis.

In order to get information on the tectonic history of the terrane, paleomagnetic study have been carried out on two different volcanic units 1) Paleogene Utror Volcanic Formation (55±2 Ma) along with later stage granitic intrusions (45-48 Ma) west of the Nanga Parbat syntaxis, and 2) Late Cretaceous Deosai Volcanics east of Nanga Parbat syntaxis. 210 samples from 20 sites of Utror Volcanic Formation and 55 samples from 10 sites of Deosai Volcanics were collected.

In case of the Utror Volcanic Formation magnetic mineralogical studies, i.e. Curie temperature analysis, IRM analysis and optical microscopic study indicate the presence of various magnetic minerals such as goethite, maghemite, titanomagnetite/magnetite, and titanohematite/hematite. Three magnetic remanence components are revealed from Zijderveld diagrams if progressive thermal demagnetization. All three remanence directions may not be of primary nature as they show scattering after the application of structural correction. The Comp-1 is of recent field and may be carried by goethite and maghemite. In the Comp-2 (Declination = 275.6, Inclination 18, α -95=13.5) and Comp-3 (Declination = 325.3, Inclination = 28.4, α -95=9.6) the mineralogical situation is rather complicated both have magnetite/titanomagnetite and a hematite/titanohematite as magnetic carriers in different sites. Only in two sites are both components observed otherwise one or the other of these is observed. The nature of these two components is seem to be CRM acquired during some hydrothermal processes as the mean paleomagnetic direction of Comp-2 and ChRM of granitic intrusion are the same. Besides this, in optical studies secondary minerals such as zeolite, which is indicator of hydrothermal alterations, is observed. Hence these rocks may possess magnetic minerals which are the result of alterations varying with micro-environmental conditions and time.

The mean paleomagnetic direction of Comp-2 of the Utror Volcanic Formation and the ChRM of granitic rocks of 48~45 Ma is the same, therefore Comp-2 may have been acquired at the time of granitic intrusion. The paleolatitude of Comp-2 (10° N) is in good agreement with the paleolatitude of Ladakh intrusives of 49~45 Ma (Klootwijk et al., 1979). The Comp-3 may be acquired during some latter stage hydrothermal alteration. The constraint on timing of acquisition of Comp-3 can be provided by zircon fission track age 35.9 Ma of these volcanics. Annealing temperature of zircon is more than 200°C suggesting some thermal or hydrothermal activity at 35.9 Ma. By comparing the paleolatitudes with the present latitude, it is calculated that after the acquisition of Comp-2 and Comp-3 there is about 2500-km and 2000-km crustal shortening respectively. There are 850° and 350° counterclockwise rotations after the acquisition of Comp-2 and Comp-3 respectively.

Magnetic mineralogical study of Deosai volcanics reveals maghemite and titanomagnetite as the major magnetic carriers. The in situ mean direction of ChRM is Declination = 347°, Inclination 24.3° (α -95 10°). The comparison of directions before and after structural correction indicates that they are post deformation magnetizations. By comparing the paleolatitude of Deosai volcanics with that of Comp-2, Comp-3, and the Ladakh intrusive ChRM directions, it can be inferred that these magnetization may be acquired between 40~35Ma. The mean of ChRM directions shows about 13° counterclockwise rotation since the time of acquisition of remanence. This is a

discrepancy, when compared with most of paleomagnetic data from the east of western Himalayan syntaxis having clockwise rotation. The similar counterclockwise rotation is also reported from Tethyan sediments from Zaskar range (Appel et al., 1995). Hence much detail paleomagnetic study is required to know the tectonic rotations related to the formation of the western Himalayan syntaxis.

A/136. Ahmad, M.N., Yoshida, M. & Fujiwara, Y. 2000. Paleomagnetic study of Utror Volcanic Formation: Remagnetizations and postfolding rotations in Utror area, Kohistan arc, northern Pakistan

The Utror Volcanic Formation forms a NE-SW belt within Kohistan island arc, which lies between the Indian and Eurasian continents in the western Himalayas of northern Pakistan. The Utror Volcanic Formation formed during Late Paleocene, when Kohistan existed as an Andean-type arc on the southern margin of Eurasia. Five to ten block samples were collected from 17 sites of the formation for paleomagnetic studies. Magnetic minerals that serve as remanent carriers are maghemite, magnetite, hematite and titanohematite. Magnetite, hematite, and titanohematite carry the characteristic remanent magnetization (ChRM). The declination values of ChRM are highly discordant before and after structural correction. While inclination values show uniformity in geographic coordinates. The ChRM carried by magnetite yields downward inclinations, whereas the ChRM carried by hematite or titanohematite have upward inclinations in geographic coordinates. The correlation between polarity state and magnetic mineralogy suggests that the acquisition of magnetization occurred during two distinct time intervals. An inclination only fold test of ChRM of these two mineral assemblages indicates that they are post-folding magnetizations. The calculated paleolatitudes for ChRM carried by magnetite and hematite or titanohematite are $9 \pm 4^\circ$ N and $13 \pm 4^\circ$ N respectively. A comparison of these paleolatitudes with the Indian apparent polar wander path (APWP) shows that the remagnetization likely happened between 55 to 45 Ma. Discordant declinations indicate that these volcanics suffered local rotations after remagnetization event.

A/137. Ahmad, M.N., Yoshida, M., Khadim, I.M. & Ali, M., 1993. Preliminary report of paleomagnetic study of Kalam (Utror) volcanics, Kalam area, upper Swat valley, N.W.F.P. Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad, 6, 42-59.

Paleomagnetic studies have been performed on the Utror volcanics in order to get information on the tectonic history of the Kohistan island arc. It has been concluded that the Kohistan arc drifted about 10 degree (ca. 1000 km) northward and made 40 degree counterclockwise rotation.

A/139. Ahmad, M.N., Yoshida, M., Khadim, I.M., & Ali, M., 1996b. Magnetic susceptibility observation across Himalaya–Karakoram Range, northern Pakistan with special reference to magnetic modeling of Kohistan Island Arc Crust. Trans. American Geophysics Union, EOS, 77 (22), Western Pacific Geophysics Meeting. Suppl., W28.

Bulk magnetic susceptibility observation was performed for rocks exposed along the Karakoram Highway, northern Pakistan, traversing from Hasan Abdal town, the north-western margin of Indo-Pakistan subcontinent, to the

Ghujerab River, southern part of the Karakoram block which is a part of the Eurasian continent. The variation of magnetic susceptibility corresponds well to the rock type, and in general the Kohistan island arc occupying between the subcontinent and the Eurasian continent appears as a relative higher susceptibility zone. This anomalous contrast in magnetic susceptibility is derived from lithologic contrast, i.e. the Kohistan island arc sequence mainly consisting of igneous rocks which are often rich in iron bearing minerals as compared to the surrounding terranes. The magnetic susceptibility is high over Main Mantle Thrust (MMT) and Main Karakoram Thrust (MKT) because of the presence of serpentinite bodies. On the basis of the susceptibility variation data of Kohistan island arc, a five layer model of magnetic structures of island arc crust is proposed. K₀ ratio of the rocks is less than 1.0 except that of mafic igneous rocks, gabbro and, norite of Chilas complex. Most of granitic rocks in the area are correlated with ilmenite-series showing low magnetic susceptibility while the granitoid body in the northern part of the Kohistan batholith arc solely belongs to magnetite-series, which is probably the indication of deep angle subduction.

A/140. Ahmad, M.N., Yoshida, M., Khadim, I.M., Ali, M. & Kausar, A.B., 1994. Geomagnetic and VLF-EM survey over northern Suture Zone and Nomal sulphid mineralized zone, Hunza, northern Pakistan. Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad, 8, 57-70.

On the basis of the discussions, the following points can be inferred.

1. The magnetic anomalies over the Northern Suture zone look to be strongly, effected by the lithologies. Geomagnetic field shows anomaly in the suture zone, hence geomagnetic method is useful to recognize the suture zone because of their typical magnetic character and subsurface structure modeling of the suture zone is also possible.
- 2 In- Phase parameter of VLF-EM sounding shows anomaly over mélangé in the suture zone due to the conductivity contrast. Therefore the VLF-EM survey is useful to survey in the suture zone.
- 3 There is no magnetic anomaly over the sulphide zone, hence it can be said that geomagnetic method cannot be used for the evaluation of Nomal sulphide

Nearly 114 km² area in the vicinity of Burawai, upper Kaghan Valley has been geologically mapped, at 1:18,000 for the first time. This thesis presents first time accounts of geomorphology, lithostratigraphy, petrography and economic geology of the area. The area constitutes rocks representing old Indo-Pak basement rocks, comprising pelites, calc-pelites and marbles, have been metamorphosed to kyanite and sillimanite grades. These are intruded by para-autochthonous sheet granites also metamorphosed. Major structure comprises an open synform possibly part of a larger structural basin. The western part comprises the nose of a larger antiform.

Marble, biotite mica and kyanite are important mineral deposits, which deem further exploration and evaluation. This thesis also includes petrogenesis of the rock units as well as numerous sketch and photographs, illustrating the geology of the area.

The project area is a part of Middle Himalayas and covers about 350 sq. km. located between Doarian and Thod in Neelum Valley (Azad Kashmir) at the scale 1: 25,000 of topographic sheet No. 43 F/13, 43 F/14 and 43 J/2 of survey of Pakistan. The studied area comprises of broader lithology of Salkhala formation containing predominantly metapelites, psammites and calcareous material. Various granitic and basic bodies are also outcropping the area. Basic bodies are present as dykes and sills. The metasediments of Salkhala formation have witnessed metamorphism and deformation. The metamorphism undergone by metasediments is of regional reverted character involved from green schist to Almandine- Amphibolite facies. The area is rich in economic rocks and mineral deposits are discussed briefly.

Phosphorite deposits are present at Kakul area in Hazara District. The chemical analysis and various techniques employed show that P₂O₅ contents are in the range of 25-30%; other impurities are well within the permissible limits except at some horizons, where carbonate and iron contents are on the high side. Moreover, acid volume, concentration and temperature effect have also been studied, and for the maximum recovery of P₂O₅ contents,

suitable volume, concentration and temperature have been determined. The techniques used are Gravimetric, Volumetric, Spectrophotometric and atomic absorption spectroscopy. A comparison of all the four methods has been made and advantages of each method have been pointed out.

A/156. Ahmad, N. & Chisti, H.M., 2000a. Thermogravimetric analysis of selected samples of Pakistani oil shales in dynamic air atmosphere. Abstracts, Third South Asia Geological Congress, Lahore, p.148.

Thermogravimetry is a rapid and widely used technique for the characterization of oil shale and other rocks with organic content of any extent. The thermal behavior of such rocks in a-dynamic air environment may show characteristic of both the organic and inorganic (mineral) content of the sample. This study presents oxidative profiles of five samples of the Cambrian and the Early Eocene oil shales of Pakistan. These profiles showed extra peaks in comparison to the profiles in an inert atmosphere, which believed to due to loss of inter-layer water from clay minerals, and oxidation of organic matter in the samples.

Some samples of the Early Eocene oil shale showed a major carbonate decomposition 'peak' ($> 600^{\circ}\text{C}$), some samples indicated minor carbonate decomposition in the same region, while the sample from the Cambrian oil shale was completely devoid of any carbonate peak. Thermogravimetric analysis of these oil shales in an inert atmosphere showed that the major DTG pyrolysis peak for all the samples was singular in nature, with an average T_{max} of 475°C for the Cambrian oil shale. However, the oxidative characteristics of the organic components of these oil shales in the $230^{\circ}\text{C} - 520^{\circ}\text{C}$ region are multi-step in nature, with two major oxidative events at about $350^{\circ}\text{C} - 450^{\circ}\text{C}$ and 480°C . The rate of weight loss of the first oxidative events was greater than the second event for all samples. Also, a shouldering effect was observed at about 346°C in the Cambrian oil shale.

Key words: Thermogravimetry, Oil shale.

A/157. Ahmad, N. & Chisti, H.M., 2000b. Geochemistry of oil shale deposits of Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, p.149.

The Eocene and Cambrian oil shales are found in the Kohat Basin and the Sat Range Formation of Pakistan. Little has been done to characterize these deposits or to estimate their economic potential and their upgrading as a viable

energy source. These oil shales were deposited in a hydrologically restricted, shallow marine, land locked sea, representing a hypersaline environment. The Jutta gypsum unit in the Kohat Basin contained an oil shale horizon occurring at about 27-30 m below the top of this unit, the gypsiferous shales of the Salt Range Formation contained 3-5 m thick layer of oil shale. The mineralogical composition varies significantly between two deposits; the Eocene oil shales consist of clays-mainly an illite/smectite mixed layer, and quartz with a subordinate amount of dolomite and pyrite, whereas the Cambrian oil shale mainly contains quartz and gypsum with a minor content of chlorite and pyrite. Major and trace element contents of both deposits also differ significantly, in particular the exceptionally higher concentrations of vanadium and chromium in the Cambrian oil shales. The oil shales were retorted in a fixed bed pyrolysis unit to determine the yield of oil. The spent shale, oil and retort water were also analyzed for trace metal content to determine the partitioning of the trace metals between the product streams. These deposits were characterized by high concentrations of alginate rich organic matter. The carbon and hydrogen content of both oil shales were similar, but the Eocene oil shale, on average, gave higher yields of oil during the retorting of the oil. The Eocene oil shale had an average oil yield of 13% with a maximum value of 20%, whereas the Cambrian oil shale exhibited an average yield of 11% with a maximum value of 14%.

A/161. Ahmad, N. & Williams, P.T., 1998. Influence of particle grain size on the yield and composition of products from the pyrolysis of oil shales. *Journal of Analytical and Applied Pyrolysis* 46, 31-49.

Oil shales from two regions of Pakistan have been pyrolysed in a fixed bed reactor in relation to particle grain size. Five size ranges were investigated, <0.5, 0.5–1.0, 1.0–1.7, 1.7–2.8 and 6.0–10 mm. The pyrolysis system consisted of a 200 cm³ stainless steel fixed bed reactor externally electrically heated. The samples were heated to 520°C at 10 K min⁻¹ and the oil shale sample was continuously purged with nitrogen to remove the pyrolysis products from the reactor and to minimise secondary reactions. The gases were analysed for their content of CO, CO₂, H₂, CH₄ and other hydrocarbons up to C₄. The derived pyrolysis oil was condensed in a series of cold traps and the total oil yield determined. In addition, experiments were carried out on a thermogravimetric analyser using the three smallest particle grain sizes under identical heating conditions to the fixed bed reactor. It was found that increasing the particle size up to the largest size used of 10 mm resulted in an increase in oil yield. The total gaseous yield was decreased, reflecting a decrease in concentration for H₂, CO, CO₂ and the majority of the hydrocarbon gases. The raw oil shale samples of various particle size ranges were analysed to determine the elemental composition and surface area to determine their influence on the compositional changes in oil and gaseous yield with particle size range.

A/163. Ahmad, R., 1963. A Cassidulid Achnoid from the so-called "Triassic Limestone" of Hazara District. Geological Bulletin, Punjab University 3, p.35.

During the 1963 summer field season the writer worked in the Thandiani locality and collected some echinoid remains from the upper beds of the so-called "Triassic Limestone" of the Hazara District. Complete specimens were not obtainable, but the evidence furnished by the fragments shows that they belong to the genus *Pygurus* of the family of the cassidulidae of the irregular echinoids (Zittel, 1900). A drawing of one of the pieces is shown in Fig. 1. The range of this genus is from upper Jurassic to Cretaceous. Its presence in the Nerinea Horizon confirms the view that at least, the upper part, of the limestone is of Jurassic age, as was indicated by the forms of *Nerinea* reported on by Aftab Ahmad (1962). This is the first time that cassidulids have been recorded in this formation.

A/164. Ahmad, R., 1981-83. Geological mapping with special studies of discontinuities in rocks and their effect on the rockmass strength at Kalabagh Damsite. M.Sc. Thesis, Punjab University, Lahore, 124p.

The Department of Geology was upgraded to an Institute in 1979. According to the new rules and regulations three year B.Sc. Applied Geology Courses were introduced. In accordance, with these rules 1 1/2 year courses in studies were established leading to M.Sc. Applied Geology Degree. This comprehensive research report about a particular geological project has been submitted as a part of the M.Sc. Examination.

Our group comprising four students was allotted a Geo-Engineering problem, with special emphasis on the study of discontinuities at the proposed Kalabagh Dam site. Kalabagh dam site is 10 miles upstream of Kalabagh Town, situated just below the confluence of Soan and the Indus River. According to initial investigation height of the dam is proposed 945 feet above mean sea level, with reservoir level 925 feet above mean sea level. This dam is going to be constructed for hydro-electric, irrigation and flood control purposes.

We spent about one and a half month at the site in July and August, 1984. Again we made a short visit in the middle of December, 1984, to review our previous work. Extensive studies relating to our problem were made under the guidance of Mr. M.H. Malik, Assistant professor, Institute of Geology.

In this Research Report conventional topics like History, Physiography Stratigraphy, Damsite Geology, and Structural Setting of the area and Hydrology have been discussed in detail. These topics are spread in six chapters i.e. from Chapter No.2 to 7.

A/167. Ahmad, S., 1972. Geochemistry and physical properties of chromites from Pakistan. Ph.D. Thesis, Punjab University, Lahore, 212p.

Seventy two chromite specimens have been studied from Hindubagh, Harichand and Fort Sandeman areas of Pakistan. Out of these sixty seven samples were selected from Hindubagh area comprising Nisai, Saplai torghar, Jung troghar and North Hindubagh. Three samples from Harichand and two from Fort Sandeman were studied for purposes of comparison.

Chromites with different structures such as orbicular, nodular, banded, disseminated and chain, have been observed and are described briefly. Colour of chromites in thin section varies from brownish yellow to deep cherry red. Brownish yellow chromites have been found to have low Cr/Fe ratio as compared to deep cherry red chromites.

Some chromites showed alteration with opaque alteration products along cracks or along the grain boundaries. Such chromites showed the presence of abnormally high amount of Fe_2O_3 as compared to other chromites which are without such alteration. Such chromites gave a number of sizable chromite separation on an isodynamic separator. The variation in chemistry of fractions of a chromite specimen from mine 155 is described. The main inference is that chromite fractions obtained at 0.1 Amp has Fe_2O_3 16.28% as compared to the fraction separated at (0.4 Amp.) which has Fe_2O_3 10.35%.

An improved scheme for chromite analysis is presented, the accuracy of which has been checked on synthetic standard. A gradual change in chemical composition of chromites was observed from Nisai (Cr/Fe ratio 2.24-2.99) to Jungtorghar (Cr/Fe 2.52-3.75). A variation in chemistry has been found with in a mine e.g. in mine 7ML Cr/Fe ratio varies. Certain physical properties such as, specific gravity and micro-indentation hardness, have been determined on all the specimens, whereas cell edge dimensions and Refractive indices were determined on some selected specimens. These physical properties were compared with chemistry and a relationship was found to be present, between specific gravity and chemistry of chromites from Hindubagh in the form of a mathematical expression. This can be used to estimate weight percentage of Cr_2O_3 , Al_2O_3 and MgO in Hindubagh chromites from known values of weight percentages of FeO , Fe_2O_3 and specific gravity. The results obtained showed the error to be within 5% of the contained oxides.

A relationship was also found to exist between cell edge dimension and weights percentages of Cr_2O_3 . This relationship helped to derive a method by means of which weight percentages of Cr_2O_3 , FeO and MgO of Hindubagh chromites can be determined within about 5% of the contained oxides. The other two physical properties, Micro-indentation hardness and refractive indices showed no definite relationship which could be used to determine the weight percentages of the constituents oxides. However a rough conclusion that can be drawn is that chromites with a higher Al_2O_3 weight percentages have higher values of Vickers hardness number and refractive index

A/168. Ahmad, S., 1976. Geochemistry of chromites from Harichand, Malakand Agency, Pakistan. Geological Bulletin, University of Punjab 12, 91-96.

Chemical analyses of three purified chromite samples from Harichand area Malakand agency are presented and compared with chromites from Muslimbagh. A number of diagrams have been drawn to present the chemical data. The analysed Harichand chromites are aluminian chromite with tendency towards chromian spinel due to high alumina. Microhardness and specific gravities of all the specimens are presented whereas cell edge dimension and refractive indices of two samples are given.

Key words: Geochemistry, Chromite, Malakand.

A/170. Ahmad, S., 1981a. Preliminary account of the occurrence of Ni sulphides in serpentinites of Souch area, Kaghan Valley, District Mansehra, North West Frontier Province, Pakistan. Geological Bulletin, Punjab University 16, 172-174.

Souch area lies between longitude 73 40' -73 45 E and latitude 34 55'-34 59' 30" N. Qadir (1979) has described in detail the Petrology of the area and classified the area into three groups.

1. Metamorphic rocks consisting of garnet mica schist, graphitic schist, marble, amphibolites.
2. Quartzofeldspathic rocks consisting of granite gneiss, pegmatites, aplites.
3. Ultramafics, consisting of dunites, Serpentinites, Pyroxenites, Talc and Carbonates.

The first outcrop of the ultrabasic is at 19 km. above Lidi a small village on right bank side of river Kunhar. Chemical analysis of two serpentinite rock samples showed Ni--0.28 to 0.32%. The rock under study was weathered to greenish black and fine to medium grain size. The major minerals are antigorite, chrysotile, olivine forsterite, with small amounts of magnesite, magnetite heazlewoodite and pentlandite. The presence of heazlewoodite and pentlandite, was identified by the Ore-microscopic techniques, such as, reflectivity, microhardness and etch tests described by Cameron (1961) and Ramdohr (1969).

These two minerals occur as small disseminated among and molded about silicate minerals, and appears to be a primary accessory of the ultrabasics. The texture of mineral assemblages and their association favours the Phenomenon of Sulphide-silicate immiscibility and consequent magmatic differentiations in situ. Such sulfide disseminated in ultramafic rocks have been reported by many workers, such as Souch, Podolsky et al (1969), from Sudbury deposits Canada and Woodal and Travis (1969) from kambalden deposits in Western Australia. In these, sulfides grade from minor disseminations in ultramafic rocks to massive ores. The disseminated ores appear to represent an early stage of the process that formed massive ores. A detail work on the other ultramafic rocks of the area is in progress and will be published soon. The author is highly thankful to Mr. Qadir for providing samples.

A/172. Ahmad, S., 1983-85. Geotechnical studies of land slides with special emphasis on slope stability along Karakorum highway between Thakot and Besham, District Swat. M.Sc. Thesis, Punjab University, Lahore, 117p.

Engineering geological investigations were carried out about the land slides and slop stability problem along the Karakoram Highway between Thakot and Besham. The project area mainly comprises of Thakot metasediments, Lahor granite, Shang granite gneiss and mineralized scree (near Besham). These are mainly controlling the rugged topography and other geomorphological features of the project area. The general trend of stresses is SE-NW.

So far the stability of the region is concerned, the detailed analysis for critical slopes is performed. Among different modes of failure encountered, the plane failure is proved to be unstable particularly near Maira and at Kandaurgai. Other than this a large variation in discontinuities is observed that controls sliding in hard rocks and highly weathered rocks which are responsible for mass wasting and rock fall. Road alignments were studied keeping in view landslide problems and slop stability, for potentially unstable regions remedial measures are also given, for potentially unstable regions remedial measures are also given. 1h; 2v cut slopes and benches are proposed. Benches may be provided at each 8 meters interval.

A/173. Ahmad, S., 1984. Necessity for geochemical prospecting in Pakistan. Abstracts, First Pakistan Geological Congress, Lahore, 45-55.

The validity of geochemical methods in the exploration of new mineral resources and development of already known deposits is well established all over the world. An application of these methods in a number of areas from Pakistan such as Kirana Hills, Kaghan Valley, Malakand, Nomal-Chalt and Swat showed encouraging results. Regular geochemical survey of the country is recommended.

The southern Tanawal region exposes a suite of metasedimentary rocks comprising of conglomerate, argillite, quartzite and dolomite. The basal sequence –unfossiliferous quartzite of Precambrian age belongs to Tanawal Formation and is unconformably overlain by thick succession of argillite, quartzite and dolomite of Cambrian age. This assemblage of younger metasediments is named as Sherwan formation.

The southern tanawal area lies on the hanging wall side of the Panjal fault and is largely influenced by the deformational pattern associated with this fault.

A/180. Ahmad, S. & Farooq, U., 2000. The distribution behavior of trace elements during combustion of Surghar Range coal and their environmental effects. Abstracts, Third South Asia Geological Congress, Lahore, p.162.

The Surghar Range coal fields comprise of Makarwal, Gula Khel and Kurd coal fields, constituting the northernmost part of the Trans-Indus mountains. The distribution behavior of hazardous trace elements, As, Be, Cd, Cr, Cu, Pb, Mn, Hg, Ni, Sb, Se, V and Zn present in the Sughar Range coal deposits, indicate that these are concentrated within clay and sulphides minerals. During combustion of coal, these elements segregate between flyash and coal ash. Although contents of trace elements in coal are only in parts per million, the amount of coal used for burning purposes is so great that quantity of elements released to the environment may become higher than the permissible among limits. As the human race is highly dependent on complex interrelations among the biosphere, atmosphere, hydrosphere and lithosphere, the dispersed particulate matter and the gaseous pollutants in general, present in the flyash could be injurious to health during mining in particular and to the environment.

Key words: Trace elements, coal, Surghar range.

A/181. Ahmad, S. & Ahmad, D., 1995. Tectonic Analysis of the Kohat plateau boundary zone, NW Himalayas, NWFP, Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

The southern most structural boundary of the Kohat Plateau is herein named as Kohat Plateau Boundary Zone. It is about 120 Km long with width ranging from 510 kms and trends East-West. Towards the west it is bounded by the Kurram fault whereas towards the East it joins the Kalabagh fault.

The Kohat Plateau Boundary Zone is characterized by strike slip, deformation in addition to the thrust slip deformation having transtensional and transpressional bends. Towards the west, the Boundary zone exhibits transtensional deformation with large-scale normal faults and form negative flower structure. Towards the east, north of Karak it exhibits transpressional deformation forming positive flower structure and is characterized by large-scale reverse faults.

All the kinematic indicators and ages of rocks involved in the deformation shows that the Kohat Plateau Boundary Zone has experienced a Plio-Pleistocene phase of strike slip deformation with sense of motion being right lateral.

Key words: Tectonics, structure, Kohat Plateau.

A/182. Ahmad, S., Ahmad, I. & Ghauri, A.A.K., 1990. The geology of southern Tanawal area, north of Haripur, Hazara, NWFP, Pakistan. Abstract, 2nd Pakistan Geological Congress, University of Peshawar, p.38.

The southern Tanawal area exposes a suite of metasedimentary rocks comprising quartzite, dolomite, argillite and conglomerate. These rock units are grouped into two stratigraphic units: (a) Lower Tanawal Formation and (b) Upper Sherwan Formation.

The Precambrian Tanawal Formation consists of unfossiliferous quartzite with thin intercalations of argillite; whereas the unconformably overlying Sherwan Formation comprises younger quartzite, dolomite, argillite and dolomite of Cambrian age. These rock units represent the hanging wall of the Panjal fault and constitute a series of north-east trending overturned folds and north dipping thrust/reverse faults. The overturned folds invariably verge; southward and the orientation of both the faults and folds vergence indicates a southward directed tectonic transport which is typical of the foreland fold-and-thrust belt of the Hazara Himalaya. The Panjal fault which runs south of the study area exhibits ramp and flat geometry beneath the southern Tanawal area and it is inferred that the structure of this region took shape during the development of Panjal fault.

Key words: Metasediments, Tanawal, Haripur, Hazara.

A/183. Ahmad, S., Ahmad, I., Ghauri, A.A.K. & Riaz, M., 1992. Revised stratigraphy of the southern Tanawal area, North of Haripur, NWFP, Pakistan. Kashmir Journal of Geology 10, 153-160.

The southern Tanawal area exposes a suite of metasedimentary rocks comprising quartzite, dolomite, argillite and conglomerate. The oldest rocks belong to the Tanawal Formation of Precambrian age. The Tanawal Formation is unconformably overlain by a thick sequence of quartzite, dolomite, argillite and conglomerate, previously named as Abbottabad Formation. Baig and Lawrence (1987) renamed this sequence as Sherwan Formation and considered it to be of Cambrian age. The stratigraphy of the area is revised in order to differentiate between the dolomite-quartzite sequence exposed north and south of the Panjal fault in the southern Hazara region.

A/186. Ahmad, S., Ali, F., Ahmad, I. & Hamidullah, S., 2001. Structural geometry of the Himalayan frontal thrust zone: Surghar Range, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.32.

Surghar Range of the outer Himalayas in Pakistan represents the active deformational front of Kohat fold-thrust belt, which is migrating southward in response to the underthrusting of Indian craton underneath its sedimentary cover. The surface expression of the range in the vicinity of Chichali pass is characterized by south facing Surghar anticline at the level of Jurassic. Its southern limb is dissected by Surghar thrust, which moderately dips towards north and is detached within or at the base of Triassic sequence. Several out of sequence thrust faults are mapped south of the major ramp structure representing migration and structural disruption from the main locus of crustal shortening in the range interior towards Punjab foreland. Variations in the structural geometries along the range front suggest that it is a strongly emergent thrust in the west (north of Kutki village) and translates into a tip-stick thrust front in the east (north of Chapri and Toila Mangli village). The restored cross-section along Kutki section reveals that 5.6 Km overall shortening has taken place along the Surghar Thrust. The available constraints on the timing of deformation suggest that the uplift along the range front started 2.3 Ma ago.

Key Words: Structural Geometry, frontal thrust zone, Surghar Range.

A/187. Ahmad, S., Ali, F., Ghauri, A.A.K. & Danishwar, S., 1994. Imprints of transpressional deformation on the southern Kohat plateau, NW Himalayas, NWFP Pakistan. Journal of Nepal Geological Society 10, Abstract Volume 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu, 5.

We present evidence for Plio-Pleistocene transpressional deformation in the Kohat Plateau, which is part of the NW Himalayan foreland Fold and thrust belt of N. Pakistan. The Karak structure in the SW Kohat Plateau is interpreted as an E-W trending positive flower structure, which is exposed for 20-km along strike and is about 5-km wide. It is bounded by the N-dipping Karak thrust in the south and the S-dipping Nari Panos backthrust in the north and internally subdivided by the south dipping Banda Kunghara backthrust. All these faults trend E-W and have moderate surface dips. A right lateral component of deformation along the Karak structure is indicated by ENE directed trends of the Daggar syncline in the footwall of the Nari Panos backthrust and of small scale thrusts in the core of this syncline. A strong lateral component of deformation along the Karak structure is also in accordance with seismic data (906-NSK-47) which indicate rapid steepening of the Karak and Nari Panos thrusts to near vertical with depth.

Right lateral transpression along the Karak structure is also supported by ENE trending en-echelon folds south of Banda Charpara. This work emphasizes the importance of transpression within the NW-Himalaya on a regional scale. Recent work by Beck et al. (in prep.) has suggested transpressive deformation along the Main Boundary Zone (MBZ) to the west of the Kohat Plateau.

Key words: Structure, deformation, Kohat Plateau.

A/188. Ahmad, S., Ali, F., Rehman, N. & Gul, J., 2000. Lithostratigraphy of the Kurram Group rocks along Mirali-Miran Shah road, North Waziristan Agency, NWFP, Pakistan. Geological Bulletin, University of Peshawar 33, 79-86.

This study focuses on the identification and description of a thick Mesozoic sequence exposed along Mirali-Miran Shah road in North Waziristan Agency, previously named Kurram Group. The detailed field investigation have resulted in establishing six distinct lithostratigraphic units, ranging in age from Late Triassic to Late Cretaceous with Dominant lithologies being limestone, sandstone, shale, and siltstone. The oldest rocks i.e. Triassic of the area is named as Spalga Formation. The contact between the Triassic and the base of Jurassic is marked by a thrust fault in the entire mapped area. The Jurassic rocks are represented by a thick sequence of limestone and shale, which are divisible into two formations named as Sarobi Formation and Isha Formation. These rocks are disconformably overlain by the Cretaceous sequence, which includes Chashmai Kharsai Formation, Marsi Formation and Zerghar Formation. Except the Triassic, all the rocks assemblages have yielded fossils of their respective age. The fauna and lithology of the area is broadly correlative with Mesozoic rocks of Samana- Kohat area towards north and Baluchistan Province in the south.

Key words: Lithostratigraphy, Kurram group, Miran shah, North Waziristan.

A/189. Ahmad, S., Ali, F., Sayab, M., Ahmad, I. & Hamidullah, S., 1999. Structural geometry of the Himalayan Frontal Thrust Zone: Surghar Range, Pakistan. Geological Bulletin, University of Peshawar 32, 13-23.

Surghar Range of the outer Himalayas in Pakistan represents the active deformational front of Kohat fold and thrust belt. The range is migrating southwards in response to the underthrusting of Indian craton underneath its sedimentary cover. The structural geometry of the range, in the vicinity of Chichali pass area is characterized by a south facing anticline i.e. Surghar anticline at the level of Jurassic. It is interpreted to be a fault bend fold above a major ramp detached within or at the base of Triassic rocks. The range front is thrust southwards over Punjab foreland along Surghar fault, which is interpreted as south verging fore thrust. The thrust sheet above Surghar fault displays contrasting structural geometries along strike. The Surghar fault is believed to be a strongly emergent thrust in the west (north of Kutki village) having shallowly folded thrust sheet. Eastwards, the Surghar fault translates into a tipstick thrust front (north of Chapri and Tola Mangli village) with its thrust sheet being tightly folded and disrupted by several out of sequence thrust faults. The restored cross section along Kutki section reveals that 5.6 km shortening has taken place along Surghar Fault. The constraints upon the timing of deformation suggest that uplift along range front started about 2.3 Ma ago.

A/191. Ahmad, S. & Mirza, K., 1999. Palynostratigraphy of the Lower Jurassic Datta Formation from the Salt Range, a major tectonic unit of Pakistan Himalaya. Terra Nostra 99 (Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany), 3-4.

The Salt Range, the most well studied area of the Upper Indus Basin, is one of the major tectonic units of the Pakistan Himalayas. It is regarded as a key region for understanding the stratigraphy of Pakistan. It is known as the "Field Museum of Geology" because of its almost complete stratigraphic sequence with excellent exposures from the pre-Cambrian through the Pleistocene. The Salt Range is situated between the Sargodha High and the Jhelum plain in the south and the Potwar Plateau in the north, respectively. The Salt Range and its Trans-Indus extensions are the result of tectonic forces imposed during the collision of the Indian and Eurasian plates. The exposed stratigraphic units are mainly unmetamorphosed sediments. The Lower Jurassic rocks belonging to the Datta Formation in this area are represented by thick sequence of variable lithological characters including shale, siltstone, sandstone, and mudstone of red, maroon, grey and white colors deposited in continental environments.

The present state of knowledge concerning stratigraphy and palynology of the Datta Formation of the Salt Range and Hazara of north Pakistan is reviewed. Detailed studies of the Datta Formation have revealed abundant and

varied palynomorphs assemblages. This unit is well developed in the western Salt Range, Trans-Indus Range, Surghar Range and a few exposures in the Hazara area are also found. Fifty samples have been collected from Gorge, Makerwal and Hazara areas. These are regarded as classical localities for palynostratigraphical investigations. In general, the preservation of the species recorded is good. Miospores from the Hazara are in an inferior state of preservation when compared with the Salt Range. It is of interest to note that saccate pollen grains have rarely been encountered. Ubiquitous forms of trilete and monolete miospores have frequently been observed. However, some endemic elements have also been recorded during the present investigations. The Datta Formation is characterized by the presence of pollen grains, i.e. *Classopollis*, together with a trilete miospore genus. These forms have been recorded in the Lower part of Datta Formation. The absence of phytoplankton (acritarchs and algae) in this unit is in harmony with respect to the continental facies. Some of the index taxa that are regarded as indicator of the Lower Jurassic of Pakistan includes: *Gleicheniidites*, *Divisporites*, *Densoisporites*, *Lycospora* and *Matonisporites*. Long ranging genera of Laevigate forms such as *Punctatisporites* and *Leiotriletes* are also profusely represented. Another miospore genus *Convolutispora* belonging to the infragenera *Muornati* has also been found occurring in the Lower Jurassic of Pakistan. These miospore forms have also been reported from the Upper Devonian of many parts of the world including North America, North Africa, Europe, Asia and Australia.

Key words: Stratigraphy, Lower Jurassic, Datta formation, Salt Range.

A/197. Ahmad, W., 1990-92. Geological study for petrography and geology of Atia Qala, District Swat. M.Sc. Thesis, Punjab University, Lahore, 57p.

Rocks of Atia Qala (Distt. Swat) are part of metamorphic hornblende complex. The area lies within the southern portion of Swat. These rocks are probably the extensions of rocks of Dir in the form of a belt running approximately in East-West direction. The area given for fieldwork comprises thirty kilometers in the Northwest of Mangora. The area mainly comprises the main rock units are Norite, Diorite, Quartz, Feldspar and Pegmatite veins. But at some places patches of Amphibolite are also found but can be considered negligible. As the field evidences and laboratory study shows that the Diorite and Norite were formed from basic magma, which have under gone regional metamorphism under the intense orogenic conditions. Quartz-O-Feldspathic and Pegmatite veins are extensively distributed all over the area, indicating the evidence of Diorite magma. Major minerals are Plagioclase, Hornblende, Epidote and Quartz with accessories as Sphene and Magnetite. These are products of regionally metamorphosed igneous rocks.

A/199. Ahmad, W. & Hamidullah, S., 1987. Island arc signatures from the Waziristan igneous complex, NWFP, Pakistan. Geological Bulletin, University of Peshawar 20, 161-180.

The Waziristan igneous complex consists of peridotite, gabbro, diorite, diabase and a variety of volcanic rocks. Petrographic studies and mineral chemistry of the rocks contradict their oceanic crust origin and evince an island arc parentage. The high Mg# (89-95) of the olivine and pyroxenes, and absence of plagioclase in the cumulus peridotite suggest crystallization at high pressures – not typical of oceanic crust. The calcic-plagioclase (An_{90-97}) and clinopyroxene (Wo_{44-46} En_{44-50} Fs_{5-12}) association in the gabbroic rocks of the Waziristan igneous complex is akin to other island arc-related gabbros. A variety of diagrams used for discrimination of clinopyroxenes from different tectonic environments, also indicate the island arc affinity of this complex.

Key words: Petrography, Geochemistry, Waziristan.

A/200. Ahmad, W. & Khan, M.J., 1990. Sedimentologic and magnetostratigraphic studies of the upper Siwalik Group, Sulaiman Range, Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 33-34.

The Siwalik Group exposed in the eastern foothills of the Suleiman Range includes Vihowa, Litra and Chaudhwan Formations. The Vihowa Formation consists of grey and brown sandstones and red to brownish-red siltstone. The overlying Litra Formation comprises light-grey sandstone with subordinate brown to reddish- brown siltstone. Chaudhwan Formation overlies Litra Formation and predominantly consists of conglomerates with ancillary interbedded pale-grey sandstone. Present studies are confined to the upper Litra and Chaudhwan Formations. Sandstone of the Litra Formation is characterized by the abundance of almandine garnet and blue-green hornblende, indicating substantial contribution from the northern provenance (i.e., Kohistan island arc). Whereas the petromict orthoconglomerates of Chaudhwan Formation indicate a western provenance (i.e., Fort Monroe anticline).

Paleomagnetic studies of the overbank deposits from the upper Siwalik sequence show that NRM of most samples is composite of (a) a secondary component of magnetization, and (b) a stable, hopefully primary, component of remnant magnetization. Secondary magnetization was successfully removed by Partial Thermal Demagnetization at 400°C, and thus the stable component of magnetization was isolated. Thereafter, all samples were subjected to a single step thermal demagnetization at 550°C (one sample at 660°C).

Considering the rates of sediment accumulation of the upper Siwaliks in general, and the faunal contents of the upper Siwaliks from a nearby locality, the observed normal magnetic- polarity is tentatively correlated with the Jaramillo subchron of the Matuyama Chron. This correlation suggests that the upper Litra Formation was deposited

during 1.5 Ma. to 7 Ma. whereas the Chaudhwan Formation was deposited between .7 Ma. and 50,000 yr. BP., in consequence of the synchronous acute tectonic uplift along Fort Monro anticline.

The alluvial fan deposits, overlying the Chaudhwan Formation, are also tilted due to the formation of Zinda Pir and Sakhi Sarwar anticlines. This manifests active forelandward (eastward) migration of the deformation front of the Sulaiman Range.

Key words: Sedimentology, Magnetism, Siwaliks, Sulaiman Range.

A/201. Ahmad, W. & Khan, M.J., 1991. Petrography of the upper Litra and Chaudhwan Formations, Upper Siwalik Group, Zinda Pir anticline, northern Sulaiman Range. Geological Bulletin, University of Peshawar 24, 191-202.

The Zinda Pir anticline of northern Sulaiman fold belt exposes, along its periphery, the Siwalik Group which comprises Vihowa, Litra and Chaudhwan Formations (in younging order). Petrographic studies of the upper Litra and Chaudhwan Formations indicate that the sandstones of these formations are texturally similar. Moderate angularity and sorting, along with high content of feldspar, indicate textural immaturity of these sandstones. The Litra Formation is characterized by the abundance of almandine garnet and blue-green hornblende, indicating substantial contribution from the northern provenance (i.e., Kohistan island arc). Whereas petromict orthoconglomerates of the Chaudhwan Formation indicate a predominant western provenance (i.e. Fort Monro anticline).

A/207. Ahmad, Z., 1992. Clays. GSP Mineral Information Series 11, 56p.

This is a general information on clay minerals, their uses, geology and origin along with distribution in Pakistan. Included are bentonitic clays of Azad Kashmir (Bhimber, Chander, Chitta Dheri) and some parts of NWFP (Chashma Valley, Karak).

Key words: Clay minerals, Azad Kashmir, NWFP.

A/208. Ahmad, Z., 1995. Base metal deposits of Azad Kashmir, Pakistan. Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, 26-27.

Base metal sulphide mineralization in Azad Kashmir is described from two main mineable deposits: one at Treri (lat. 34° 26' 48"N; long. 73° 43' 10"E) and the other at Lamnian (lat. 34° 14' 19"N; long. 73° 46' 52"E). Both occur in the Panjal Sequence which is developed along the eastern syntaxial limb of the Azad Kashmir Himalayas.

Various descriptive and genetic attributes of the lead-zinc sulphide ore deposits of Treri area correspond to those of the Mississippi Valley type (MVT) deposits. The deposit formed as a stratabound Pb-Zn ore deposit in the shallow-water deposited platform carbonates of Triassic age by epigenetic crystallization from solutions evolved in the sedimentary basin. The process involved filling of preexisting open spaces as well as replacement of lithified carbonates. Upper part of the deposit also involved ponding beneath an impermeable shale cap. The solutions were not derived from high heat-producing igneous bodies, but from the dewatering of associated shale especially the black carbonaceous shale. The incursion of saline warm brines carrying Pb-Zn-Cu-Fe from deeper shale basin to its margins and further into the fracture system in dolomite may have occurred by gravitational flow, or by stratafugic dewatering by compaction or by episodic excess pore pressure. The sulphides precipitated by reduction of sulphate in the formation fluids with concomitant recrystallization of coarse calcite observed in the deposit. Unlike most MVT deposits, the Treri deposit is not associated with barite or fluorite mineralization.

Key words: Base metal, Azad Kashmir.

A/209. Ahmad, Z., Alam, G.S., Khan, R.N., Hussain, A., Khattak, A. K., Saleemi, B. A., Khan, R., Ahmad, S. & Qureshi, S.A., 1976. Investigation of placer mineral deposits in the Indus, Gilgit, Hunza and Chitral Rivers, Pakistan GSP Records 35, 25p.

The placer mineral deposits of parts of the Indus, Gilgit, Hunza and Chitral rivers of Pakistan were collected by spot sampling and analyzed. A few high terrace gravel deposits were also sampled. A measured volume of sand and gravel was washed and whatever gold was recovered from any sampling site was calculated as oz/l. ton for that site. The gold contents of the alluvium deposits, as determined during the reconnaissance survey, are low. In the upper Indus Valley, between Thore and Sasi in Gilgit Agency range between the lowest of 0.0004 Oz/l. ton to the highest of 0.011 oz/l. ton. On the high side, there is only one exception; one sample from a high terrace in the Bunji-Jaglot area was found to contain 0.05 Oz/l. ton of gold. Among the lower Indus Valley deposits, the lowest and highest gold contents range between 0.002 Oz/l. ton and 0.014 Oz/l. ton, and in the Chitral and Mastuj Valleys, the same are 0.0003 and 0.0108 oz/l. ton, respectively. A few deposits are being recommended for detailed study to see if any portion of them contain values higher than the ones recorded during this survey.

A/217. Ahmad, Z.H. 1987-89. Geology, petrography and structure of Harno area District Abbottabad. M.Sc. Thesis. University of Azas Jammu & Kashmir.

A comprehensive geological study of Harno area (70 sq km), a northeastern section of the Attock Hazara Belt, including geological mapping 1:9434 is presented. In early Jurassic to Early Eocene shelf sedimentary sequences overlie metamorphosed Hazara slates. Possible depositional environments of various stratigraphic units interpreted on the basis of petrographic study. The area has suffered a 4 phase deformation. The first phase related to metamorphism of Hazara slates, the next two to the NE-SW trending structures and the fourth and final phase related to gentle NW-SE cross folds produced during formation of Hazara Kashmir syntaxis. Asymmetric to overturned tight to isoclinal folds and high angle dip slip strike faults of both normal and reverse type are related to the second and third phase of deformation. A chapter on the economic geologic potential of the area is also included.

Key words: Petrography, Structure, Abbottabad.

A/219. Ahmed, A., 1986. Geochemical characterization of the upper crust from southern Malakand Agency, Pakistan. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, p.3.

Whole rock major and trace element contents of extensive Proterozoic crystalline schists of the southern Malakand Agency and adjacent regions have been determined. The chemistry and mineralogy of samples, consistent with a sedimentary origin, display protolith variations. Chondrite normalized rare earth element 'petterns' of all the samples show very steep LREE enriched gradients with LaN /YbN ranging from 11.311 to 119.536. All analyzed samples exhibit negative Eu anomalies which may be due to mixing of various source lithologies during sedimentation. The patterns are comparable to that of average post-Archean upper crust except the higher PEE contents of some samples.

Key words: Geochemistry, Malakand Agency.

A/220. Ahmed, A. 1989. Shallow seismic reflection investigation for determination of seismic velocities on exposed rock units S/W Margala Pass and Thatta Khalil area, District Rawalpindi. M.Sc. Thesis Quaid-i-Azam University, Islamabad.

The seismic velocities are determined on the exposed rock units in the area lying between Margalla Pass and Thatta Khalil, near Taxila in Rawalpindi District. These lithologies are limestone, sandstone and conglomerate. The experiment was carried out on sixteen points by laying spreads of varying length of 65 meters and 55 meters by using OYO, McSeis-1500 system. A 10 lbs hammer was used as energy source. The data was processed by computer package "Simple refraction" H.P. model 216. The results show that the seismic velocity on limestone of weathered layer ranges from 590 m/s to 1250 m/s and corresponding (average) thickness varies from 1.5m to 2m, sub-weathered layer ranges from 1900 m/s to 2910m/s and its thickness varies between 4.1m to 8m and the 3rd-layer velocities are 3200 m/s to 4400 m/s. The seismic velocity on sandstone, of surface layer ranges from 850 m/s to 1580 m/s and the (average) thickness varies from 4.4m to 7.2m. The velocity of 2nd-layer ranging from 2340m/s to 2900 m/s, could be of sandstone of Murree Formation in the area, and the seismic velocity of surface layer on conglomerate.

Key words: Seismicity, Margala pass, Rawalpindi.

A/221. Ahmed, A., Mateen, A., Rogers, G., Chaudhry, M.N. & Butt, K.A., 1997. Rb-Sr geochronology of the Lower Swat granite gneiss, NW Himalaya, Pakistan. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p.6.

The regionally metamorphosed granites forming several plutons and loop-shaped bodies within the Pacha Formation and designated as "the Lower Swat Granite Gneiss", have been exposed in the Northern Buner district, Mingora and Manglaur areas. The augen gneisses were previously correlated to the Mansehra granites of Hazara (Jan et al 1981, Shams 1983) and were believed to represent the granitoid magmatism related to the crustal evolution in the region during the Late Precambrian to Cambrian periods (Le Fort et al 1980). Some authors assigned Lower Cambrian age and have argued that these granite gneisses (e.g. Hum Granite Gneiss) occurred in different tectonostratigraphic framework, being emplaced in the Swat Higher Himalayan tectonic block between MMT and MCT as part of crystalline basement (Chaudhry et al 1992). Rival models concerning the geology of the Lower Swat area predict that the granite gneisses are either Precambrian or Paleozoic in age. In order to test these rival hypotheses a Rb-Sr whole-rock geochronological study of two sets of granite gneiss bodies has been undertaken. On the basis of existing major and trace element data, samples were selected which covered the compositional range in order to obtain a wide variation in Rb/Sr ratio. Five samples from Karaker area (Hum Granite Gneiss) gave an isochron age of 260 ± 52 with an initial $87\text{Sr}/86\text{Sr}$ ratio of 0.709 ± 10 . While the second set of representative samples from Mura Kandao, Prona (Saidu) and Manglaur yielded age of 285 ± 8 Ma with initial $87\text{Sr}/86\text{Sr}$ ratio of 0.7093 ± 7 . The results obtained indicate that none of the studied granites are Precambrian or Cambrian in age, thus negating the views of Le Fort et al (1980). The Mura -Prona -Manglaur granite gneisses gave the best fit age of 285 ± 8 Ma is Lower Permian. The age estimates of Hum granite gneiss could be the same as it shows considerable scatter of the data. The geochronological history of the Swat Granite Gneiss is discussed in context with the petrogenetic evolution of Permo-Carboniferous alkaline rocks from Buner Swat (e.g. 300 Ma Koga alkaline-carbonatite

complex). The granites are suggested to be related to the bimodal magmas of Eastern Australia and Europe emplaced in the India -Australia rift zone along the Tethyan margin.

Key words: Geochronology, granite gneisses, Buner, Swat.

A/222. Ahmed, B., 1988. Reservoir seismicity of Tarbela Dam. M.Sc. Thesis, Quaid-i-Azam University, Islamabad, 64p.

Tarbela reservoir located in a seismically active region of previously reported basement faults like IKSZ and HLSZ, and surficial faults like Punjal-Tarnawal fault and Hazara thrust system. The present study reveals that the presence of reservoir has caused induced seismicity to pad up the tectonic seismicity of the region. Initial period (1975-1979) energy release or seismic activity gradually decreases in middle of the period (1980-82) is increased and reached a maximum position. The energy release patterns over 8 years (1975-1982) period are largely uncorrelated with the cyclic fluctuation of reservoir. Whereas in the second cycle (1981- 1986) the pattern of reservoir fluctuation and energy release are not so widely uncorrelated. But energy release related with the immediate region of 10 km distance discloses a mild correlation between the patterns of energy release and lake fluctuations during 1981 to 1984 after which the energy release (1984- to 1986) is increased prominently without maintaining relationship with the reservoir fluctuation. As a result the reservoir fluctuation apparently has negative relations with energy release. However, within an immediate region of 10 Km distance or less positive relations may exist. The analysis of the region lying in 10 km radius in short-term changes reveals that a subtle relationship exists. Therefore, using an expanded area and the located earthquake epicentres occurring in a half cycle (below and above average water level of reservoir) in a specific time give very important results, i.e. seismicity related with water fluctuation is increasing (when water below average level) with the passage of time.

Key words: Seismicity, dams, Tarbela.

A/223. Ahmed, C.I., 1998-99. Geological mapping of Rawalpindi-Sihala (Islamabad) area with special emphasis on engineering geological impacts on quality of ground and surface water (Soan River Basin) Rawalpindi-Islamabad, Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 91p.

About 105 sq. km of Rawalpindi-Sihala area has been mapped on survey of Pakistan toposheet No. 43-J/2 on a scale of 1:12500. The investigated area lies in the Soan basin. There are two main available sources of water, wells and river water. The physio-chemical parameters have been investigated for ground and surface water (Soan River Basin). The quality of water is going on increasing and it is going on for beyond the limits established for standards by AEPA, WHO etc. Physiochemically the area is high risky. Chemically the quality of water is risky. The water quality is chemically beyond the safe limits in the upstream areas like upper Sihala area where as its quality is highly risky at Soan Bridge area and Morgah Town area. The test results show that the quality of the investigated ground and surface water is of sodium bicarbonate type.

A/225. Ahmed, F., 1997-98. Structure, stratigraphy, micropaleontology and petrography of Jabri-Bodla areas District Haripur & Abbottabad Hazara (NWFP), Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 78p.

The Jabri-Bodla area lies in the Attock-Hazara fold-and-thrust belt of the northwestern Himalaya of Pakistan. Precambrian to Cenozoic sedimentary rocks are folded and imbricated during the Tertiary-Himalayan collision.

The oldest exposed stratigraphic unit is the Precambrian Hazara Formation. The formation is composed of slates, shales and phyllites. The presence of ripple marks and graded bedding shows that the Formation is deposited in shallow water turbidity environments. The Middle Jurassic Samana Suk Formation, Late Jurassic to Early Cretaceous Chichali Formation and Early Cretaceous Lumshiwal Formation were deposited in shallow marine conditions. The late Cretaceous Kawagarh Formation was deposited in deep to shallow water shelf environment.

The late Cretaceous to Early Paleocene uplift in the area caused the regression of the Tethyan Sea. The Tethyan regression initiated the deposition of ferruginous sandstone of the Hangu Formation.

The lower Tertiary sequence of Early to Late Paleocene Lockhart limestone, Late Paleocene Patala Formation, Early Eocene Margala Hill Limestone and Early to Middle Eocene Chorgali formation mark the complete cycle of transgression and regression of the Tethyan Ocean. The presence of early Paleocene to Late Eocene foraminiferal assemblage like globorotalia, globogorina, lockharia, assilina and nummulites in the limestones and shales of the Lower Tertiary sequence show the tropical sub-tropical open sea upper slope to outer shelf environments.

The Paleocene-Eocene boundary cannot be marked on the basis of microfossils in the area because the Patala Formation lacks microfossils. However, the tentative Paleocene-Eocene boundary between the Patala Formation and the Margala Hill Limestone can be marked at the base of Margala Hill Limestone on the basis of first appearance of Early Eocene microfossils.

Key words: Structure, Stratigraphy, Micropaleontology, Petrography, Abbottabad, Hazara.

A/226. Ahmed, G., 1992-94. Lithostructural mapping and geology of the Sirgah and microfacies study of the Cretaceous Kawagarh Formation of Jabri Area, Hazara, Northwest Himalaya. M.Sc. Thesis, Punjab University, Lahore, 153p.

A comprehensive study of Geology and structure of the area around Dhamtaur and Sirgah is presented. There is also a special section on the sedimentology of Kawagarh Formation of Jabri area, some distance to the south of Dhamtaur area. Geological mapping at the scale (1:10,000) is presented. The lithostratigraphic units range from Precambrian Hazara Slate basement to the Paleocene Patala Formation. Structurally the area comprises NE-SW trending double plunging/cylindrical folds with a general vergence to the Southeast. The folded sequence has been disturbed by a series of reverse faults. A small number of normal faults also exist. Faulting is dip slip to oblique slip and in general involves a maximum displacement of few hundred meters. Apart from the regular fault, decoupling is frequently noted at the formational boundaries leading to the slip and discontinuity of thin marker horizons.

The Kawagarh Formation of Jabri is divided into three internal units and twenty-one microfacies for the first time. It is basically a transgressive unit deposited during Cretaceous global transgression. The maximum depth of the sea at that time was about 250 meters. On the basis of planktonic fossils the age of the unit ranges from upper Coniacian to lower Campanian.

Key words: Structure, Cretaceous, Kawagarh formation, Hazara.

A/227. Ahmed, I., 1986-88. The geology and petrology of Chilas ultramafics complex in the vicinity of Chilas (District Diamar) with special emphasis on geology of the area. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 113p.

The project area covers about 368 sq. Km. located in the vicinity of Chilas, District Diamar. The work has involved geological mapping of the area on a scale of 1:50,000. This thesis deals with the geology, petrography and petrogenesis of the Chilas complex and adjacent southern rock units. The possible relation of Chilas complex with the southern Jijal complex has also been discussed.

The geological sequence of the area consists of metadiorite rocks of the Chilas complex and granodiorite. The rocks of the Chilas complex are divided into two main associations, the ultramafic-anorthosite association and the main norite/gabbro-norite association. Both the associations represent lower and upper cumulates respectively and are in a complicated contact possibly due to syndepositional folding-and faulting. Diorite is the most evolved unit of the Chilas complex.

Field evidences suggest that Chilas complex was intruded into an old pluton, the metadiorite which was included in Kamila amphibolite by Coward (1982). The relationship of Jijal with Kamila amphibolite also shows that the Jijal complex was accommodated in the rocks represented by Kamila amphibolites, suggesting an older age of Kamila rocks than Chilas and Jijal complexes.

The Chilas complex is unmetamorphosed and is present in an anticlinal position with ultramafics chiefly restricted to the core of the anticline. The ultramafics are overlain by more evolved rocks i.e. gabbro-norite association and diorite capped on both limbs by metadiorite roof rock. On the southern limb, the metadiorite roof rock unit is intruded by a granodiorite pluton which seems to be younger in age than the Chilas complex.

Key words: Petrology, Ultramafics, Chilas Complex, Diamir.

A/233. Ahmed, M., 1989. Seismicity of Tarbela region. M.Sc. Thesis, Quaid-i-Azam University, Islamabad, 91p.

Nine year (1977-86) computerized earthquake data of magnitude range 3 to 5 on Richter scale when plotted on two maps with respective hypocentral depths less than 10 km and more than 10 km, gave very interesting results.

The map (fig. 5.1) showing seismic events (with hypocentral depth exceeding 10 km) shows that besides IKSZ and HLSZ, there could be a third basement structure parallel to them.

The other map (fig. 5.2) having seismic events of hypocentral depth range less than 10 km shows that the shallow seismicity is more scattered and can also be associated with the surface structures such as Darband fault, Punjal fault and Main Mantle Thrust. In this case it indicates that Darband/Thakot fault and Punjal fault are active in the north at a considerable distance from Tarbela Dam. In Tarbela region their activity is minor one, however, it may increase in future if southwards migration is believed to be in progress.

Key words: Seismicity, Tarbela.

A/234. Ahmed, M., Ali, K.S.S., Khan, B., Shah, M.A. & Ullah, I., 1969. The Geology of the Warsak area, Peshawar, West Pakistan. Geological Bulletin, University of Peshawar 4, 44-78.

The Warsak Area, Peshawar, West Pakistan, has been geologically mapped and the petrography of the area described in detail. The area consists of a series of metasediments of the greenschist facies (slates, phyllites, mica schists, garnet schists, hornblende schists, calcareous schists and marbles), which have been divided into a lower,

Middle and Upper Series. On the eastern side the metasediments disappear under the alluvium of the Peshawar plain. They range from Siluro-Devonian of Upper Paleozoic in age, and are intruded by sills of metagabbro and metadolerite (? Cretaceous), porphyritic microgranites (?Upper Cretaceous to Lower Tertiary) and the Warsak alkaline granite (? Lower Tertiary). The chemistry of alkaline nature of the granites (which contain aegirine, riebeckite and astrophyllite) is briefly discussed. The structure of the area is shown to be a northwards plunging syncline, faulted on the east on the northern side of the Kabul River. The joint patterns and other structural features are described, and the economic geology of the area discussed.

Key words: Warsak, Peshawar.

A/235. Ahmed, M. & Javed, M., 1992. Seismic risk evaluation for northern Pakistan using probabilistic approach. Abstracts, First South Asia Geological Congress, Islamabad, p.2.

The instrumental seismic data for Northern Pakistan recorded by world-wide seismological network during the current century was used to evaluate the seismic hazard through the probabilistic approach of seismic risk evaluation. For this purpose, seismic data was collected from various International and local agencies and a composite list of earthquakes was made. From this list, frequency-magnitude relationship for the area was developed and 'a' and 'b' parameter determined. A statistical analysis was performed using the recurrence relationship developed above and the popular attenuation law of Joyner & Boore (1981), horizontal ground acceleration for various probabilities of exceedance during the life time of a project were calculated and the results presented in the paper.

Key words: Seismicity, Northern Pakistan.

A/247. Ahmed, S.A., Mazhar, F., Sayab, M. & Abbasi, I.A., 2001. Lithofacies, sedimentary cycles and depositional environments of the Miocene-Pliocene, Dhok Pathan Formation, Bannu Basin, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.22.

The molasse sediments of the Miocene-Pliocene Dhok Pathan Formation in the Qubul Khel and Mochimar areas, Bannu basin are studied to work out their origin and depositional setting. The formation has variable thickness in different parts of the basin and is comprised of interbedded siltstone, sandstone and conglomerate in variable proportions. The coarse to fine ratio is 1:3 in the lower part, which changes to 1:5 in the middle and upper part of the formation. Four main lithofacies are recognized in the formation, comprising; a) massive, clast supported conglomerate (Gm), b) trough cross bedded coarse sandstone with hard bands (St), c) parallel bedded fine sandstone (Sh) and d) laminated siltstone/shale (F).

The lithofacies Gm is interpreted to have been deposited in the core of major longitudinal basin associated with wide and shallow braided river system. Lithofacies St and Sh were deposited in the sand flats/bars and channels of a sand rich river system, whereas, the lithofacies F resulted due to vertical accretion in the flood plain. Abundant clast supported exotic conglomerates; pebbly sandstone and common scouring at the base of the sandstone bodies reflect deposition under high-energy conditions usually associated with a trunk braided river system. High ratio of flood

plain sediments in the middle and upper part of the formation is due to gradual shifting of the trunk river from this area and deposition of fines in the flood plain.

Key words: Lithofacies, Miocene, Pliocene, Bannu basin.

A/249. Ahmed, S.N., McGann, G.J. & Aizad, T., 1992. Dhurnal oil field, Potwar basin. Abstracts, First South Asia Geological Congress, Islamabad, p.3.

The Dhurnal Oilfield is located 74 kilometers southwest of Islamabad in the Potwar Basin, and was discovered in March, 1984. The total recoverable reserves are estimated at about 50 MMBO.

The field was developed with four producing wells and three water injection wells. Three main reservoirs are present, of Eocene, Paleocene and Permian age. All of the reservoirs are limestone.

The Limestones are extremely tectonically fractured and all production is derived from fractures. The average thickness of these carbonates are 430, 540 and 325 feet respectively. The overlying thick claystones and shale of Murree Formation (Miocene) provided a vertical and lateral seal to the Paleogene and Permian limestones.

The surface expression of the Dhurnal structure is an eastwest trending sinuous syncline. At Eocene level, the field is a WSW- ENE trending anticline with well define axial plunge. The northern and southern flank are bounded by major thrusts. The tectonic history of the Dhurnal structure is complex and resub from a combination of thrust faulting and flexing, modified by later salt flowage. The field has a maximum areal closure of 3325 acres at Eocene level. There are different original oil-water contacts in the Eocene, Paleocene and Permian reservoirs. The field began production in May 1984, reaching a mulmum rate of 19370 BOPD In November. 1989. The present average production is about 13,200 BOPD (3840 dog API) plus 31 MMSCFDP of gas. The cumulative production as of May 31, 1991 was 36.151 MMBO plus 87,658 MMSCF of gas. Cumulative water injection was 44,617 MMBW. Water injection for pressure maintenance was initiated in 1987, about three years after field was brought on stream. The current Injection rate is 30,000 BWPD.

A/259. Ahmed, W., & Alam, S., 1992. Geochemistry of saturated hydrocarbon biomarkers in crude oils of Potwar basins, Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.3.

The Potwar basin is a productive oil province with reservoir oil present at a number of stratigraphic levels from Cambrian to Miocene. Distribution of sterane and triterpanes was determined to classify and correlate these oils. The samples were analysed at Federal Institute of Geosciences and Natural Resources (BGR), using 30 m fused silica capillary column coated with SE 54 and connected to mass spectrometer operated in the selected ion Monitoring mode. The mass ion fragments /mz 191 and 217 were recorded. Hopane, gammacerane, tricyclic diterpane and three steranes with 27, 28 and 29 carbon atoms are dominant biomarkers. The mass fragmentograms of these biomarkers appears to be similar. There are little variations, which are probably caused by different maturity level and analytical variance. The results indicate that the oil produced from Potwar basin is similar and appears to be genetically related to one family.

A/260. Ahmed, W., & Alam, S., 2000. Organic geochemistry and source rock characteristics of Salt Range Formation, Potwar Basin. Abstracts, Third South Asia Geological Congress, Lahore, 111-112.

Salt Range Formation which is widely distributed in Salt Range contain, low grade oil shales. These shales are developed in the middle part of the formation and are laterally quite persistent. In some localities, the top of the formation contain high grade shales, which are lenticular in nature and are highly localized.

To assess source rock potential of the formation, 64 outcrops and well samples were collected and analysed for TOC, extraction, pyrolysis vitrinite reflectance, and low temperature carbonization analysis (Fischer Assay).

The results indicated that the formation has best oil source rock potentials. The formation exposed in the eastern Salt Range is extremely rich in organic carbon, TOC up to 30% and has excellent geochemical source rock parameters.

(HI upto 879 and EOM/TOC upto 255). Also the low grade oil shale encountered in west-central and western Salt Range are excellent potential Oil source rocks having TOC 2.5%, HI up to 746 and EOM/TOC up to 204. The organic matter consists predominantly of pre-bitumen and solid bitumen and partly contains major proportions of liptinite. The oil yield of high grade oil shale varied from 15 to 20% of rock weight.

A/261. Ahmed, W. & Gauhar, S.H., 1986. Plate tectonics, crustal evolution and metallogeny of Pakistan. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, 8-9.

A study of the metallogenic zonation of different regions of Pakistan shows a close genetic and temporal relationship with various aspects of crustal dynamics and plate boundary features such as subduction, continental collision, rifting, and emplacement of ophiolites. In the perspective of delineating their exploration potential and priorities, these zones have been further classified into different 'metallotect' belts by combining the plate tectonic environments of each separately discernible geological region with its characteristic metallogenic imprints. Thus besides serving the general purpose of a review article of the state of art on the accumulated knowledge about the evolution of crust in this part of the world, the present paper also attempts to give a brief yet unified synthesis on the mineral potential of Pakistan as interpreted in terms of the current concepts of metallogenesis and plate tectonics.

Based on mineral prognosis and plate tectonic interpretations, a number of new target areas have been identified for initiating scientific exploration. Some of the more important of these include; copper and other base metals in shield protrusions and shield derived sediments in the Punjab and Sind; rifting-related hot spot and brine solutions in the Salt Range and the Punjab Plains for sucking and concentrating metals in early Paleozoic sediments; barite-fluorite associated lead-zinc-silver deposits in shelf sediment~ in parts of Baluchistan and NWFP; porphyry copper and massive sulphides in Chagai and Kohistan regions; epithermal gold in clay altered volcanic rocks in Chagai; Lithium in pegmatites in Chitral and adjoining areas; chromite in northern ophiolites; and tin, tungsten and base metals in porphyries of Chagai and in the magmatic granitoids and their contact Paleozoic carbonate rocks in NWFP and Northern Areas.

Unlike most podiform deposits, the chromite layers in the area show considerable lateral persistence. Chromite grains have always rounded outlines. Cataclastic shattering, healed by serpentine, is frequent. Octahedral cleavage is well developed in most samples. Chemical assay of seven cleaned chromite samples show that they contain 39.06% to 50.66% Cr₂O₃; the MFe ratio varies from 2.06 to 2.53. Plots of the chromites on "Stevens triangular diagram" show that six belong to the "alumina chromite" field and one to the "chromian spinel" field

(Eds.), *Geology in South Asia-II. Geological survey & Mines bureau, Sri Lanka*, Professional paper 7, 281-299.

The Panjal Sequence along the eastern syntaxial limb of the Azad Kashmir Himalayas contains base metal deposits at Treri, Lamnian and certain other localities. The Treri deposits are of the Mississippi Valley type. Epithermal galena-rich sulphide ore of the Lamnian area occurs in epigenetic quartz veins in the carbonaceous phyllite. Some of the veins contain albite. Accessory tourmaline occurs extensively in rocks of the Panjal Sequence. The Precambrian augen-gneiss at Reshian resembles a para-gneiss and lacks the skarn mineralization reported by previous workers. The granitic orthogneiss occurs in the Chham area. Whereas at Nauseri the granitic gneiss is migmatitic. The pyrite- and pyrrhotite-rich silicified bodies of the Reshian area seem to be associated with a fault zone, which is traceable towards NW by similar bodies occurring at diverse stratigraphic levels in the Nera, Tara, Nauseri and Bagnad areas, respectively. On the Nera-Kafir Khan hillslope of the Harijala area, such bodies occur in Triassic metasediments above the limestone horizon. South of Tara, in the Panjkot area, such bodies occur at the upper contact of metavolcanics with the Triassic limestone. In the Nauseri area, they occur in the Panjal Thrust contact zone. At Bagnad, the silicified bodies occur within the Precambrian Nauseri gneiss. Another fault is revealed by the different stratigraphic levels of the zone of black, carbonaceous and pyritous with limonitic, gypsiferous and sulphurous weathering patches, and by slicing effects and displacements of strata in the Reshian, Klietar, Treri, Nauseri, Harijala, Tararan and Jabre Saiyidan areas.

A/270. Ahmed, Z., 1982. Porphyritic-nodular, nodular and orbicular chrome ores from the Sakhakot-Qila complex, Pakistan, and their chemical variation. *Mineralogical Magazine* 45, 167-178.

A new kind of chromitite texture—a porphyritic nodular texture, found in an alpine-type complex in Pakistan, is described. The chromite from phenocrystic nodules and that from their disseminated chromitite groundmass show comparable trivalent elements and postcumulus to subsolidus Mg-Fe²⁺ variations, which are also recorded from

'normal' nodular ore samples. The nodular ores differ from all other textural types of chromitite from this complex in an unusual, though slight, increase in $\text{Cr}/(\text{Cr}+\text{Al})$ with $\text{Mg}/(\text{Mg}+\text{Fe}^{2+})$ between stratigraphically different deposits, which is caused by magmatic differences. The implications of major element variations in chromites and olivines of nodular chromitites are discussed and a cumulus origin is supported. Temperatures of final chromite-olivine equilibration ranged from 750 to 900 °C the individual nominal values being higher for chromitite with coarser chromite crystals and, or, higher chromite/silicate ratio.

A/272. Ahmed, Z., 1984. Stratigraphic and textural variations in the chromite composition of the ophiolitic Sakhakot-Qila complex, Pakistan. *Economic Geology* 79, 1334-1359.

The deposits and their host rocks compare well with podiform ores hosted by alpine-type peridotites of ophiolites. Unlike most alpine-type complexes, predominant stratigraphic variations in the chemical composition of chromite exist. The chromite deposits fall in two major zones, the first consisting of three subzones. Regular compositional correlations between the accessory chromites of the host rocks and the associated segregated chromites are drawn, indicating relatively later crystallization of the former. Relict cumulate chromitite textures cover the podiform range and are examined in the light of compositional data. The inequigranular textural varieties probably developed by crystallization of successive crops from magmatic fractionation, with their coarser grained, massive chromite components always being slightly higher in $\text{Mg}/(\text{Mg} + \text{Fe}^{+2})$ than the associated finer grained chromite components. The $\text{Mg}-\text{Fe}^{+2}$ exchange between chromite and silicates seems to start during the cumulus stage and continues during the postcumulus stage, but is reduced to a very small intensity during the subsolidus stage until it ends at about 700 degrees C.

A/274. Ahmed, Z., 1985b. A new occurrence of uranium-bearing thorium monazite, northern Pakistan. *Acta Mineralogica Pakistanica* 1, 27-33.

A new type of occurrence of uranium- and thorium-bearing monazite is described from a chloritic rock from near Musa Mena in Malakand Agency. The locality is being reported for the first time and may prove an economically viable mining area for uranium, thorium, and rare earth elements such as lanthanum, cerium, and neodymium, in addition to titanium-mineral rutile. Monazite forms euhedral porphyroblasts, which appear zoned and occur along with euhedral rutile in schist of low metamorphic grade. Microprobe analyses of rutile, monazite, apatite and chlorite are presented. The chlorites of monazite-bearing and adjacent monazite-lacking schists are chemically different. Zoned monazite crystals display increased Th and Ca and decreased Ce, Nd, Sm, Gd and Dy towards the rims. This is different from the usual trends.

A/278. Ahmed, Z., 1985f. Mineral microanalytical data on the doleritic dykes from Mansehra-Amb State area, Hazara Division, Pakistan. *Acta Mineralogica Pakistanica* 1, 98-115.

The mineral phases present in a suite of doleritic sills and dykes cutting across the granitic-pelitic metamorphic rocks of Mansehra-Amb State area, have been analyzed by electron microprobe. Doleritic rocks represent a variety of rocks produced by magmatic differentiation, subsequent metamorphism of varying intensity and rock alteration. Plagioclase and biopyroxene compositions exhibit strong variations in different doleritic samples. Sphene, epidote and hydrogrossular, found in small amounts in some samples, may indicate some auto-metasomatism. Magnetic and ilmenite are abundant among opaques and oxidized titanomagnetite is also present. A large part of magnetite formed from pyrite and chalcopyrite.

A/279. Ahmed, Z., 1986a. Mineralogy of Proterozoic metamorphites of southern Malakand Agency, Pakistan. *Acta Mineralogica Pakistanica* 2, 24-46.

Mineral assemblages of a variety of lithological samples of the greenschist facies metamorphic rocks that occur widespread in southern Malakand Agency and adjacent areas, have been investigated and chemically analyzed by microprobe. Mineral chemical data is presented in respect of chloritoid, chlorite, muscovite, fuchsite, talc, biotite, spessartine, Mn-bearing garnet, apatite, sphene, ilmenite, monazite and rutile. Data on fuchsite is supplemented by its lattice parameters. Chlorite zone is extensively developed with regional metamorphic chloritoid found in a portion. The chloritoid has low Mg, Mn and inferred Fe^{3+} . It equilibrated with chlorite at a temperature higher than that of the comparable rocks from Turkey. The celadonite and Ti contents in muscovite show progressive increase with metamorphic grade. From under the base of an ophiolite an even higher-grade spessartine-bearing rock is found affected more by higher pressure than by higher temperature. Its chlorite has relatively high MnO and CaO contents. At or near the contact of ophiolitic rocks, evidence of metasomatic and hydrothermal activity is noticed.

A/281. Ahmed, Z., 1986c. Ophiolite related mineral resources of Pakistan. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, 2-3.

A review of various metallic and non-metallic mineral resources genetically linked to the ophiolitic rocks of Pakistan is presented. Geotectonic and geological features of all the known ophiolitic rocks of Pakistan are summarized. Distribution and characteristics of certain mineral commodities have been outlined and described. Many Pakistani ophiolites lack the upper portions of the ophiolite sequence; others exhibit intimate association of non-ophiolitic and ophiolitic volcanic rocks. Metallic grade chromite is the most widespread of the minerals and forms rich concentrations. Precious gem quality emerald deposits show ophiolitic derivation, probably not observed elsewhere.

A/282. Ahmed, Z., 1987a. Mineral chemistry of the Sakhakot-Qila ophiolite, Pakistan: Part 1, Monosilicates. *Acta Mineralogica Pakistanica* 3, 26-41.

This paper is the first of a 4-part serial characterization of the mineral chemistry of the Sakhakot-Qila Ophiolite. Monosilicates from this ophiolite include olivine, sphene and garnets. Olivine with a Fe content of 73% to 97% shows variations in Mg and Fe contents related to the primary rock-types, and to the textural components within rock samples. Olivines with the highest Mg and lowest Fe from inclusions in chromite crystals. Olivine grains embaying into the boundaries of chromite crystals are intermediate between such inclusions and discrete grains. Olivines with the highest Fe and lowest Mg are those from the Fe-websterite dyke. Sphene is a late-stage crystallization product found only in metadolerites and plagiogranite differentiates. Its chemical variation is insignificant. Garnets are all metasomatic and present in various type of rodingitic veins and dykes. Grossular is the most common garnet and often coexists with hydrogrossular, or rarely, andraditic grossular. At interfaces of rodingites with the chromitite wall rocks, uvarovite or Cr-rich titanian grossular may develop. The garnet compositions are commensurate with the mother fluids having a seawater source.

A/283. Ahmed, Z., 1987b. Mineral Chemistry of the Sakhakot-Qila complex, Pakistan: Part 2, polysilicates. *Acta Mineralogica Pakistanica* 3, 140-158.

Polysilicates contained in the SQO include enstatite, bronzite, diopside, endiopside, salite, augite, magnesio-anthophyllite and a variety of calcic amphiboles. Their compositions vary mainly with the primary rock types, and too much less extent, with the effects of secondary metasomatic activity. Orthopyroxenes exhibit a relatively restricted range in Fe variation, except for more magnesian inclusions in chromite crystals and more Fe-rich crystals in websterite dykes. Primary Mg-Fe variations in clinopyroxenes are superimposed by the metasomatic Ca-enrichment. The primary amphiboles exhibit a less marked Fe-enrichment, Si-depletion trend with increasing SiO₂ in the rock. This is overshadowed by the secondary tremolite-actinolite formation by the interaction of fracture-controlled SiO₂ rich solutions. Minor element variations in polysilicates are not significant.

Key words: Mineralogy, ophiolite, Malakand.

A/284. Ahmed, Z., 1988a. Bulk-rock chemistry and petrography of the Sakhakot-Qila ophiolite, Pakistan. *Acta Mineralogica Pakistanica* 4, 4-29.

Petrographic observations on the Sakhakot-Qila ophiolitic rocks are supplemented by their characterization in terms of bulk-rock contents of major, trace and rare-earth elements. The thick, mantle-rock sequence exhibits Mg-rich compositions with very small variations. Strong magmatic differentiation is shown by non-cumulate dyke rocks. REE abundance levels progressively increase during the magmatic evolution, maintaining LREE-depleted pattern. The criteria used by Ishiwatari (1985) indicates derivation of this ophiolite after a moderate degree of partial melting of an Iherzolitic mantle.

Key words: petrography, geochemistry, ophiolite, Malakand.

A/285. Ahmed, Z., 1988b. Mineral chemistry of the Sakhakot-Qila ophiolite, Pakistan: Part 3, phyllosilicates. *Acta Mineralogica Pakistanica* 4, 45-64.

Phyllosilicates of the Sakhakot-Qila ophiolite are products of secondary processes and include rock-forming and vein-serpentine, chlorite and clintonite. Serpentine of rock-forming and vein types appear chemically indistinct, and are rich in Mg. Structure of the asbestos chrysotile is 2Mc1. rarely, within samples, earlier serpentines may contain higher SiO₂, MgO and lower FeO, Al₂O₃, NiO, MnO than the later ones. Chlorite shows diversity in mode of occurrence and composition. Rodingites and chromitites often contain “IIb-even” structure type chlorite with b cell dimension varying from 9.18 to 9.24 Å. Chlorite has variable Al, Fe and Mg; and a trend of Fe-enrichment and Mg-depletion is depicted from earlier towards later magmatic differentiates. Clintonite forms in rodingites by localized Al-metasomatism.

Key words: Mineralogy, Ophiolite, Malakand.

A/286. Ahmed, Z., 1988c. Mineral chemistry of the Sakhakot-Qila ophiolite, Pakistan: Part 4, disilicates, tectosilicates and non-silicates. *Acta Mineralogica Pakistanica* 4, 65-80.

The rocks of Sakhakot-Qila ophiolite contain disilicate: clinozoisite and vesuvianite; tectosilicate: quartz and albite; and non-silicates: chromian spine, ilmenite, corundum, perovskite, apatite, nantokite, native Cu and a nickeliferous opaque mineral assemblage comprised of awaruite, pentlandite, heazlewoodite, PGE-rich awaruite, and troilite. In clinozoisite, theoretical pistacite content increases from the lower level towards the higher-level within the metagabbros. The accessory chromite in ultramafic rocks is more ferruginous and less magnesian than the associated ore forming chromite. Both types conform to compositions known from ophiolitic rocks, except the Liguria-type ophiolites. Rodingitizing fluids cause increased Al-activity that is reflected by the presence of corundum: the elevated Cu and Cl concentrations in the fluid are reflected in native Cu, nantokite and chlorapatite; and reaction of rodingitizing fluids with chromite may result in some local perovskite. Serpentinizing fluids form a variety of nickeliferous opaque minerals whose composition depends upon host-rock chemistry.

A/288. Ahmed, Z., 1990b. Geochemical characterization of Proterozoic upper crustal metamorphic terrain of southern Malakand Agency, Pakistan. *Precambrian Research* 46, 189-194.

Proterozoic crystalline schists that have extensive outcrops in the southern Malakand Agency and adjacent regions were sampled from localities west of Dargai town to include lithologically different samples. Their major and trace element chemistry and mineralogy indicate a sedimentary origin, protolith variations, and a passive continental margin tectonic setting. The REE contents indicate considerable mixing of various source lithologies during sedimentation. The samples have high TREE and LREE/HREE compared with the post-Archaeon upper crustal values. The chemical data indicate their derivation from a typical granodioritic upper crust with a large component of K-rich granitic rocks.

A/289. Ahmed, Z., 1991. Comparison of the chemistry of ophiolitic pyroxenites with a strongly fractionated dyke of pyroxenite from the Sakhakot-Qila ophiolite, Pakistan. *Chemical Geology* 91, 335-355.

Exceptionally strong fractionation has been found amongst the pyroxenite dykes crosscutting the ultramafic rocks of the Sakhakot-Qila ophiolite, Pakistan. One such dyke, an “Fe-websterite”, is particularly fractionated and anomalously Fe-enriched and Mg-depleted. This is supported by the data from whole rock analyses of major, trace and rare earth elements, as well as by the mineral chemistry of the constituent chromian spinel, olivine, clinopyroxene, orthopyroxene and magmatic amphibole. Secondary sulphides of the “Fe-websterite” include troilite-

pentlandite instead of the awaruite-hazlewoodite-pentlandite assemblage typical of all the other ultramafic rocks of the host ophiolite. The non-cumulate parent liquid of the magnesian pyroxenites crystallized in an initial episode when the surrounding cumulates were still hot. In a belated second episode, the Fe-websterite may have crystallized in isolated pockets after its differentiation to an extent much greater than that known from most pyroxenite dykes in ophiolites.

Chemical analyses and refractive indexes are reported for eleven garnets. They are dominantly consisting of almandine component.

Key words: Garnets, Swat.

A/292. Ahmed, Z. & Bevan, J.C., 1981. Awaruite, iridianawaruite and a new Ru-Os-Ir-Ni-Fe alloy from the Sakhakot-Qila Complex, Malakand Agency, Pakistan. Mineralogical Magazine 44, 225-230.

The authors report the first occurrence of awaruite in Pakistan, in the Sakhakot-Qila ultramafites. Electron-microprobe analysis reveals a considerable variation in the compositions of awaruites from different parts of the complex. The presence of copper in awaruite, in amounts up to 5 atomic percent, is also reported for the first time. In one chromitite body, an iridian awaruite with up to 27 wt% of iridium occurs in association with 'normal' awaruite and a new Ru-Os-Ir-Ni-Fe alloy. The awaruites are discussed in relation to those from other localities.

Key words: New minerals, ultramafics, Malakand.

A/293. Ahmed, Z. & Chaudhry, M.N., 1976. Geology of Babusar area, Diamir District, Gilgit, Pakistan. Geological Bulletin, University of Punjab 12, 67-78.

A geological map of 67.4-km² area near Babusar, Gilgit Agency, Pakistan, has been prepared on a scale of 1:63,360. Detailed petrography of various rock units with 20 selected modal analyses is given. Ten chemical analyses are reported. Regional metamorphites of both ortho- and para- type occur in the Babusar area in addition to a small peridotite body. Pelitic, carbonaceous and calcareous schists of upto almandine grade belonging to the Precambrian Salkhala Series lie in the south. Between these and the Thak Valley Igneous Complex to the north are concordantly present meta-igneous rocks of chlorite to almandine grade and a higher grade banded amphibolite. Minor dykes and sills intruding these metasedimentary and meta-igneous rocks, were subjected to amphibolite facies regional metamorphism. A Tertiary alpine peridotite was intruded into the banded amphibolite as a curved L – shaped lensoid body.

A/295. Ahmed, Z. & Hall, A., 1982. Nickeliferous opaque minerals associated with chromite alterations in the Sakhakot-Qila complex, Pakistan and their compositional variation. *Lithos* 15, 39-47.

Chemical compositions of the awaruite-heazlewoodite-pentlandite assemblage from the Sakhakot-Qila ultramafic complex, Pakistan, indicate its genesis in highly reducing conditions with f_{O_2} and f_{S_2} much below those yielding nickel sulphide ores. The compositions from various parts of the complex exhibit larger variations than those reported so far from a single complex, and include unusually high Ni contents. Awaruite compositions extend beyond the previously known limit of Ni content, and are unique in containing Cu and not Co as the third constituent after Ni and Fe; with sympathetic relation between Cu and Ni. Previous reports indicate genesis of such minerals by serpentinization only, but the present example links them to chloritization and the formation of 'ferritchromit' as well. Their petrographic distribution is related to that of chromite grains and segregations and not to that of serpentine.

Key words: Chromite, Ultramafics, Malakand.

A/296. Ahmed, Z. & Hall, A., 1984. Petrology and mineralization of the Sakhakot-Qila ophiolite Pakistan. In: Gass, I.G., Lippard, S.J. & Shelton, A.W. (Eds.), *Ophiolites and Oceanic Lithosphere*. Geological Society of London, Special Publication 13, 241-252.

The Sakhakot-Qila complex is an incomplete, dominantly ultramafic ophiolite. The geology, rock and mineral compositions, and occurrences of chromite ore deposits are described. The predominant ultramafic rock types are harzburgite, wehrnite and dunite, and dykes of pyroxenite. The mafic components of the complex are a metamorphosed gabbro and dykes of metadolerite. Postmagmatic alteration is common, and several kinds of rodingite are abundant. They formed by addition of Ca, Al, Cl and Cu and removal of Si, Mg, Fe and Ni from pre-existing rocks, and contain corundum, clintonite and Al-depleted ferritchromite in addition to the more usual minerals such as grossular and vesuvianite. The rodingites appear to have developed independently of serpentinization, probably with the participation of seawater. There are numerous small chromite deposits, varying widely in texture and composition. There is a strong reciprocal Cr-Al variation and lesser Mg-Fe²⁺ variation, partly related to the stratigraphic position of the chromite. Nickeliferous opaque mineral assemblages are well developed.

A/297. Ahmed, Z., Hussain, S. & Awan, A., 1977. Petrology of Thelichi area, Gilgit Agency. *Geological Bulletin, University of Punjab* 14, 27-38.

Near Thelichi, Gilgit Agency, 181 square Kilometer area lying along the newly constructed Karakorum Highway, has been geologically mapped and studied in detail. Detailed petrography including 49 modal analyses of various rocks is presented. Field and microscopic evidences show that there are two major dioritic plutons of Cretaceous-Eocene age, separated by regionally metamorphosed epi- and meso- zonal rocks and a sill of porphyritic diorite. The metamorphics including amphibolites were derived from original sedimentary rocks of different composition. The dioritic rocks lack pyroxenic basic rocks or ultrabasics. They show systematic mineralogical variations due to magmatic differentiation and assimilation. Residual agmatic fractions crystallized the widespread pegmatites and hydrothermal quartz veins. A brief survey of the economic mineral potential of the area is included.

A/304. Ahsan, N., Baloch, I.H., Chaudhry, M.N., Chaudry, M.M. & Gondal, M.M.I., 2001. Petrography and geotectonic study of Allai River bed aggregate near Banna, NWFP, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 55-56.

The Allai River is an important tributary of the River Indus. The Allai River conflues the Indus near Besham at Kund Syyadian. A number of dams with a total hydroelectric potential of about 1000 MW are likely to be built on the Allai River and its tributaries. Therefore tens of thousands of cubic metre of fine and coarse aggregate will be required for the dam and related civil structures. The gravel and associated sand deposit occurs on the bed of the Allai River and its tributaries near Banna. These deposits were studied petrographically as well as from engineering point of view. The Allai River derives its sediments both from the Indian plate edge as well as from the Indus suture zone and Kohistan island arc. The Indian plate edge in the area is composed of high grade pelites, psammite, S-type Mansehra granite, Susil Gali granite and metasediments belonging to Hazara Group as well as Tethyan sediments which are composed of thick sequence of dolomite, dolomitic limestone, limestone and slates. The suture zone and Kohistan island arc is composed of ultramafics, norites, diorites and amphibolites. Since the Allai River flows near

the boundary of the Indian plate and the Kohistan island arc, therefore the composition of the sand and gravel along the river varies widely. However, we have chosen Banna because of the large quantity of available sand and gravel. All fractions of the coarse aggregate have been studied petrographically. The range in composition of all the sieves is composed of amphibolites (1.3 to 15.6%), diorite (0-33.8%), granite (8.2% to 19.5%), S-type granite gneiss (0-10.7%), granite mylonite (0-7.1%), marble (12.7% to 25.5%), mylonite (0 to 6.8%), pegmatite (0-2.5%), schist (0-20.5%), vein quartz (0-3.7%), norite (0-12.2%) and dunite (0-28.4%). The fine aggregate is composed of granite/granodiorite (1.1% to 24.6%), diorite/tonalite/ amphibolite (0 to 32.8%), quartzite (8.1% to 21.8%), phyllite/slate* (7.2% to 20.4%), greywacke group* (0-0.4%), chert* (0-0.8%), quartz mica schist/gneiss (4.6% to 8.5%), quartzpolygrain quartz (21.1% to 53.6%), feldspar (4.4% to 8.3%), biotite (1.3% to 2%), muscovite (1.4% to 2.4%), amphibole (0.9% to 3.7%), epidote (1.5% to 1.8%), magnetite (1.0% to 3.0%), garnet (1.1% to 1.2%), tourmaline (0-0.1%) and zircon (0-0.3%). The physical properties of the coarse and fine aggregate fulfil the parameters set by BS812: 1965 and ASTM part 4.

A/306. Ahsan, N. & Chaudhry, M.N., 1998. Facies and microfacies analysis of Kawagarh Formation of Hazara basin, Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 5-6.

The Upper Cretaceous in the Hazara Basin is marked by a transgression which deposited Kawagarh Formation (Latif, 1970, Shah, 1977). At the type locality (lat. 33° 45' 30" N; long. 70° 28' 30" E) the Kawagarh Formation is composed of dark marl, cleaved calcareous shale and nodular argillaceous limestone. The section of the Kawagarh Formation at the type locality is incomplete due to folding and faulting. A study of four sections of Kawagarh Formation of Hazara Basin at Jabri, Changla Gali, Giah and Borian is presented and discussed in the following.

The Kawagarh Formation near Jabri (lat. 33° 55' N; long. 73° 15" E) is composed of light brown to chocolate, whitish grey to light grey and pinkish grey limestones. The basal portion contains thinly laminated dirty to earthy grey and rusty grey marls interlayered with arenaceous limestone (Ahsan et al., 1993). The formation here is divided into eight facies which are composed of glauconitic arenaceous mudstone facies, mixed arenaceous limestone/marl facies, mud to wackestone facies, mixed grainstone to mudstone facies, wackestone to mudstone facies, mixed grainstone to mudstone facies, mudstone facies and mixed dolomitic limestone facies.

The Kawagarh Formation at Changla Gali (lat. 33° 55'30" N; long. 73° 22'30" E) consists of medium to dark grey limestone which we attiers to offwhitish grey, yellowish grey and light grey shades. Earthy grey, rusty to yellowish grey and splintery mart (20.52m thick) is present at the top. However, eight marly horizons intercalated within the limestone also occur. The formation is composed of four facies which are dolomitic arenaceous mudstone facies, packstone-, dolomitic packstone-dolospar and mad facies, mixed wackestone packstone-marl facies and marl facies (Ahsan et al. 1994). The Kawagarh Formation at Giah (lat.34° 6' 30"; long.73° 21'26") is white to light grey, bluish grey and dark grey limestone (Chaudhry et al., 1992). It is composed of four facies which contain mixed dolomitic limestone-dolospar facies, biomicrite facies, sandy biomicrite facies, sandy dolomitic limestone facies, sandy dolospar facies. Towards top it contains coarse grained detrital quartz. The Kawagarh Formation at Boriati (lat. 34° 9' 15" N; long. 73° 17' 15" E) is composed of light to dark grey, light yellowish grey, whitish maroon, reddish maroon to maroonish grey limestone (Ahsan et al. 1993), The formation consists of four facies which contain mixed wackestone-packstone-dolomite facies, mixed mudstone to wackestone facies, mixed mudstone-wackestone facies and mixed mudstone-wackestone-intraclast bearing wackestone-dolostone facies. The sections of the Kawagarh Formation at Jabri 3rd Changla Gali which are located southwards of the Nathiagali Fault contains fair amount of marls and arenaceous limestone. Arenaceous limestone and mars constitute 23.13m of lower part of the Jabh section. The Changla Gali section is composed of alternations of marl and limestone horizons. The sections situated/the north of the Nathia Gali Fault do not contain mads or limestones of significant clastic matter. The sections south of the Nathia Gali Fault which contains fair amount of the marl were deposited at relatively shallower depths of around

80 to 100 m since they lack benthic fauna and contain pelagic foraminifera. However, the sections to north of the Nathia Gali fault which lack marl were deposited towards the very shelf edge at about 200 to 250 m as indicated by presence of *Oligostegina*. Carbon oxygen isotope studies of selected samples show that it was deposited in warm water conditions. It has been established that Indian Plate established its first contact with Kohistan Arc at about 67 ± 2 Ma (Bard et al., 1979). It resulted in uplift of shelf and lateritization of the Kawagarh Formation in Maastrichtian (Chaudhry et al., 1994). The burial of Kawagarh Formation started with deposition of shelf carbonates and shales in Thanetian and continued upto deposition of Murree Formation, The total thickness of sediments is about 3800m. The deposition of Siwaliks is not certain in the studied area. The maximum temperature was about 125°C and pressure reached about 0.9 kb. Non ferroan microcrystalline calcite is penecontemporaneous to the bioclasts. The Mg^{++} bearing solutions from Chichali Formation deposited authigenic dolomite during burial. The ferroan recalcification of dolomite, groundmass and some bioclasts is associated with final uplift and is due to influx of reducing waters. Microstylolites were developed at pressure of about 0.9 kb.

Key words: Facies, Microfacies, Kawagarh Formation, Hazara Basin.

A/307. Ahsan, N. & Chaudhry, M.N., 1999. Sedimentology of Lumshiwal Formation, Attock Hazara fold and thrust belt, NW Lesser Himalayas, Pakistan. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 4-5.

The Middle Cretaceous Lumshiwal Formation (Shah, 1977; Chaudhry et al., 1994, 1997) is a time transgressive unit of the Attock Hazara Fold and Thrust Belt, "AHFTB" (Ghazanfar and Chaudhry, 1990) and Salt - Surghar Ranges of North Western, Pakistan. This unit is composed predominantly of marine glauconitic sandstone in the AHFTB and parts of Salt Range. This unit overlies the Lower Cretaceous marine black shales, which were deposited in an anoxic basin with poor circulation. The deposition of Lumshiwal Formation marks the onset of relatively open marine conditions with better circulation. In the Attock Hazara Fold and Thrust Belt of North Western Pakistan, five sections of this formation were measured and studied in detail for facies, microfacies, provenance, environment of deposition and diagenesis in the north western part of the oil and gas producing Indus Basin. The Lumshiwal Formation is producing gas in the northern part of Punjab Platform.

Facies: It is composed predominantly of glauconitic arenite and quartz wackes. Arenaceous limestones, arenaceous dolomites and oolitic limestones are subordinate to arenites. Shales and sandy shales are rare. They are well to very well sorted, subangular to rounded, compositionally mature and texturally submature to mature. Diastems at places are marked by sub-marine hard grounds. These horizons are cemented with iron oxides and may occasionally contain collophanite or dahalite.

Cement Stratigraphy: Based on detailed textural studies in various sections of the following general cement stratigraphy has been worked out. Glauconite and calcite is present as very early cements. The formation of glauconite itself suggests slow rates of sedimentation (0.96 mm/1000 years, Chaudhry, et al., 1998) and mildly reducing conditions. Other events in younging order includes i) Flint cement, ii) Kaolinite cement, iii) Early calcite cement, iv) Dolomite cement, v) Ferroan calcite cement, vi) Deep burial quartz cement, vii) Late diagenetic kaolinitic cement and viii) Iron oxide cement.

Provenance: Plagioclase, microcline, schorl, indicolite, zircon, epidote and sphene are the accessory minerals. These minerals indicate sialic basement with minor basic component as the ultimate source. The granitoid component was S-type. Thermal aureoles contributed indicolite. The restricted suit of heavy minerals, compositional maturity and shape of grains strongly suggest significant recycling. Lack of high grade metamorphic minerals suggest absence of high grade schists and gneisses. Their fine grain size and palaeocurrent indicators suggests derivation from low relief area on the Indian Shield to the south.

Environment of Deposition: The Lumshiwal Formation of the Attock Hazara Fold and Thrust Belt contains marine fossils like pelecypodes, brachiopods and belemnites. They indicate better circulation conditions during the Tithonian with a depth of less than 80 meters within photoic zone. Slightly reducing conditions, at least below the water sediment interface, are indicated by the ubiquitous presence of organic matter, glauconite and pyrite. Towards the end of Lumshiwal deposition, the shallower subtidal shelf rapidly deepened during the worldwide Cretaceous transgression to receive the Upper Cretaceous pelagic Kawagarh Formation (Ahsan et al., 1993; Ahsan and Chaudhry, 1998) which contains pelagic fauna.

Diagenesis: The textural evidence suggests that glauconite formed from clays during the early stages of burial. The clays were present within the pores of quartz arenites. During these stages, calcite formed which was then replaced by dolomites due to rising of Mg^{++} rich solutions from the underlying clay rich Chichali Formation. Suturing of quartz grains occurred during deep burial and provided silica for cementation. The other silica contributing sources

are clays and siliceous Skeletons of organisms. Iron oxides and some manganese oxides appear to have precipitated due to halmyrolysis. Iron oxides also formed during late diagenetic processes involving circulation of oxygenated meteoric waters through Fe-rich glauconitic sandstones during uplift replace all other minerals.

A/310. Ahsan, N., Chaudhry, M.N. & Hameed, A., 2001. Petrology and environments of deposition of Lumshiwal Formation, Jhamiri village, Haripur-Jabrian Road, Hazara basin, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 53-54.

The section of Lumshiwal Formation (Shah, 1977) exposed at Jhamiri (Fatmi, 1972) on Haripur-Jabrian Road, Hazara Basin (Chaudhry et al., 1998; Ahsan and Chaudhry 1999) is 21.60m thick. The formation is mainly composed of very fine to coarse-grained sandstone, which is blackish brown, dark greenish grey and mustard brown to reddish grey on surface. At places, fresh surface shows greenish tinge that becomes darker green on wetting. The basal part is coarse grained with large quartz grains. A few maroonish, rusty to brownish thin layers of splintery shale are present.

The formation at Jhameri village contains twelve microfacies. These include: 1) Coarse to medium grained iron oxides and glauconite cemented quartz arenites, 2) Medium grained carbonate and glauconite cemented quartz arenites, 3) Medium grained iron oxides cemented quartz arenites, 4) Fine grained clay and iron oxides cemented quartz arenites, 5) Fine grained glauconite and clay cemented quartz arenites, 6) Fine to medium grained clay and iron oxides cemented quartz arenites, 7) Fine grained clay cemented quartz arenites, 8) Fine to medium grained glauconite cemented quartz arenites, 9) Fine to medium grained glauconite and iron oxides cemented quartz arenites, 10) Fine-grained glauconite and carbonate cemented quartz arenites and, 12) Fine to medium grained glauconite cemented quartz arenite.

Textural parameters show that the arenites of the formation are generally supper mature and are angular to subrounded. The accessory minerals include tourmaline, zircon, rutile, sphene, epidote, muscovite, microcline, albite, quartz, chert, flint, chlorite and biotite. The suite of heavy minerals indicates derivation of sediments from the south from S-type granitic or gneissic source. The formation was deposited in marine middle subtidal zone (Flugel, 1982). The lower contact with Chichali Formation (Chaudhry et al., 1998) and upper contact with Kawagarh Formation (Ahsan and Chaudhry, 1998) is transitional.

Key words: Petrology, Deposition, Lumshiwal Formation, Hazara Basin.

A/311. Ahsan, N., Chaudhry, M.N., Mahmood, T. & Masood, K.R., 2001a. Facies analysis and environment of deposition of Lockhart limestone, Chahla Bandi, Azad Kashmir, northwest Himalayas. Abstracts, 4th Pakistan Geological Congress, Islamabad, 22-23.

The Lockhart Limestone near Chahla Bandi Azad Kashmir (Ghazanfar et al., 1987) is 72.80m thick. It is dark grey on fresh surface and weathers to light grey, pale grey, bluish grey to blackish grey. Lithologically the limestone is divided into nodular limestone and massive to thick-bedded limestone. The limestone contains abundant corals, mollusks, echinoids and rare algae. Prominent benthic foraminifera include *Ranikothalia sindensis*, *Miscellanea miscella*, *Lockhartia haimei*, *Discocyclusa ranikotensis* and *Lockhartia conditi*. The Lockhart limestone at Chahla Bandi is divided into five facies from bottom to top. Mudstone facies (I) contains splintery, very thin bedded, and

clayey limestone with pyrite nodules at the base. In the middle part this facies is composed of argillaceous nodular limestone. Mudstone to wackestone facies (II) composed of thin bedded, nodular (3cm x 3cm) limestone. Wackestone to packstone facies (III) is composed of very well bedded nodular limestone. Most of the nodules (4 cm X 5 cm) are of equal size. It is thin bedded. Mudstone to wackestone facies (IV) contains nodular (20 cm X 10cm) limestone. It is medium bedded. Wackestone to packstone facies (V) is massive and contains rare nodules. The nodules where present are 30 cm x 20 cm in size and there is no clayey/shale partings interbedded in this facies. The upper contact with Patala Formation is transitional, whereas the lower contact with Hangu Formation is unconformable (Shah, 1977; Chaudhry and Ahsan, 1998).

The groundmass of the microfacies is nonferroan calcite. Neomorphism to ferroan calcite is a common phenomenon. Evidences of physical and chemical compaction are present. Dolomite is rare and where present has been recalcified. This lithostratigraphic unit was deposited in subtidal environment probably on a carbonate shelf. The lower most facies is a shallow shelf deposit with some reworked allochems (echinoids). The rest of the formation is a middle subtidal deposit. There is an overall dominance of Acritarchs and Algal spores, with sporadic occurrence of Pteridophytic spores and Angiosperm pollen. Gymnosperm pollens are absent. Mycorrhizal and Fungal spores also exist in all samples.

Key words: Facies, deposition, Lockhart Limestone, Azad Kashmir.

A/312. Ahsan, N., Chaudhry, M.N., Mahmood, T. & Masood, K.R., 2001b. Microfacies and environment of deposition of Hangu Formation at Chahla Bandi, Azad Kashmir, NW Lesser Himalayas. Abstracts, 4th Pakistan Geological Congress, Islamabad, 52-53.

The Hangu Formation at Chahla Bandi, Azad Kashmir, overlies unconformably the Abbottabad Formation, while in the Hazara Basin (Chaudhry et al., 1988; Ahsan and Chaudhry, 1998) it overlies the Kawagarh Formation of Cretaceous age (Shah, 1977; Latif, 1970; Butt, 1989).

The Hangu Formation at Chahla Bandi contains eleven microfacies. These include: 1) Black shale with occasional quartz grains of 1-2mm in size. It weathers to orange to rusty grey. Some streaks of siltstone also occur; 2). Clay/sericite cemented coarse-grained quartz arenite that weathers to rusty brown colour, 3). Clay/sericite, iron oxide cemented medium grained quartz arenite that weathers to rusty brown to light grey. 4). Clay/sericite cemented coarse to medium grained quartz arenite that weathers to off-white, grey and orange, 5). Clay/sericite, iron oxide cemented coarse-grained gritty quartz arenite. Its fresh colour is off-white and it weathers to rusty brown; 6). Clay/sericite cemented coarse-grained quartz arenite that weathers to brownish grey, 7) Clay/sericite cemented medium grained quartz arenite that weathers to orange to black; 8). Clay/sericite and carbonaceous cemented quartz arenite that weathers to maroon colour; 9) Coal with medium grained quartz weathers to dull black; 10) Coal with fine-grained quartz that weathers to dull black; and 11) Bauxitic clay that weathers to rusty orange.

The basal microfacies, black shale/marks the on set of a transgression after a gap of about 505 million years that deposited 227 cm thick black shale (microfacies 1). The microfacies 2 to 7 represent deposition at upper shore face to lower shore face. The microfacies 8 to 10 are coal bearing and represent supratidal marshy depositional regime. The microfacies 11 is residual deposits (70 cm thick) of continental origin that is composed of pisolitic bauxite. It marks an episode of regression at the end of Danian.

Hangu Formation contained poorly preserved palynoflora presenting a case of marginal palynology. Microfossils were fragile, impregnated with high amount of fixed carbon, posing special problems in correct identification. Pollen and spores were equally represented with sporadic occurrence of Dinoflagellates and Acritarchs at certain horizons. Pollen Were of stephanocolpate and polycolpate type whereas spores were predominantly trilete and psilate.

A/313. Ahsan, N., Chaudhry, M.N. & Majid, C.M., 2000. Mineralogy, engineering properties and alkali aggregate reaction potential of Mira sand, Thakot, Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, 150-152.

The Kawagarh Formation of Jabri area is divided into eight internal units and thirty- six microfacies for the first time. It is basically a transgressive unit deposited during Cretaceous global transgression. The maximum depth of the sea at that time was about 250m. On the basis of planktonic fossils the age of the unit ranges from Upper Coniacian to Lower Campanian.

Key words: Engineering properties, alkali aggregate, sand, Thakot.

A/314. Ahsan, N., Chaudhry, M.N. & Rehman, Z., 2000. Lithofacies and microfacies studies of Margala Hill Limestone at Khaira Gali, Murree-Ayubia road, Hazara, Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, p.150.

A preliminary sedimentological account of Margala Hill Limestone exposed at Khaira Gali is presented for the first time. This formation is divided into 12 lithofacies units and 63 microfacies. The 2 lithofacies units are separated by 11 marly horizons. These horizons formed as a result of influx of clay into the basin of deposition due to fluvial channel shifting. The entire formation is free of oolites and pellets. Sedimentary structures like ripple marks, cross bedding etc. are deposited in open marine conditions on a carbonate ramp under subtidal conditions. The unit is marked by a number of minor changes in sea level resulting in deposition from upper subtidal to lower subtidal environs. The organic content on the average is about 2%. However, some horizons contain as much as 5% organic content. The porosity (other than fracture porosity) is around 2% but varies from traces to 5%. Fracture porosity on the out crop scale is dominant. Both mechanical and chemical compaction have played an important role in volume reduction.

A/316. Ahsan, N., Iqbal, M.A. & Chaudhry, M.N., 1994. Deposition and diagenesis of Kawagarh Formation, Changla Gali, Murree - Ayubia road, Hazara, Pakistan. Pakistan Journal of Geology 2, 17-23.

A field and petrographic study of Kawagarh Formation from Changla Gali was carried out in order to work out microfacies, environment of deposition and diagenesis. The formation has been divided into 30 microfacies. They include dolomitic arenaceous mudstone, packstone, dolomitic packstone, dolospar and wackestone with occasional intercalated marls. These microfacies are grouped into four units from bottom to top. CU-1 was laid down on top of Lumshiwal Formation in upper subtidal zone probably at a depth of about 50 to 80m. CU-II marks a rapid transgression and was deposited under pelagic shelf conditions below upper subtidal zone. This was followed by a CU-III, sequence of wackestone to packstone with marly intercalations deposited in lower subtidal zone CU-IV marks on-set of regression culminating into subareal exposure. Post depositional changes such as cementation, neomorphism, compaction, dolomitization and dedolomitization are discussed.

Key words: Deposition, diagenesis, Kawagarh Formation, Murree, Ayubia, Hazara.

A/317. Ahsan, N., Majid, C.M. & Chaudhry, M.N., 1997. Strength evaluation of blends of Lawrencepur, Chenab and Ravi sands with Lockhart and Margalla Limestones for use in concrete. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 2p.

Concrete is a composite material consisting of inert coarse and fine aggregates bound by a binding medium. The cement water and air combine to form a paste that binds the aggregates together. Pakistan is gifted with enormous quantities of coarse and fine aggregates. The coarse aggregates from the Lockhart Limestone and Margalla Hill Limestone were used with fine aggregates from Lawrencepur, Chenab and Ravi to evaluate their strength properties with ordinary Port land cement. The Lockhart Limestone and Margalla Hill Limestone showed excellent physical and mechanical properties: bulk densities 84 lbs/cft and 86 lbs/cft water absorption 0.8% and 0.6%. Los Angeles abrasion values 24% and 26% impact value 13% and 16% crushing value 25% and 27% and soundness by Na_2SO_4 1.71% and 1.60% respectively. The Lawrencepur, Chenab and Ravi sands were tested and found that the Lawrencepur sand is the best which generally meets the requirement given in BS 882/1965. However the Chenab

sand showed the desired results when mixed with Lawrencepur sand in the proportion of 25-30: 75-70 while the Ravi sand is not good for use in concrete as it is fine and does not come up to the required standards. The coarse and fine aggregates were blended with ordinary Portland cement keeping in view the desired water-cement ratio for acquiring desired strength. The Lockhart Limestone and Margalla Hill Limestone were found excellent coarse aggregates with pure Lawrencepur sand and a blend of Chenab and Lawrencepur sand. They gave high compressive strength (upto 8000 psi). The Ravi sand with its very fine size was not found satisfactory as an individual fine aggregate. It is not an economic deposit when blended with the Lawrencepur sand. The Chenab sand is however economical when blended with Lawrencepur sand.

Key words: Sand, concrete, limestone, Lawrencepur, Chenab, Ravi, Margala.

A/318. Ahsan, A., Naveed, N., Khawaja, A.A. & Chaudhry, M.N., 2001. A preliminary account of facies and determination of Ca, Mg, Sr, Mn, Fe and Na in Kawagarh Formation, Kala Pani, Abbottabad-Thandiani Road, Hazara, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 54-55.

Kawagarh Formation (Shah, 1977; Chaudhry, et al., 1998. Ahsan and Chaudhry, 1998) at Kala Pani is composed of light grey to grey limestone. The formation is generally medium to thick bedded but nodular at the base. The lower contact of the formation is transitional with Lumshiwal Formation (Ahsan and Chaudhry, 1998) and upper contact is unconformable with Hangu Formation. Petrographically it is established that faunal constituents of the formation are composed of planktons and oligosteginids. On the basis of the proportion of these allochems, the formation is divided into planktonic facies, planktonic-oligosteginid facies and oligosteginid-planktonic facies. The planktonic facies constitutes 23.34% of the formation and is composed of 34.48% plank-mudstones, 41.37% plank-wackestones and 24.14% plank-packstones. The planktonic-oligosteginid facies constitutes 60.49% of the formation and contains 17.33% plank-oligo- mudstone, 73.33% plank-oligo- wackestones and 9.34% plank-oligo- packstones. The oligosteginid-planktonic facies is 16.17% of the formation and is composed of 10% oligo-plan -mudstone, 70% oligo-plank-wackestones and 10% oligo-plank-packstones. 20 whole rock samples of the formation were analyzed to determine major (Ca, Mg) and minor (Fe, Sr, Mn and Na) trace elements by atomic absorption spectroscopy using air-acetylene flame. The Ca varies from 19.23% to 39.11% with an average of 33.92%, Mg varies from 0.132% to 1.854% with an average of 0.335%, Mn ranges from 0.319 ppm to 1.723 ppm with an average of 0.929 ppm, Sr varies from 0.715 ppm to 4.213 ppm with an average of 2.975 ppm, Na ranges from 4.7 ppm to 8.5 ppm with an average of 5.969 ppm and Fe varies from 6.11 ppm to 36.11 ppm with an average of 17.244 ppm. Moreover a comparison was made in the estimation of Ca and Na by using flame photometer and atomic absorption spectrophotometer. The values obtained by the two methods, were almost the same.

Key words: Facies, Kawagarh Formation, Abbottabad, Hazara.

A/319. Ahsan, Z., 1981-83. Lithostructural mapping and biostratigraphic study of Burikhel Bandakha Area (Western Salt Range) District Mianwali. M.Sc. Thesis, Punjab University, Lahore, 93p.

Detailed Lithostructural Mapping and Biostratigraphic study of Barikhel- Bandakha Area (Western Salt Range) District Mianwali, has been done at 1:10,000. Area is exclusively a sedimentary terrain. Stratigraphy along with micropaleontology of certain formations is described. In addition to this macrofauna have been described. Lateral extension of limnic permean coal is noted. Tectonic style of the area is described with the help of structural details i.e. study of folds, faults and joints etc.

Key words: Lithostructure, biostratigraphy, Salt Range, Mianwali.

A/322. Akbar, J., 1977-79. Mineralogy Petrology of Udigram Area, District Swat. M.Sc. Thesis, Punjab University, Lahore.

The project area lies in northwestern extension of Himalayas in Pakistan. It is part of edge of the Indian plate at its subduction zone. The project area is partly meta-sedimentary and meta-igneous. It consists of the Lower Swat-Buner Schistose group.

The four major rock units have the following sequence from top to bottom.

Green Schist; Phyllitic Schist; Schistose marble; Amphibolite;

The meta-sedimentary sequence has the following grade chlorite, biotite, garnet, kyanite. The green schist formation at the extreme of the project area and extends northward 35-km to the Shangla area where blueschists are developed proving the fossil trench position. The meta-sedimentary sequence is of Paleozoic age and therefore older than the plate movements which took place during the Cretaceous period of blueschists. Therefore the original metamorphism was older than subduction episode but retrograde metamorphism had occurred during plate subduction.

The green schist belongs to the edge of subduction zone, as it is well known that subduction zone rocks are composed normally of igneous detritus, oceanic floor basalts and basic intrusions mixed with sediments. Therefore, green schist evolved out of such a mixed lithology, predominantly from the basic igneous rocks. The zonation of pressure/temperature is so placed that towards Shangla high temperature-low pressure lithologies were formed, while towards project low temperature-low pressure rocks were formed such as green schist. Under the same action, meta-sedimentary sequence suffered retrograde metamorphism of low temperature and low-pressure type.

A/323. Akbar, M., 1980-82. Geology and Petrology of Hasis-Gahkoch-Gupis (Gilgit Agency). M.Sc. Thesis, Punjab University, Lahore, 90p.

The project area (HESIS-GUPIS) lies in the Punial-Gupis Valley, District Gilgit, Latitude 30° 4' 32' - 36° 24' 35' and Longitude 73° 25' 0' - 73° 47' 0' has been mapped tectonically. The area is located in the Centre of Karakoram Mountains and represents a part of a cross section through this mighty range. Area is intensely disturbed tectonically being involved in Himalayan Orogeny, which is evident from the strained, crushed and deformed lamellae of the mineral in the rock

Structure found in area is orthotectonic. Following features are present in the project area, which is characteristics of an orthotectonic region. Cleavage is well developed in the project area i.e. slaty cleavage, schistosity, fracture cleavage and crenulation cleavage. Igneous activity is present and it shows a magmatic phase on the origin. Folding of isoclinal nature because of the prevalence of severe stresses. The basin, in which deposition has been taking place, is completely destroyed so it is too difficult to reconstruct the geological history of the area. This is a typical characteristic of an orthotectonic region. The project area is composed mainly of igneous and metasedimentary rocks. Metasedimentary rocks are originally deposited in eugeosynclinal conditions as argillaceous sediments and afterwards.

Key words: Petrology, Gupis, Gilgit.

A/324. Akbar, M., 1981-83. Geological mapping and site investigations of dam site and reservoir area of Basha Dam (Chilas Diamer). M.Sc. Thesis, Punjab University, Lahore, 101p.

The electric power demand of Pakistan is very high and the present generation capabilities of the country are insufficient to cope with the increasing load created by industry, agriculture and domestic consumers. In order to tide over the situation water and power development of Pakistan initially identify thirteen sites on the Indus River upstream of Tarbela upto Skardu, because the drop along Indus plains show attractive locations for hydro power development. To study the potential/plan the development of 13 identified sites and feasibility of one best site first

Canadian Technical Assistant has been arranged. Basha damsite is the site selected by the Canadian Consultant for the feasibility purposes which is located on the Indus river near the village Basha about 45 km downstream of Chilas in Gilgit Agency.

A/327. Akhtar, J., 1987. Vertical magnetic survey of the lead-zinc deposit in Lahor-Serai area, Besham, N.W.F.P., Pakistan. M.Sc. Thesis, Quaid-i-Azam University, Islamabad, 31p.

Vertical magnetic investigations were carried out (as a part of integrated geophysical survey) to demarcate the lateral subsurface extent of Pb-Zn ore in Lahor-Serai area of Besham. This study shows that strong magnetic anomalies are solely generated by magnetite concentration in carbonate rock units; whereas the magnetic signal over Pb-Zn ore is very weak.

Analyses of magnetic anomalies yielded that, magnetic patterns of low amplitude (i.e. in the range of -500 to +150.0 gammas) can guide ore exploration within a depth range of 10-20 metres at places located along structurally weak zones.

A/330. Akhtar, M., 1983. Stratigraphy of the Surghar Range. Geological Bulletin, University of Punjab 18, 32-45.

Sedimentary rocks of marine and non-marine origin ranging in age from Permian to Pliocene constitute most of the stratigraphic sequence in the Surghar Range. The sequence comprises 10 lithostratigraphic units with a cumulative thickness of more than 5000 meters. The lithologies consist predominantly of limestone, shale and sandstone with subordinate marl, dolomite and minor interformational conglomerate. Permian-Triassic boundary is marked by a slight lithological break indicating a paraconformity. Cretaceous-Paleocene and Eocene-Miocene sequences are also intervened by unconformities.

Key words: Stratigraphy, Surghar.

A/331. Akhtar, M. 1984-86. The geology and mapping of Muzaffarabad area from Chehla Bandi to Chhattar Kalas with special emphasis on landslide problems along roads. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 64p.

Nature does not supply all the things to man, but merely offers opportunity to secure all things, and a condition where man controls the elements is inestimably superior to a condition where the elements control man.

This field report comprises a complete geological study based on mapping of nearly 100 sq. kms of Muzaffarabad – Chhattar Kalas area. Special emphasis has been put on describing the stratigraphy and landslide problems in the project area. The stratigraphic succession has been established. The rock units present in this area Hazara Formation (Cambrian), Abbottabad Formation (Cambrian), Patala Formation (Paleocene) Margala Hill Limestone (Eocene), Kuldana Formation (Eocene) and Murree Formation (Miocene). The major tectonic features in the proximity are Jhelum fault, Muzaffarabad anticline.

The Muzaffarabad-Kohlala road is the main way of transportation and communication between the Pakistan and Azad Kashmir. A number of huge slides occur on this road which blocks it for hours and sometimes for days. Due to the vital importance of the road it is unbearable. So this field report is prepared with the aim to study the area in detail and to explore the reasons of sliding on this road.

The samples are taken for laboratory tests. The purpose of laboratory test is to evaluate the strength parameters which are responsible for driving and resisting the moment. In this report an attempt is made to explore the reasons of failures in the area as well as economical and adequate remedial measures were suggested.

A/343. Akhtar, S., 1982-84. Report on geology and structure of Balakot-Kummi Area. M.Sc. Thesis, Punjab University, Lahore, 101p.

The present work constitutes a comprehensive report on the geology of Balakot -Kummi area and is submitted in partial fulfillment of the requirements for the degree of M.Sc. at the University of the Punjab. The report includes a detailed geological map at 1:6,000 of about 65 km. sq. area along with a number of geologic sections and sketches. The various chapters include geomorphology, stratigraphy, structure and tectonics. Stratigraphically, the Balakot-Kummi area includes a number of diverse sedimentary and metamorphic elements ranging in age from Precambrian to Miocene with a fairly large gap in the Mesozoic period. Structurally, the area incorporates part of the core and western limb of the Hazara-Kashmir syntaxis and through it pass the major Murree and Panjal Faults. The Balakot-Muzaffarabad anticline is the major fold overturned and overthrust to the southwest. No major economic mineral deposit was found within the project area, although a lot of material is available as rock crush, aggregate components and building stones.

Rock magnetic properties of the loess deposits for 24 samples collected from two different sites of Haro river in the Pakistan area were studied. Magnetic methods such as isothermal remanent magnetisation acquisition experiment and the magnetic analysis indicated the presence of magnetite, accompanied by trace amount of maghemite and goethite. Hysteresis loop parameters show that most of the magnetic grains are of multi domain nature and some of them are of pseudo single domain. The hysteresis loop parameters such as coercive force and ratio of remnant magnetisation to saturation magnetisation increase with the increase of finer $W_{60} < 0.3\mu m$ of the clay percentage, which proves that magnetic methods can be used for grain size differentiation in these loess deposits. Magnetic susceptibility is not high in the case of paleosols as compared to the other loess beds, which shows a very different behavior from weal loess-paleosol sequences in the Chinese Loess Plateau.

Key words: Magnetism, Paleomagnetism, Quaternary Deposits, Haro River, Attock.

A/352. Akram, H. & Yoshida, M., 1997. Ultra-fine magnetite/maghemite and their magnetic granulometry in the Late Pleistocene loess-paleosol deposits, Haro River area, Attock Basin, Pakistan. In: Khadim, I.M., Zaman, H. & Yoshida, M. (Eds.), *Paleomagnetism of Collision Belts*. Geoscience Laboratory, GSP, Islamabad, 153-169.

Variation of magnetostratigraphic properties in late Pleistocene (18-130 ka) loess-paleosol sequence of Haro River area, Attock basin, Pakistan were studied. Isothermal remanent magnetization (IRM) acquisition experiment and thermomagnetic analysis indicate that magnetite and maghemite are the major ferromagnetic (ferromagnetic) minerals present in these samples. Hysteresis loop parameters such as coercivity (H_c), remanence coercivity (H_{cr}), coercivity ratio (H_{cr}/M_c), and remanence ratio (M_r/M_s) show that the magnetite/maghemite grains are mostly of pseudo-single domain (PSD) size, while less amount of multi domain (MD) and superparamagnetic (SPM) grains are also present. Anhyseretic remanent magnetization (ARM) and its normalized parameter discloses the relative enrichment of (SD to SPM size) magnetite/maghemite grains in the paleosols as compared to loess deposits, which are considered to be of pedogenic origin. Bilogarithmic plot of saturation isothermal remanent magnetization (SIRM) and volume magnetic susceptibility also shows relative concentration of ultra-fine ferrimagnetic minerals in the paleosols. This magnetostratigraphic data was correlated with the mechanical sedimentological analysis data. The magnetic granulometry is informative to understand the particle-size distribution of natural sediments like in the case of loess-paleosol deposits, particularly for the SPM.

This report comprises a complete geological study of nearly 320 sq. km; located between and around Balakot-Garhi Habibullah. In the project area micaceous quartzites, quartz mica schists, garnet mica schists, dolomite, limestone, Sandstones and slates are encountered. A stratigraphic sequence has been worked out. The rocks extend in age from Precambrian to Miocene.

Structurally, the rock, are folded into a number of major structures. The area comprises of major structures like Balakot Anticline, Garhi Habibullah syncline, Muzaffarabad fault and Murree Fault. Micro structures of the project area has also been discussed in detail. Hazara Kashmir syntaxis has a great influence on the stratigraphy, structure, and tectonics of the investigated area. In the field of economic geology a number of deposits including clays, graphite, limestone, feldspar, granites and sandstone have been discussed. This report also includes a petrographic description of the rock units as well as numerous sketch section and photographs, illustrating the geology of the area.

A/360. Alam, I., Ghauri, A.A.K. & Ahmad, S., 2001. Structural and tectonic setup of the area south west of Kohat NWFP, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.32.

The study describes the stratigraphy and structural setting of the 250-km² areas constituting a part of Kohat foreland basin and located southwest of Kohat city. No rocks older than Eocene are exposed. The outcropping rocks consist of Panoba shale, Sheikhan Formation, Kuldana Formation and Kohat Formation of Eocene age, unconformably overlain by the Murree and Kamlial Formations of the Rawalpindi Group. The imprints of the ongoing Himalayan tectonics are well recorded in the outcropping rocks and represented by a series of south verging anticlines and synclines with a common east-west axial trend. In addition to these folds, several east-west trending and north and south verging thrust faults are also present. The part of the Kohat Plateau has undergone three distinct phases of deformation. The earliest phase D1, was responsible for development of the large overthrust sheet. This thrust sheet was later on folded in second phase of deformation D2. During D2 the entire package of rocks and structures (including autochthonous rocks and overlying allochthonous thrust sheet) was folded. The third phase of deformation D3, represents the collapse of structurally elevated rocks due to gravity.

Key words: Structure, stratigraphy, tectonics, Kohat.

A/366. Alam, S., 1995-96. Structure, stratigraphy, micropaleontology and petrography of Shahdara and Pirsohawa areas, Margala Hills, Islamabad, Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 107p.

The Shahdara pirsohawa area lies in the Attock-Hazara fold and thrust belt of the northwest Himalaya of Pakistan. The Mesozoic to Cenozoic rocks in the area are entirely sedimentary in nature. The rocks are strongly folded and imbricated during Tertiary Himalayan collision. The study deals with the structure, stratigraphy, micropaleontology and petrography of the area.

The early Paleocene Hangu Formation unconformably overlies the late Cretaceous Kawagarh Formation. The late Cretaceous subduction of the Indian plate below the Kohistan Island arc caused the deepening of the Tethyan shelf in the subduction zone and initiated the deep marine deposition of the Kawagarh Formation. The abrupt change from Late Cretaceous deep marine environment of the Kawagarh Formation to terrestrial deposition of Hangu Formation indicates the initial Early Paleocene collision of the Indian plate and Kohistan island arc. The Lower Tertiary sequence of Early to late Paleocene Lockhart Limestone, Late Paleocene Patala Formation, Early Eocene Margalla Hill Limestone and Late Eocene Kuldana Formation mark the complete cycle of transgression and regression of the Tethyan Ocean. The presence of Early Paleocene to Late Eocene foraminiferal assemblage like globorotalia, globigerina, lockhartia, assilina, nummulites and fasciolites in the limestone and shales of the Lower Tertiary sequence show the tropical to sub-tropical open sea upper slope to outer shelf environments. The Kuldana Formation includes marine limestone, continental clays and shales and evaporitic gypsiferous beds. The rock assemblage shows transgression of Tethyan Ocean and initiation of continental deposition of the Kuldana Formation due to Himalayan uplift.

The Paleocene- Eocene boundary can not be marked on the basis of microfossils in the area because the Patala Formation lacks microfossils. However, the tentative Paleocene-Eocene boundary between Patala Formation and Margalla Hill Limestone can be marked at the base of Margalla Hill Limestone on the basis of first appearance of Early Eocene microfossils.

The two phases of D1 and D2 deformations related to Himalayan collision are recorded in the Mesozoic to Cenozoic shelf and platform sediments of the Attock-Hazara fold-and-thrust belt of Shahdara-Pirsohawa area. D_{1a} is the main phase of southeast-directed thrusting and the southeast vergent F1 folding. D_{1b} is related with the folding of MBT due to backsteepening. The backsteepening is documented by southeast dipping thrust faults and at places northwest

vergent Makhnia and Pirsohawa synclines. The D2 deformation phase is related with the folding of earlier northeast-southwest trending D1 structures along northwest plunging F2 fold axes. The F2 cross folds are mainly antiforms and synforms. The F2 cross folds are related with the development of Hazara-Kashmir syntaxes.

Key words: Structure, stratigraphy, micropaleontology, petrography, Margala, Islamabad.

A/367. Alauddin, A., Khan, A., Masood, H., Begum, F., Khattak, M.A. & Khan, M.A., 1994. Studies of potash bearing evaporate basins of Kohat Karak Salt Range, NWFP, Pakistan. Pakistan Journal of Scientific and Industrial Research 37(11), 491-00.

Potash-bearing minerals occur in nature with common salt and usually deposited in the evaporite basin on evaporation of brine water. In view of the huge deposits of common salt in Pakistan, particularly in Kohat-Karak evaporite basin, NWFP; investigations to locate the potash deposits in the common salt of the area were undertaken. The geology of the potash bearing deposits reveal their occurrence in the form of lenticular beds associated with rock salts. The present study has successfully brought into focus areas of potash concentration in the above area, which after refining may be exploited to meet the requirement of potash for fertilizer.

Key words: Potash, Evaporate, Kohat, Karak, Salt Range.

A/369. Alauddin, M., Hussain, V. & Jan, N., 1992. Characteristics of glass making sands of Munda Kuchha, District Mansehra and their beneficiation and utilization for the production of colorless container glass. Pakistan Journal of Scientific and Industrial Research 35(4), 151-00.

Large deposits of silica sand occur at a distance of 50-km to the northeast from Mansehra town, near Munda-Kuchha village along the Siran river. Estimated reserves up to a workable depth of 300 feet are 57 million tons. Twelve representative samples were collected from the area for studying their suitability for glass industry. The chemical composition and grain size distribution of these samples were determined. Beneficiation studies by physical and chemical methods were undertaken to remove color-imparting impurities, which are a factor for producing the glass of inferior quality. The objective of this study was to upgrade the quality of silica sand to the acceptable limits for the production of colorless container glass. Using physical methods a maximum of 41.66% of the iron, the most undesirable impurity, was removed; by chemical treatment seven of the twelve samples can be brought into the specification for colorless container glass, five can be brought into, or very near, the specification for optical glass.

Key Words: Silica sand, glass, beneficiation, Munda Kuchha, Mansehra,

A/370. Aleem, S., 1989-91. Geology and Geochemistry of Battal Village and its surrounding area with special emphasis on the Geochemistry of altered products near Ahl Village, and water & Soil chemistry along the Karakoram High way (KKH), District Mansehra, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 113p.

The present study has been basically focused on the geology and geochemistry of a part of the lesser Himalayas. The study has been divided into four parts. The first part deals with the geological mapping and tectonic setup of the area which reveals that the studied area lies between the syntaxial loop and Oghi shear zone of the lesser Himalayas, comprising of mainly metamorphic rocks, granitic rocks and granite gneiss of Precambrian, Cretaceous/Tertiary and Cambrian age respectively. Tectonically, the area represents a sandwich between the two major thrusts, i.e., Main Central Thrust (MCT) in the north and Main Boundary Thrust (MBT) in the south, also, there runs a NS Oghi shear zone in the west and syntaxial loop of NW Himalayas in the east. The second part deals with the detailed geochemical and mineralogical investigation of the area. Three types of rocks are characterized in the studied area; a) metamorphic rocks of garnet mica schist grade comprising mainly of quartz, garnet, muscovite, biotite and chlorite. b) granite gneiss mainly composed of quartz, K-feldspar, plagioclase feldspar, muscovite, biotite and

sphene; c) minor basic intrusions as amphibolites; mainly consist of amphiboles (hornblende) along with quartz, sphene and muscovite. The third part deals with the geochemistry of the altered products near Ahl Village. The variation of major oxides in the altered products as: $\text{SiO}_2 > \text{Al}_2\text{O}_3 > \text{Na}_2\text{O} > \text{K}_2\text{O}$, with FeO, and CaO & MgO as minor constituents. It suggested that this aluminum-silicate rich material could be used for ceramic purpose. The fourth part deals with the water and soil chemistry of the studied area to explore the weathering style and water and soil characteristic in the area. The chemistry of water samples show that they are rich in Ca^{+2} and HCO_3 indicating the decomposition of plagioclase feldspar; the X-ray diffraction patterns of the soil samples show the presence of quartz, albite, muscovite and anorthite which are the unaltered constituents of the same parent rocks while the presence of illite and phlogopite in all the soil samples, and saponite and sepiolite in some samples represents the intensity of the weathering in term of bauxitization. The water quality of the studied area is well within the permissible limits of drinking standards. The soil samples of the studied area classify into the category of normal soils with pH ranges from 6.4 to 7.7 and other parameters like EC, ESP & RSC are also within the permissible limits for cultivation purpose. The cultivation of tea at various localities where pH of the soil is relatively lower is recommended for the uplift of socioeconomic condition of the area.

A/372. Ali, A., 1976-78. Geology of Jogabunj-Sadiqa Banda Area Dir District. M.Sc. Thesis, Punjab University, Lahore, 115p.

The project area lies in central Punial area, adjoining to Yasin Valley, Gilgit Agency. The area is located in Karakoram Mountains. Area is intensely disturbed tectonically being involved in Himalayan Orogeny. Evidence is provided by crushing and strained effect on minerals. Project area is composed mainly of igneous rocks and metasedimentary rocks.

These different rock units are shown on map, which was previously prepared by enlargement of toposheet. The major units in the project area are granite, diorite, amphibolite and paragneiss. Special emphasis was given to the mineralogy description and petrographic analysis of the rock units and is reported in detail. The petrogenesis of these rocks units has been discussed as well.

Granite is considered to be a part of Karakoram axial granite, which is emplaced as a partially fused and mobile mass rich in alkali feldspar during synthetic phase of orogeny. Diorite is probably tholeiitic basaltic magma injection. Granodiorite produced during differentiation with decrease of calcic contents.

Key words: Geology, granites, Dir.

A/374. Ali, A., 1997-98. Geological mapping and hydrogeological studies of Rawlakot area (District Poonch) A.K. with special emphasis on pollution studies and waste disposal. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 52p.

The spring water and stream water has been investigated from Rawlakot Azad Kashmir to the quality of water for drinking and other uses. The area lies under the influence of lesser Himalayas. The total of 74 samples were collected from spring and stream waters in two phases. 40 samples were collected in wet season and 34 samples were collected in dry season. Chemical constituents such as Ca, Mg, Si, carbonate and bicarbonate were determined. Physical properties colour, taste, odour and temperature were noted in the field. Turbidity, TDS and conductivity were determined in the laboratory.

The effects of solid and liquid wastes and sewage water effected the quality of ground and surface water. The concentration of Pb, Zn, Cu and Ni increases due to waste disposed off into streams and nala water. The waste water from households seepage of water through sewage system, waste water from CMH and the suspended load of finer particles from Murree formation are main pollutants. The waste disposed by shopkeepers and municipal wastes also pollutes the surface and ground water. The experimental data show that the waste dispose sites should be selected by Municipal Corporation and the treatment plant is essential for supplying good quality drinking water in Rawlakot area. The water available from Hussain Kot springs can be developed and supplied to the inhabitants of Rawlakot. Pure water can also be developed by drilling tube wells in Rawlakot valley. Kanapara, Baikh, Chotagala, Khaigala, CMH Rawlakot, Rawlakot city, Tirar, Banjosa and Dhamni localities. It is concluded that the ground and surface water resources are available and need development on scientific grounds.

A/375. Ali, A., 1997. Structure and Stratigraphy of a part of Kohat basin between Lachi and Banda Daud Shah, N.W.F.P., Pakistan. M.Phil. Thesis, University of Peshawar, 58p.

The detailed mapping of the study area have resulted in establishing nine lithostratigraphic units which range in age from Eocene to Pliocene. These units fall within three groups which are from bottom to top as Chharat, Rawalpindi and Siwalik Groups. The Chharat group is represented by five formations in the area including Panoba shale at the base, overlain by Jatta Gypsum along with its lateral equivalent Sheikhan Limestone, Kuldana and Kohat Formations. The Chharat group is unconformably overlain by the Murree and Kamlial Formations of the Rawalpindi group. The representative units of the Siwalik group in the area are Chinji and Nagri Formations. The structural geometry of the area comprise large scale, east-west trending folds and thrust faults. The fold structures include narrow anticlines and anticlinoria mostly cored by thrust faults. The synclinal folds are open, with both their limbs overturned and reflect fan-geometry. The faults include fore and back thrusts. The back thrusts are mostly overturned at their surface exposures and have changed their vergence from north to south.

The proposed structural model based on surface and subsurface seismic data shows a series of large scale hinterland dipping listric thrust faults emerging from the basal decollement. All these faults are steeply dipping at surface and becomes gentle with depth. Other prominent features are associated pop-ups and triangle zones which are the result of north verging splays from the listric thrust faults. The presence of triangle zones bounded by thrust faults of opposing vergence have resulted in the tectonic overprinting and delamination of different horizons at various levels. All the above mentioned features are characteristic of the foreland fold and thrust belts in different parts of the world. The basal detachment is located at the base of salt range formation at a depth of around 8 km and 8.4 km in the southern and northern parts of the study area respectively. The restored version of the deformed state cross-section shows about 19.5 km shortening for the mapped area with maximum structural relief of about 4000 meters above the regional level.

A/380. Ali, F., 1994. Structure and tectonic set-up of area north and north-west of Karak, N.W.F.P., Pakistan. M.Phil. Thesis, University of Peshawar, 83p.

The Karak area which constitute southern edge of Kohat plateau exposes a suite of evaporite deposits, shelf sediments and a thick molasses sequence of Cenozoic age. The oldest rocks in the area are of Eocene age and constitute Bahaderkhel Salt and Jatta Gypsum followed by shelf sediments which comprise Kuldana and Kohat Formations. These units are overlain by molasse sediments of Miocene to Pliocene age which include rocks of Rawalpindi Group (Kamlial Formation) and Siwalik Group (Chinji Formation, Nagri Formation, Dhok Pathan Formation and Soan Formation).

Structurally the area is interpreted as an east-west trending positive flower structure which is exposed for 20 Km along strike and is about 5 Km wide. It is bounded by the north dipping Karak Fault in the south and the south dipping Nari Panos Fault in the north and internally subdivided by the south dipping Banda Kunghara Fault. All these faults trend eastwest and have moderate surface dips.

A right lateral component of deformation along the Karak structure is indicated by (a) the east-north-east directed trends of the Daggar syncline in the foot wall of the Nari Panos backthrust, (b) by small scale thrusts in the core of this syncline and (c) by east-north-east trending enechelon folds south and south east of Banda Charpara. The idea is supported by interpretation of seismic data (906-NSK-47) which indicates rapid steepening of the Karak, Nan Panos and Banda Kunghara Faults to near vertical with depth and east-west trending slickenlines present on different fault surfaces of the area. This work emphasizes the importance of transpression within the NW Himalaya on a regional scale. Recent work by Beck et al. (in prep.) has suggested transpressive deformation along the Main Boundary Zone (MHZ) to the west of the Kohat Plateau.

Key words: Structure, Tectonics, Karak.

Key words: Deformation, Kohat Plateau, Karak, Himalaya.

A/382. Ali, F., Ahmad, S., Ahmad, I. & Hamidullah, S., 2000. Imprints of transpressional deformation on the southern Kohat Plateau, Karak area, NW Himalayas, NWFP, Pakistan. Geological Bulletin, University of Peshawar 33, 87-95.

A suite of evaporite deposits, shelf sediments and molasse sequence of Early Cenozoic age from Karak area marks a part of southern Ghat Plateau. Structurally the area is interpreted as east-west trending positive flower structure, which is exposed for about 20 km along strike with widths varying from 3-5 km laterally. It is bounded by the north dipping Karak Fault in the south and south dipping Nan Panos Fault in the north and internally subdivided by the south dipping Banda Kunghara Fault. All these faults trend east-west and have moderate surface dips. A right lateral component of deformation along the Karak-Nari Panos structure is indicated by: 1) the north-east directed trend of

the Daggar Syncline in the footwall of the Nari Panos Fault, 2) the local scale thrusts in the core of this syncline and 3) east-north east trending right stepping folds located south-east of Banda Charpara in the footwall of Banda Kunghara Fault. The idea of transpressional deformation is also supported by the seismic data, which shows that all the major fault structures become steep, converging at deeper level and the presence of horizontal to sub-horizontal slicks on different fault surfaces. The region has experienced an early phase of compressional deformation overprinted by later phase of transpressional deformation of Plio-Pleistocene age.

Key words: Deformation, Kohat Plateau, Karak, Himalaya

A/383. Ali, F., Khan, I. & Ahmad, D., 1996. Significance of mesoscopic shear zones in the Precambrian limestone belt around Gandghar and Attock-Cherat Ranges, NW Himalayas, Pakistan. Abstract volume, 11th Himalaya- Karakoram- Tibet Workshop, Flagstaff, Arizona (USA), p.17.

The south and southeastern boundary of the Pakistan basin exposes a belt of Precambrian limestone (Shekhai, Utch Khattak and Shahkot formations). This limestone belt has well preserved mesoscopic scale, brittle-ductile shear zones, which are related to the movements along the Panjal Fault in the Gandghar Range and Khairabad Fault in the Attock-Cherat Ranges.

The detailed geometric analysis of these steeply dipping conjugate shear zones in the Gandghar Range shows that sinistral shear zones strike NNW and dextral shear zones strike WNW. The conjugate shear zones mapped in the Attock-Cherat Range are moderately dipping with sinistral shear zones, striking NE and dextral shear zones striking NW. The slip linear and the acute bisectors of these conjugate shear zones indicate that the Gandghar Range has developed in response to NW oriented compressional stresses and the Panjal Fault which lies south of it, is an oblique ramp with left lateral strike-slip adjustments in addition to major thrust-slip movements.

The Attock-Cherat Range has experienced NS directed compressional stresses and the Khairabad Fault which is the northern most tectonic boundary of the Attock-Cherat Range is south verging frontal ramp.

Key words: Shear zone, Limestone, Gandghar, Attock-Cherat, Precambrian.

A/388. Ali, K., 1992. Geology and Tectonic setup of a part of Dara Adam Khel Kotal Pass Transect (Kohat Hill Range), Kohat Division, N.W.F.P., Pakistan. M.Phil. Thesis, University of Peshawar, 61p.

This study describes the geology and structural set-up of a 168 km² area along the Darra Adam Khel-Kotal pass transect in the Kohat Hill Range. The area comprises, from bottom to top, the Jurassic Samana suk, the Cretaceous Chichali, the Lumshiwal, the Kawagarh, the Palaeocene Lockhart and Patala, (Palaeocene), the Eocene Kohat and the Miocene Murree Formations. The area is deformed into complex structures. The principal structure is a "pop-up". It comprises a south verging thrust (Main Boundary Thrust) at the southern flank against the Kohat plateau and a pair of north verging back thrusts at the northern flank against the Peshawar plain. Between these divergent thrusts, there are large scale fold structures (some with half-wave length > 7 kms) which have a fan shaped geometry, conforming to the pop-up style of deformation exhibited by the thrusts.

Overall four phases of deformation are recognized in the studied part of the Kohat Hill Range. D1 phase of deformation resulted in local duplex structure, just to the south of the Kotal pass. At least two horses have been recognized each with a stratigraphic range between the Samana suk and Kawagarh Formations, stacked below a roof thrust in the Kawagarh Formation. D2 is the principal phase of deformation related with the development of Main Boundary Thrust (MBT), the back thrusts and fan-shaped folding and pop-up shape of the Hill range thrust sheet. D3 is post folding and is represented by out-of-the-syncline thrusts in the southern limb of the wahabian valley syncline, D4 is marked by low angle normal faults, which represent gravity collapse of the abnormally uplifted Hill range in the latest stages of deformation. The deformation in the Kohat Hill Range started after the deposition of the Miocene Murree Formation and probably continued until recently.

A/390. Ali, K.A. & Anwar, J., 1969a. Stratigraphic studies of Nowshera Reef Complex, Nowshera Tehsil, N.W.F.P., M.Sc. Thesis, University of Peshawar, 48p.

Consult the following account for further information.

Key words: Stratigraphy, Reef Complex, Nowshera.

A/391. Ali, K.A. & Anwar, J., 1969b. Stratigraphic studies of the, Nowshera Tehsil, West Pakistan. Geological Bulletin, Peshawar University 4, 33-43.

A belt of Siluro-Devonian limestone and quartzite, pink or yellowish-pink in colour, is exposed on either side of the Nowshera-Risalpur road. This belt was identified as a 'Reef Complex' in 1965, and is the first of its kind to be discovered in the Indo-Pak sub-continent. Prior to this discovery, the limestone belt had been erroneously assigned a Precambrian age and regarded as part of the Attock Slates.

The entire belt unconformably overlies the Kandar Phyllite and is divisible into four definite units: 1. Carbonate Rocks, 2. Reef Core, 3. Reef Breccia, and 4. the Misri Banda Quartzite. The first three collectively are known as the Nowshera Formation. With the exception of the last, these units represent the characteristic structural layers of a reef.

The age of the reef complex on the basis of its fossil assemblage ranges between Upper Silurian and Devonian. However, there is no fossil present which may pinpoint an exact age. The uncertainty about the precise age of the reefs largely due to the destruction of many organisms by the process of dolomitization.

In the opinion of the writers, the Nowshera Formation and the Misri Banda Quartzite were deposited in the southernmost extremities of the basin in which the Muth Quartzite, of Siluro-Devonian age, was formed.

In their opinion, the Nowshera Formation and the Misri Banda Quartzite can be correlated with the middle and upper parts of the Muth Quartzite. .

Key words: Stratigraphy, Reef Complex, Nowshera.

A/392. Ali, K.S.S., Ahmad, M. & Khan, B., 1969. Geology of the northern part of Warsak area. M.Sc. Thesis, University of Peshawar, 62p.

The northern part of the previously unmapped Warsak area, bounded by 34° 10' and 34° 14' North Latitudes, 71° 20' and 71° 26' east longitude has been mapped on a 1 inch to 0.314 mile scale and the petrography and structure of the rocks is described in detail.

The rocks of the thesis area are typical of the Paleozoic metasediments of the Mohmand Agency that have been intruded by ultramafic (near Tangi etc) basic and acidic rocks, including pegmatites and quartz veins.

The oldest rocks of the area are metasediments represented by quartz-biotite schists, hornblende schists, phyllitic schists, garnet-chlorite schists and calcareous schists. These were intruded by a series of basic intrusions represented by metagabbros and metadolerites, and acid intrusions represented by porphyritic microgranites and alkali granites. The alkali granites possibly represents a differentiated fraction of the porphyritic granite. The intrusions are probably late Mesozoic to early Tertiary, and many are concordant. Quartz veins are commonly associated with all of these rocks. During recent times, the eastern low hills of the area were covered by alluvium.

The structure in the investigated area is simple, most of the rocks strike north-west and dip north-east. However, the rocks to the south-west (in Khyber agency) are folded and faulted, and the relationship of the rocks of the area with those of Khyber Agency are not well understood. Economic minerals were looked for but the results were not encouraging. However, marbles, granites and some other rocks can be exploited profitably for building and decorative purposes.

Key words: Metasediments, Warsak.

A/393. Ali, L.M. & Nadar, H., 1984. Geology of portion of Kohat quadrangle, Darra Adam Khel, Kohat, North West Frontier Province, Pakistan. M.Sc. Thesis, Peshawar University, 97p.

Key words: Darra Adam Khel, Kohat, NWFP.

A/394. Ali, M., 1995-96. Structure, stratigraphy, micropaleontology and petrography of Darthian, Narota & Karwali areas District Haripur Hazara (NWFP), Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 95p.

The Darthian, Narota and Karwali area are part of Attock-Hazara fold-and-thrust belt of the northwest Himalaya of Pakistan. The lithographic units exposed in the area are mainly sedimentary in nature and range in age from Mesozoic to Cenozoic. The area is deformed by folding and faulting during the Tertiary-Himalayan collision.

The Early Cretaceous Lumshiwal Formation has disconformable contact with the overlying Late Cretaceous Kawagarh Formation. The presence of glauconite in the Lumshiwal Formation reveals that the formation was deposited in marine condition during regressive as well as transgressive phases. The Late Cretaceous subduction of the Indian plate below the Kohistan Island arc caused the deepening of the Tethyan shelf in the subduction zone and initiated the deep marine deposition of the Kawagarh Formation. The contact between Kawagarh Formation and Early Paleocene Hangu Formation is marked by break in deposition which is evidenced by the presence of laterite/haematite and sandstone. The abrupt change in facies from deep water marine environment of Kawagarh Formation to terrestrial deposition of Hangu Formation indicates the initial Early Paleocene collision of the Indian Plate and Kohistan Island arc.

The Lower Tertiary sequence exposed in the area is Early to Late Paleocene Lockhart limestone, Late Paleocene Patala Formation, Early Eocene Margala Hill Limestone, Early Eocene Chorgali Formation and Early to Middle Eocene Kuldana Formation. The Lower Tertiary sequence marks the complete cycle of transgression and regression of the Tethyan Sea. The presence of early Paleocene to Late Eocene foraminiferal assemblage like globorotalia, globogorina, lockharia, assilina and nummulites in the limestones and shales of the Lower Tertiary sequence show

the tropical sub-tropical open sea upper slope to outer shelf environments. The Kuldana Formation is composed of marine limestone, continental variegated clay, shales and evaporitic gypsiferous bands.

A/395. Ali, M. & Ahmed, S., 1978. Interpretation of Bouguer anomalies over Gilgit valley, northern area, Pakistan. Geological Bulletin, University of Punjab 15, 40-51.

The Bouguer anomalies and up to third degree trend surface gravity analyses of the Gilgit valley, reveal that under the alluvial cover, the metasediments of Permo-Carboniferous age extend towards East and steeply dip under the thick basic igneous complex in the southeast. These basic rocks in the northeastern segment are overlain by intrusions of granodioritic rocks of Cretaceous to Eocene age, which continue up to the eastern boundary. The Permo-Carboniferous rocks in the West, contain a dyke intrusion of a granitic complex of Oligocene to Miocene age.

Key words: Geophysics, Bouguer anomaly, Gilgit.

A/396. Ali, M. & Das, A., 1997. Gravity modeling across Peshawar Basin. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p.8.

Peshawar basin studied extensively by several workers is manifested by high angle vertical faulting in association with magnetic activity. Our gravity interpretation from Peshawar to Dargai suggests that the basin is a rifted-graben structure which is bounded by east-west trending Charsadda basement fault in the south and the Vale rift zone in the north. Charsadda fault is a consequence of the gravity modelling of steep gravity gradient in that zone. Large to small scale dykes appear intruding in rifting and Malakand granite is the major intrusion in weaker zone. Gravity traverse across the eastern section of Dargai complex supports the idea that it is a smaller ultramafic body that migrated from Dir ultramafic complex.

Key words: Gravity, Magnetism, Peshawar.

A/398. Ali, M., Latif, Y. & Nazeer, M., 1997. Bed rock studies in Behrain with the use of seismic refraction. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p.9.

The application of seismic methods in civil engineering and construction work has increased rapidly because of the recognition of the importance of shallow geological structures in all phases of site selection and foundation studies. Seismic refraction experiment conducted in igneous/metamorphic terrain of Behrain for the delineation of bedrock configuration indicates that the bedrock represented by seismic velocity more than 3000 m/sec is faulted/fractured on places and lies under overburden that varies in thickness from 10 to 40 meters.

Key words: Seismology, geotechnical.

A/399. Ali, M. & Mujtaba, G., 1992. Gravity and magnetic studies in the region of Main Boundary Thrust, west of Himalayan syntaxis. Geological Bulletin, University of Peshawar 25, 51-58.

Interpretation of gravity measurements in the west of Hazara Kashmir syntaxis, particularly around Main Boundary Thrust region suggests that the crustal thickness in the region is around 47 km, and the Moho dips at an angle around 1.0 degree towards northeast against the calculated dip of about 4.0 degrees just south of Margala ranges. The residual gravity, which corresponds reasonably to a generalized litho-structural model of the area, predicts also some anomalous situation which get support from magnetic results. The density modeling along Islamabad-Haripur

sections gives the possibility of existence of basement or ultra-basic slices near Islamabad at a depth of 5 km. Further, the MBT and langrial faults to be changing dips downwards to 25° or more.

Key words: Gravity, Magnetism, MBT, Himalayan Syntaxis.

A/400. Ali, M., Yoshida, M., Khadim, I.M. & Ahmad, M.N., 1994. Total gamma-ray observation along the Karakoram Highway, northern Pakistan: An attempt of geological interpretation by radioactivity of rocks. Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad 8, 81-93.

The purpose of this survey was to see the possibilities of lithogeological application of radioactivity of rocks and radiometric pollution of air and soil across major rock units exposed along the KKH between Hassanabdal and Khunjerab river. The following conclusions were arrived at:

- (1) The change of total intensity of the natural gamma-ray radiation along the KKH is closely related to surface geology as well as lithology. It means total gamma- ray survey is applicable for geologic mapping, especially for regional reconnaissance survey.
- (2) Most anomalies in total gamma-ray radiation are probably derived from potassium (K^{40}) in rocks. Granitic rocks and micaceous metasediments shows relatively high intensities of total gamma-ray radiation.
- (3) The hot-spring area around the Nanga Perbat gneiss body shows the highest value of radiation in the surveyed route. It may due to radioactive radon-gas associated with the hot-spring water. It also suggested that the hot-spring is supplied from subsurface fracture-type reservoirs in the country rocks.
- (4) Further spectral gamma ray-survey is recommended for detailed geological and mineralogical interpretations.

Key words: Geophysics, KKH.

A/401. Ali, M., Yoshida, M., Khadim, I.M., Ahmad, M.N. & Fujiwara, Y., 1993. An isotropy of magnetic susceptibility measurement of some igneous-metamorphics rocks in northern Pakistan. Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad 6, 66-81.

An isotropy of magnetic susceptibility (AMS) of the Jijal and Chilas complexes and Mansehra granite were performed for the purpose of structural analyses. It is tentatively concluded that the directions of AMS of the Chilas and Jijal complexes closely correspond to their internal structure, such as foliation. The paper also emphasizes that AMS measurement is not only useful in solving the micro-structural problems, but informative on magnetomineralogical viewpoints such as SD grain ratio.

The Lumshiwal Formation from Kundla is divided into XII Lithofacies on the basis of field observations. These include lower grey sandstone facies, fossiliferous limestone facies, phosphatic glauconitic, lower grey sandstone

facies, silty sandstone facies, green sandstone facies, light grey sandstone facies, carbonaceous sandstone facies, hard ground facies; upper grey sandstone facies, and grey arenaceous carbonates facies. These facies contain 19 microfacies that repeat at random. The formation was deposited in intertidal to subtidal environment but not below 80 m. Diagenetically, glauconite was the first cement to deposit in the sands from the alteration of mixed layer clays, then quartz, carbonates, flint and iron oxides were precipitated. The sandstone are compositionally mature. Texturally these are submature to super-mature. They are very fine grained to coarse grained. Tourmaline, zircon, epidote and sphene indicate derivation from sialic metamorphic-igneous basement. However some basic sources also contributed during the deposition of the formation. Palynomorphs were represented by Dinoflagellates (*Baltisphaeridium* sp. And *Michrystribium* sp. Pollen and spores (*Densoisporites*, *Leptolepidites*, *Punctatisporites* and *Acropolis*) and some *Acritarchs*.

A/408. Ali, S., 1997-98. Geological mapping of Rawlakot area with special emphasis on engineering characteristics of geo-material as aggregates. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 43p.

Geological mapping of Raw and has been conducted at the scale 1:50,000 and the total area of research is about 100 sq. km. The aggregates available in the area are Murree Sand stones. These natural sandstone aggregates from Rawlakot are being used for manufacture of concrete for building construction and other Civil engineering projects. The durability of the aggregate has not yet been evaluated by any organization or through any research work. Theses work summarizes the main characteristics for consideration of aggregated to be used as concrete which is still little understood, specially those leading to cracking and deterioration. It considers the specifications of aggregates through experiments and local experience and emphasis the need of testing to be used more specifically in different climatic and geological settings, the strong influence on aggregates performance is mineralogical composition and the changing environmental conditions. Presently work related to mineralogical composition, Losangles, Abrasion Value, Crushing Value, Impact Value, Specific Gravity, Water Absorption, Flakiness Index & Elongation Index are performed and related to mineralogical composition according to ASTM standards. The percent value of chert, clays, silt, plagioclase chlorite, muscovite and hematite effect the aggregates when in contact with water. Reserves of minerals sandstone estimated from Dharamsal and Dhamni are 10.2×10^5 million tons and Damsite and Dhoke Kohian are 5.8×10^6 million tons.

A/416. Ali, S.T., Abdullah, S.K.M., & Rashid, M.A., 1965. Bentonite deposits of Azad Kashmir: Geological Survey of Pakistan. Information Release 31, 20pp. 2 maps.

The bentonite deposits of Bhimber and Mirpur areas are found in 3 to 8 inches thick beds associated with volcanic ash extending for about 40 miles, laterally. Bentonite is of white, bluish grey, black and brownish varieties, is mostly a calcium bentonite and is categorised as a non-swelling type. The reserve estimates indicate that about 4800 tonnes, per foot of depth of white and bluish grey varieties of bentonite. Very large reserves of brownish-black variety of bentonite are available in both the areas.

A/418. Ali, S.T., Ashraf, M. & Malik, R.H., 1983. Mineral deposits of Azad Jammu Kashmir-a review. *Kashmir Journal of Geology* 1, 119p.

The territory of Azad Jammu and Kashmir lies between Pakistan (on its west) and Indian occupied main land mass of the disputed State of Jammu and Kashmir (on its east). The total area of Azad Jammu and Kashmir is about 12,000 km². It has a fairly rugged mountainous topography.

Geology is simple and well exposed. Almost all the rock units are of sedimentary origin, ranging in age from Precambrian to Recent. Acidic and occasional small basic intrusive bodies are present in the Neelum Valley. Large scale regional metamorphism is encountered in the northern half of the State. The major tectonics are controlled by the collision of the Indo-Pak Plate with the Eurasian Plate north of the Nanga Parbat, the fourth highest mountain peak in the world. One of the most important tectonic features in this area is the Syntaxial bend of the Himalayas as just around Muzaffarabad, the capital town of the States of Azad Jammu and Kashmir.

Major metallic mineralization has not been met with up till now, however, workable deposits of bauxite, bentonite, coal, dolomite, fireclay, graphite, gypsum, limestone, marble, mica, quartzite, silica sand, slates, soapstone, and volcanic ashes are well established as a result of numerous exploratory surveys carried out by various concerned agencies. Reported occurrences and showings include phosphate, gemstones, feldspar, iron ores, lead, oil, gas. Pozzulana materials, gold barite and rare earths. The possibilities of discovering minerals like scheelite, ilmenite, monazite and zircon exist.

A/428. Ali, S.S., 1992. Shallow seismic refraction study in Darbokach (Kohat). M.Sc. Thesis, Quaid-i-Azam University, Islamabad, 50p.

Seismic data of a line is obtained for interpretation collected in DARBOKACH area near KOHAT. The survey was done by OGDC and the objective was to establish velocity lithology relationship and to detect any subsurface structures present in the area. The seismic line is shot at 100 meters interval. Splitspread shooting scheme with 96 channels recording system was used. The offset distance on either side of the shot is 75 meters and the intergeophone spacing is 25 meters. The reverse profiles were prepared at 50 meters interval using the splitspread data.

Parameters such as depth Z_0 and velocities V_0 and V_1 are determined and their distribution along the seismic line is established. Depth under each geophone for reversed profiles using delay time and Plus Minus methods is determined. From the obtained results it is concluded that weathering layer thickness ranges from 18.5 m to 25.5 m with refractor being almost horizontal. Weathered layer velocity ranges from 1320 m/sec to 1820 m/sec and consists of sandstone with interbeds of shale. The refracting surface is faulted towards southeast end with downthrown side towards northwest. The average displacement in the bed is 42.6 m.

A/431. Ali, Z., 1991-93. Geology of Dubran Area District Haripur with microfacies study of Langrial Algal limestone. M.Sc. Thesis, Punjab University, Lahore, 127p.

Geological mapping of some 64-km² area around Dubran in District Haripur has been carried out at the scale 1:12500. The geomorphology, soils, stratigraphy and structure have been described. Stratigraphically a Mesozoic-Tertiary sedimentary cover is overlying a Precambrian to Eo-Cambrian basement of Hazara Group now metamorphosed in the lower greenschist facies. Numerous faults, high angle north dipping Nathiagali Thrust is the main fault that passes through the area and has thrust the Precambrian Hazara Slates over the younger sedimentary sequence. Dubran syncline lying on top of a major anticlinorium makes an interesting structure.

A/434. Alizai, S.A.K. & Khan, G.M., 1990. Remote sensing applications to geologic/mineral studies. In: Siddiqi, F., Husain, V., Kaifi, Z. & Ghani, A. (Eds.), Proceedings, First SEGMITE Conference on Industrial Minerals, March 1990, Peshawar, 68-73.

The application and interpretation of RS is described with respect to geological work. With the help of Landsat images, brief comments are made on the structure of five selected ranges of Pakistan: the Balochistan arc, Western Salt Range and Khisor Range, Eastern Salt Range and Potwar Plateau, Southern Sulaiman Range, and Coastal Makran Range. The author lays emphasis on combining field studies with RS. The western Salt Range and Khisor Range have complex structure, with considerable impact of salt tectonics. The Siwaliks of the Himalayan foreland are viewed as vertical sequence of individual stream channels overlain by related flood plain facies (shales and certain sandstones).

A/438. Allen, J.E., 1964. Quaternary stratigraphic sequences in the Potwar Basin and adjacent Northwest Pakistan. Geological Bulletin, Peshawar University 1, 2-5.

Prof. Ahmad Hassan Dani and Farzand Ali Durrani of the Department of Archaeology; Univ. of Peshawar kindly permitted the writer to accompany them upon a number of their trips to the remarkable Archaeology "digs" near Charsadda, Senghao and Thana which were under investigation during 1963-64.

The problem faced by them in the dating of the formations within which artifacts occur at once aroused the writer's interest since they are in large parts geological problems in Quaternary stratigraphy. Nothing has been published on this aspect of the area, the nearest work has been in Kashmir (De Terra. 1939) many miles to the north-west, and in Gujrat (Zeuner 1950-63) over farther to the south. Both are indifferent drainage systems, which might not correlate with Potwar System.

After a number of trips to various parts of the region, a pattern emerged in March of 1964, and tentative correlations appeared possible between similar sequences of unit found near the Swat River a mile south-east of Thana, along the Sher Garh nullah 17 miles north of Mardan and north of Katlang near Sanghao, Because of the absence of the previous publications, it seemed worthwhile to present the available data and some conclusions reached as a guide to further investigation, inspite their highly tentative and incomplete nature.

A/440. Allen, T. & Chamberlain, C.P, 1989b. Petrologic constraints on the tectonic history of the northern Shyok suture and the main Karakorum Thrust, Baltistan, Northern Pakistan. Geological Society of America Abstracts with Programs, 21(6), p.A181.

The Northern-Shyok Suture and the Main Karakorum Thrust (MKT) separate rocks in the Asian plate from rocks in the Kohistan-Ladakh Island Arc. We determined the P-T history of the metamorphic rocks both north and south of this suture in effort to place constraints on the suturing process. The terranes north and south of the MKT have different, unrelated metamorphic histories. Our data is consistent with a tectonic model that involves metamorphism of the Kohistan-Ladakh Arc due to plutonic activity and metamorphism of the Karakorum Metamorphic Complex as a result of subduction related processes. After metamorphism the two terranes were juxtaposed by the late south directed MKT, which obscures the original Northern-Shyok Suture.

A/441. Allen, T. & Chamberlain, C.P., 1991. Metamorphic evidence for an inverted crustal section, with constraints on the Main Karakorum Thrust, Baltistan, northern Pakistan. Journal of Metamorphic Geology 9, 403-418.

The Shyok Suture Zone separates rocks in the Asian plate from rocks in the Kohistan-Ladakh island arc. In Baltistan, this suture has been reactivated by the late 'break-back' Main Karakorum Thrust (MKT). The P-T histories of metamorphic rocks both north and south of the MKT have been determined in an effort to place constraints on the tectonic history of this zone. The terranes north and south of the MKT have different, unrelated metamorphic histories. Rocks from the Kohistan-Ladakh island arc south of the MKT have undergone a static low-P (2-4 kbar, c. 500° C) thermal metamorphism. The P-T paths and metamorphic textures of these rocks are consistent with metamorphism due to emplacement of plutonic rocks into the island arc. This metamorphism pre-dates folding and deformation of these rocks. Rocks in the Karakorum Metamorphic Complex, north of the MKT, have experienced a complex deformational and metamorphic history. Prograde metamorphic isograds have been deformed by subsequent south-verging folding and by gneiss dome emplacement. However, decompression metamorphic reactions occurred during nappe emplacement. Higher pressure rocks are associated with higher level nappes,

creating an inverted pressure metamorphic sequence (8–9-kbar rocks over 5–6-kbar rocks). There is little variation in temperature with structural level (550–625° C). These two different terranes have been juxtaposed after metamorphism by the late south-directed MKT.

A/445. Alvi, D.H., 1985-87. The mineralogical/geochemical studies of rocks, soils and water from Khanaspur Dewal Area. M.Sc. Thesis, Punjab University, Lahore, 102p.

This report gives an account of Mineralogical and geochemical studies carried out in Khanspur and Dewal area. The prescribed area lies to the north of Murree, in extreme east of Abbottabad and southwest of Muzaffarabad. Except an area of about 6 sq. km. which belongs to District Rawalpindi, the area lies in Abbottabad District, N.W.F.P. It is a mountainous region with fairly high relief.

Geological mapping of approximately 56 sq. km. on lithostratigraphic basis, at the scale 1:10,000 was carried out. The stratigraphic succession ranges from Datta Formation (Jurassic) to Murree Formation (Miocene). The lithology is mainly limestone, shales and sandstone. Extensive sampling of rocks, soils and water was carried out and these samples were studied in laboratory and data regarding these studies are given in this report.

A brief systematic description of various rock units in hand specimen and thin section is included. A brief description of chemical staining techniques applied to the limestones and that of performed limestone analysis is also given. A chapter regarding the detailed geochemical studies of soils of the project area is also included. This chapter gives an account of all the parameters necessary for soil study and according to these parameters, the soils of the area are categorized as non-sodic, non-saline.

Geochemistry of two main streams of the area has also been studied in detail and the data regarding the chemical analysis of the water are reported and interpreted by various graphical techniques. According to these data, the mineral components and other parameters lie within the safe limits, established for water to be used for domestic and agriculture purposes. Chemical characteristics of waters of various springs of the area, originated in different rock units have also been studied and interpreted in detail. Spring waters are also fit for irrigation and drinking purposes. Finally, there is a general discussion about the waters of the area and the effect of various encountered rock units on the chemistry of water passing through them.

A/447. Ambraseys, N., Lesen, G., Moinfar, A. & Pennington, W., 1981. The Pattan (Pakistan) Earthquake of 28 December, 1974: Field Observations. In: *Quarterly Journal of Engineering Geology* 14, 1-16, Edinburgh.

In the early evening of 28 December 1974, a magnitude 6.0 (*mb* USGS) earthquake occurred in a remote and mountainous region of northern Pakistan, resulting in loss of life and damage to property. The Pakistani Army Engineers involved in construction and maintenance of the Karakorum Highway, a one-to two-lane gravel road along the Indus River valley, quickly established an efficient relief operation. Since the highway was damaged and unusable during most of the relief operation, helicopters were used to carry supplies from Besham, at the end of the usable highway, to Pattan, where a hospital camp was set up.

Two seismic reconnaissance teams visited the affected area: the first arrived from Tarbela Dam on 1 January 1975, and included one of the authors (Pennington); the second team, with the other three authors (Ambraseys, Lensen and Moinfar) arrived later in January. The following report is based largely on their field studies (Ambraseys *et al.* 1975; Pennington 1975).

The earliest known earthquakes of the Northwest Frontier Provinces (NWFP)

As early as the 4th century BC, the region north of the Jhelum was reputed for its destructive earthquakes. Historians who accompanied Alexander the Great on his expedition in Swat allude to such events; they briefly state that as a result of earthquakes in this track of country even the beds of rivers are changed. Alexander must have reached Aornos (modern Pir-sar about 20 km from Besham) late in 327 BC (Stein 1927, 1929;

A/450. Amin, M., 1982-84. Geology and Petrotectonic Study of Shino-Kaghan-Batal Area, District Mansehra Pakistan. M.Sc. Thesis, Punjab University, Lahore, 189p.

This field report comprises a complete geological study based on a first time mapping of nearly 328 km² of Central Kaghan Valley. Special emphasis has been put on, describing the stratigraphy and deciphering petrotectonic relationships of the rocks. A tentative stratigraphic correlation of the rock units has also been attempted. Between Shino and Batal a large number of rock unit including volcanics, tillites, metaconglomerates, schists, quartzites, marble, granites and migmatites are encountered. A stratigraphic sequence has been worked out. The rocks extend in age from Permo-Trias to Precambrian, have been correlated with Panjal Volcanics, Agglomeratic Slates, Tanols, Slates (Hazara/Dogra) and Salkhalas/Sharda Group.

Structurally, the rocks are folded into a number of major structures, which are now separated from each other by mostly north dipping high angle thrust faults. The area thus comprises a large number of thrust sheets over riding

each other. A study of the petrostructural relationships of the various rock units brings out the very interesting discovery of a third suture in NW Himalayas. This suture is much older than the two already described (MKT & MMT) and coincides with the position of MBT. In the field of economic geology a number of new potential economic deposits including quartzites, marble graphite and gypsum being reported. This report also includes a petrographic description of the rock units as well as numerous sketch sections and photographs, illustrating the geology of the area.

A/456. Anczkiewicz, R., 1998. Structural and geochronological study of the Indian-Kohistan arc collision, lower Swat region of Pakistan, NW Himalaya. Ph.D. thesis, Swiss Federal Institute of Technology, Zurich.

The NW Himalayan collisional system comprises three distinct crustal domains. From south to north they are: the Indian plate, the Indus Suture Zone (Main Mantle Thrust) and the Kohistan paleo-island arc (KIA). The studied area is located in the Mingora-Alpurai region, Lower Swat district of Pakistan, where the Indus Suture Zone (ISZ) forms one of the largest exposures. Structural mapping of the Indus Suture Zone lithologies and neighbouring parts of the northern Indian margin and of the basal part of the Kohistan arc were carried out. Geochronological studies were conducted in order to provide time constraints on pre- syn- and post-collisional magmatic, metamorphic and deformational evolution in the three domains. In addition, geochronological studies were carried out on the garnet granulites of the KIA in the Jijal-Patan area were conducted.

The Indian plate

The lowest crustal level in the Indian plate domain is represented by the Swat and the Choga granite gneisses. The Choga granite gneiss consists of peraluminous granites, whose U-Pb zircon dating yielded a 468 ± 5 Ma magmatic emplacement age. The alkaline Swat granite, which intruded overlying Alpurai metapelite, yielded a 268 ± 7 -3 Ma

U-Pb zircon age interpreted as the time of intrusion. The granitoids together with the overlying Alpurai and Saidu schists underwent amphibolite and greenschist facies metamorphism during collisional time. The earliest, collision related, deformational phase is associated with southward-directed thrusting and formation of large-scale recumbent folds. This period was followed by the reactivation of the ISZ as a normal fault. As a result of normal faulting the greenschist facies Saidu schists were juxtaposed against amphibolite facies Alpurai schists. Strike-slip faulting, most likely, occurred at this stage. The extension related structures are folded by N-S trending folds, whose formation is probably contemporaneous with building of the Besham syntaxis.

Sm-Nd dating of garnet from the Alpurai schists and $^{40}\text{Ar}/^{39}\text{Ar}$ dating of hornblende and muscovite indicate that the Lower Swat region remained under lower amphibolite facies conditions (or higher) until ca. 35 Ma. The main period of exhumation is most likely related to the extensional period. Its maximum age was constrained by dating late kinematic alkali granite dykes, which post-date the main metamorphism and are deformed by the extension related N-vergent folds. U-Pb zircon dating yielded 29.3 ± 0.2 Ma magmatic emplacement age, which was also confirmed by a 28.6 ± 1.4 Ma Ar/Ar muscovite age.

Indus Suture Zone

A new subdivision of the Indus Suture Zone lithologies is proposed. The main mapped units represented by Sheared Olistostromic Unit, Interlayered Blueschists and Greenschists, Volcaniclastic metaturbidites and serpentinised ultramafics. They are separated by fault contacts and form a zone of imbricated blocks, which underwent multiphase deformational history. Due to different rheological properties and strong brittle overprint structural comparison between the units is ambiguous. Very well preserved extensional structures within the 'Sheared Olistostromic Unit', similar to those observed in the Indian plate, suggest that Indian plate and the ISZ lithologies have shared a similar deformational history since this stage or earlier.

Rb-Sr dating of blueschist facies assemblages yielded ages of 77.0 ± 0.4 and 79.7 ± 0.4 Ma. This was confirmed by a 80.4 ± 0.7 Ma $\text{Ar}-\text{Ar}$ muscovite age. These dates are interpreted as reflecting peak blueschist facies conditions. Lack of collision-related metamorphic overprint is probably due to underplating of the blueschists to the hanging wall of the MMT prior to collision or earlier obduction onto the Indian plate.

Kohistan arc

Sm-Nd and Rb-Sr garnet dating of the Kamila amphibolites in Kwazakhela area yielded concordant ages of 94.6 ± 5.3 and 99.5 ± 15.7 Ma, respectively. Similar ages were obtained for the amphibolitised garnet granulite, from the Jijal-Patan complex, which yielded 95.7 ± 2.7 and 101.3 ± 10.4 Ma by Sm-Nd and Rb-Sr techniques, respectively. Petrological observations and comparison with other studies indicate that garnet is a relic of the earlier, granulite facies metamorphism. These dates are interpreted as reflecting, or shortly postdating the granulite facies metamorphic peak. Rb-Sr and $\text{Ar}-\text{Ar}$ dating of the amphibolitisation process leads to more

A/457. Ancykiewicz, R., Burg, J.P., Hussain, S.S., Dawood, H., Ghazanfar, M. & Chaudhry, M.N., 1998. Stratigraphy and structure of the Indus Suture in the lower Swat, Pakistan, NW Himalaya. *Journal of Asian Earth Sciences* 16, 225-238.

We present a geological map, detailed structural description and new subdivisions of the Indus Suture Zone lithologies in northeast Pakistan (Lower Swat region). The Indus Suture Zone is a dominantly fore-arc related assemblage obducted onto the Indian Plate. Initial southward thrusting was followed by the reactivation of the Indus Suture as a ductile-brittle normal fault. Significant strike-slip faulting may have taken place at this stage. Later brittle reverse faults demonstrate that shortening outlasted normal faulting. The comparison of the structural evolution of the Indus Suture Zone and the Indian Plate shows that both remains were sharing the deformational history, possibly since the earliest stage of collision. The Lower Swat area records a full orogenic cycle from early rifting through continent-arc collision to orogenic collapse. We present a geodynamic model that integrates all these elements.

A/458. Ancykiewicz, R., Burg, J.P., Meier, M., Oberli, F., Vance, D., Dawood, H., Hussain, S., Ghazanfar, M. & Chaudhry, M.N., 1997. Tectonometamorphic evolution of the Indus Suture viewed by structural and isotopic data, lower Swat, Pakistan NW Himalaya. Abstract volume, 12th Himalaya- Karakorum-Tibet International Workshop, Rome, Italy, 2-4.

In NW Himalaya the Indus Suture separates the Kohistan paleo-Island Arc (KIA) from the Indian continent. The Indus Suture in the Mingora-Alpurai region of Lower Swat (NE Pakistan) represents a complex exposure of greenschist and blueschist facies mafic, ultramafic and metasedimentary rocks wedged in-between ortho-amphibolites of KIA to the north and metapelites of the Indian plate to the south (map).

In the studied area Indian plate lithologies comprise the Manglaur schists, associated Swat granite gneiss, and overlying metapelites. These rocks were subsequently metamorphosed during the Kohistan-India collision. Preliminary U-Pb zircon dating of the Swat granite-gneiss (map, samp. 95/198) yielded an upper intercept age $276 \pm 40/-9$ Ma which represents the time of magmatic emplacement. Amphibolite facies metamorphism dated by Sm-Nd techniques on metapelitic schists of the Alpurai group (map, samp. 94/1) at 36 ± 2 Ma. This event was followed by a second magmatic episode expressed by syn- to post-kinematic pegmatitic dikes, which intrude the Swat granite gneiss.

The dominant style of deformation within the Alpurai para-amphibolites and overlying Saidu schists is characterized by asymmetric, north-vergent folds with gently to moderately south dipping axial planes. Similar style of folding is also observed in the basal unit of the Indus Suture Zone where extension is indicated by numerous shear bands and normal faulting (cross-section). Comparable north-vergent folds from the neighboring Naran region were shown to be synconvergent collapse features related to the backsliding of the Kohistan arc.

The lithologies of the Indus Suture Zone represent a sequence of imbricated blocks that bear evidence of metamorphism and deformation prior to collision. This early phase is indicated by the age of blueschist facies metamorphism and conjugate box type folds preserved in metacherts, which underwent first phase of deformation probably in the forearc environment. All units were juxtaposed, metamorphosed and deformed when collision occurred. The Kohistan amphibolites show features mainly related to southward directed shearing which resulted in anastomosing shear zones and south verging folds. Rare asymmetric quartz clasts mark a late stage of northward-directed movement. The latest stage of ductile deformation is expressed by NE-SW trending strike-slip faults with unconstrained amounts of vertical and horizontal displacement.

A/459. Anczkiewicz, R., Oberli, F., Burg, J.P., Meier, M., Dawood, H. & Hussain, S.S., 1998. Magmatism south of the Indus Suture, lower Swat, Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 7-9.

The lower Swat magmatism is dominated by the so-called Swat granite, which intruded the Manglaur Formation and is unconformably overlain by the Alpurai schists (Fig.1). Its age of emplacement has been assumed to be similar to that of the Mansehra granite, which gave a Rb-Sr total-rock isochron of 516 ± 16 Ma age (Le Fort et al., 1980). We present results of petrological, geochemical and geochronological studies of the Swat granitoids in the northern part of the Loe Sar dome and Alpurai regions (Fig. 1).

At the northern edge of the Loe Sar dome the granitoids occur as two sill-like bodies. We investigated the upper sill at the northern edge of the dome. It exhibits dominantly augen and flaser type textures, which show alkaline composition. U-Pb single zircon dating of sample 95-198 (Fig. 1) yielded $268 \pm 7/-3$ Ma. Preliminary dating of sample 95-196 confirms the Permian age, which we interpret as the time of magmatic emplacement. The body is intruded by alkaline syn- to post kinematic pegmatitic dykes, which are truncated and sheared at the contact with the overlying Alpurai schists (Fig. 2a). U-Pb zircon dating gave an age of 29.2 ± 0.2 Ma interpreted to represent an intrusion age. This date establishes also the maximum age for shearing. Scarce kinematic indicators suggest a thrust sense of movement. Thus, the Tertiary alkaline volcanism appears to be associated with regional thrusting (see also Le Bas et al., 1987) rather than rifting as proposed by Kempe and Jan, 1980.

Taking into account field observations and age data we suggest an intrusive rather than an unconformable nature for the contact between the Swat granite gneiss and the Alpurai schist. This interpretation is based on i) the existence of a fine-grained fabric at the border of the granite gneiss, ii) the occurrence of xenoliths of garnet-amphibolite that may have been derived from the Alpurai schists and iii) the Permian age of the granite, which has intruded Middle Carboniferous to Permian beds at the base of Alpurai schists (Marghazar Formation of DiPietro et al., 1997). Regional shearing at ca. 30 Ma is responsible for the truncation of the pegmatitic dykes at the Swat granite gneiss / Alpurai schists interface and have obscured the original intrusive character of this contact.

Based on similar stratigraphic position with respect to the Alpurai schists, the Choga granite gneiss (Fig. 1, 2a,b) of the Alpurai region has been commonly assigned to the Swat granitoids. Microprobe analyses of major mineral phases in sample 95-21 1, however, are different from those of samples 95-198 and 95-196, which originate from the northern part of the Loe Sar dome (Fig. 1). This observation is corroborated by a U-Pb zircon age of 468 ± 5 Ma

obtained for Choga granite, which we interpret as an intrusion age. Based on similarities in major mineral geochemistry, we consider the Choga granite to be related to the granitoids in the core of the Loe Sar dome (lower sill).

Because our investigations have been focussed on a rather limited part of the Swat granitoids, it is still uncertain, whether the Permian age determined for their northern margin is representative for the entire upper unit or whether the Permian magmatites form smaller intrusions within Cambro/Ordovician granitoids. The results extend the spatial distribution of alkaline magmatism, previously restricted to the Peshawar Plane igneous province, to the Swat area. Furthermore, they give clear proof that this magmatism was generated in at least two cycles unrelated in age.

A/460. Anczkiewicz, R., Spencer, D.A., Hussain, S.S., Dawood, H., Chaudhry, M.N. & Ghazanfar, M., 1995. Emplacement and subsequent tectonic history of the Indus Suture in the Mingora-Shangla-Malam Jabba area (NW Himalaya, Pakistan). Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

A complex exposure of the Indus Suture in the Northwestern Himalayan area is situated on the western side of the Besham Syntaxis (northeastern Pakistan). Between Mingora and Lilauni, the Indus Suture bifurcates into a wedge-shaped complex, which comprises of predominantly mafic rocks of blueschist and greenschist facies grade. It is separated by the tectonic contacts from the amphibolites of the Kohistan Island Arc to the north and from the metasediments of the Indian Plate to the south. The enclosed Indus Suture Mélange Group was previously subdivided into three units: the Mingora Ophiolitic Mélange, the Charbagh Greenschist Mélange and the Blueschist Mélange. These were suggested to have been separated by major thrusts that were active when the continental collision occurred. The mélange units are thought to represent oceanic crust material, which is of either Island Arc, Mid Oceanic Ridge or subduction zone origin.

Preliminary results of fieldwork in the Mingora, Shang La and Malam Jabba areas indicate that the interpretation of a mélange-type subdivision can no longer be sustained. We were not able to confirm the existing divisions of the three units separated by the thrust contacts. Only the lower and upper contact of the suture zone are marked by the presence of distinctive shear zones which show a thrust sense of movement, although occasionally evidence for extensional movement is found.

Initial petrological studies of the Alpurai schists revealed distinct variation in the metamorphic and deformational history within this unit. Schists from the vicinity of the village Kashora show two stages of the growth of garnet which postdate the formation of the main foliation while schists from Makad show one stage of growth and are cut by the main foliation.

A/461. Anczkiewicz, R. & Vance, D., 2000. Isotopic constraints on the evolution of metamorphic conditions in the Jijal-Patan complex and Kamila belt of the Kohistan arc, Pakistan Himalaya. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 321-331.

Pressure-temperature data and Sm-Nd and Rb-Sr garnet ages presented for retrogressed granulitic rocks of the Jijal-Patan complex and the Kamila Amphibolite Belt. Despite the retrogression and hydration, the two samples contain garnet and hydrous minerals that yield pressures and temperatures similar to previous estimates for pristine granulite facies rocks from the same area. The Sm-Nd and Rb-Sr garnet ages are concordant at 95-100 Ma for the two samples and for both isotopic systems, these ages are interpreted as dating cooling through 700-800°C following magmatic crystallization and granulite facies metamorphism. In the case of the garnet amphibolites from the Kamila Belt, the garnets system is very close to the recorded temperatures. For these reasons, the age of 100 Ma must represent a time close to that when the pressure and temperature preserved in the mineralogy and its chemistry was recorded. The isotopic equilibrium between garnet and paragonite at 90-100 Ma suggest that the regional hydration event that affected the lower crust of the Kohistan arc also occurred at this time. Cooling rates calculated from the Rb-Sr and Sm-Nd ages for the partially retrogressed granulite give a minimum of 3-6°C Ma⁻¹ and imply a different

tectonic mechanism for the exhumation of the lower crust than is typical for granulites. This process may be related to early regional decompression following the collision of the Kohistan arc with Eurasia.

A/462. Anczkiewicz, R., Villa, I.M., Miller, W., Burg, J.P., Meier, M., Dawood, H. & Hussain, S.S., 1998. Rb/Sr and $^{39}\text{Ar}/^{40}\text{Ar}$ dating of blueschist facies metamorphism in Shangla region, Pakistan, NW Himalaya. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 9-10.

Geochronological studies of high-pressure rocks in many metamorphic terrains show that Ar-Ar dating often yield ages inconsistent with other dating techniques (e.g. Li et al., 1994). Therefore an independent control by other isotopic geochronometers is needed. We present preliminary results of coupled Rb-Sr and $^{39}\text{Ar}/^{40}\text{Ar}$ dating of the Shangla blueschists.

The Shangla blueschists are squeezed within the Indus Suture Zone, on the western limb of the Besham (Indus) syntaxis (Lower Swat region of Pakistan). As such, they outcrop within the so called 'm61ange zone' between the Indian plate and the Kohistan. The blueschist facies event has been previously dated at ca. 80 Ma by $^{39}\text{Ar}/^{40}\text{Ar}$ phengite dating (Maluski and Schaeffer, 1982; Maluski and Matte, 1984). Glaucophanes yielded $^{39}\text{Ar}/^{40}\text{Ar}$ data scattered between > 450 and 50 Ma (Schams 1980; Maluski and Schaeffer, 1982; Maluski and Matte, 1984).

Prior to dating, we carried out detail microprobe analyses in order to eliminate samples exhibiting retrograde features (invisible on the micro-scale) and detect possible mixing between various phases. Back-scattered electron imaging and quantitative microprobe analyses of the blue amphiboles showed no or very weak zoning. Compositions are all within the range of glaucophane-riebeckite series. Similarly, phengites do not display any significant zoning. Blue amphiboles eventually contain sub-microscopic inclusions of phengites.

Two metasedimentary and three metavolcanic types of blueschists were selected for the geochronological studies. Both show crossite/ glaucophane+epidote paragenesis, which is diagnostic for the transitional blueschist-greenschist facies, typical for the Shangla region. Five glaucophanes and three phengite high-purity mineral concentrates derived from five rock samples were subjected to $^{39}\text{Ar}/^{40}\text{Ar}$ dating by stepwise heating technique. In addition, two of them were dated by the Rb-Sr method.

Rb-Sr isochrons of blue amphibole-phengite pairs allow to better ascertain the age of blueschist facies metamorphism. Low $^{87}\text{Rb}/^{86}\text{Sr}$ ratios for blue amphiboles together with high ratios for phengite (see table 1) allow precise age determination at 77.0 ± 0.4 and 79.7 ± 0.4 Ma (errors with 95% c.l.). The estimated thermal peak for the Shangla blueschist (300-380°C) (Jan 1981; Guiraud, 1982) is significantly lower than the commonly accepted closure temperature for Rb-Sr system in phengite and amphibole. Therefore, we interpret our age determination as representing time of metamorphic crystallisation under transitional blueschist-greenschist facies conditions at ca. 80 Ma. $^{40}\text{Ar}/^{39}\text{Ar}$ dating was performed on 5 glaucophane samples. Extensive handpicking and preliminary K concentration measurements ($K < 500$ ppm) let us hope to have eliminated 'contamination' by phengites. However Ca/K vs. Cl/K trajectories coupled to mass balance calculations show that true blue amphibole has $K < 23$ ppm, and about 0.4% modal phengites intergrowths by far dominate the K-Ar budget. All ages group around 80 Ma and agree with Rb/Sr dating. Three out of 5 glaucophanes preserved pre-blueschist facies amphibole (?) relics, which give reproducible step ages around 400 Ma in the last 5% of the gas release. This corresponds to about 1 modal % 'relict amphibole', which appears to preserve a signature of the Ordovician volcanism.

A/464. Anderson, R.V.V., 1928. Tertiary stratigraphy and orogeny of the Northern Punjab. Geological Society of America, Bulletin 38, 665-672.

The Tertiary of the Punjab is divided into two principal parts, the marine and estuarine Eocene (Nummulitic) system below, and, unconformably overlying this, a great succession of nonmarine beds representing continental sedimentation from the Oligocene to the late Pliocene or early Quaternary. This nonmarine succession, here named the "Ni-madric System," includes the Murree and Siwalik series. It comprises over 20,000 feet of fairly well stratified, alternating sandy and silty beds, mainly fine-grained, but coarsely conglomeratic in its uppermost division. It is interpreted as the product of mainly fluvial, but in part eolian, deposition over fairly flat plains, under a semitropical climate of medium rainfall. The plains extended into the region now occupied by the Himalaya. Evidence of the validity of thickness measurements is afforded by the comparative constancy of individual fine-grained formations, the great thicknesses superimposed in single sections, and by the record here presented of a well 6,000.

A/465. Andrews, S.C.P. & Brookfield, M.E., 1982. Middle Paleozoic to Cenozoic geology and tectonic evolution of the Northwestern Himalaya. Tectonophysics 82, 253-275.

Previously published data and data collected by the authors from the northwestern Himalaya are summarized and assessed. The account focuses on Kohistan and the Karakorum Range in Pakistan, and on Ladakh and the Zaskar Range in India.

Five palaeotectonic units are recognized. From south to north these are:

- (1) Palaeozoic-Eocene continental shelf sequence on the northern margin of the Indian continent;
- (2) a Triassic-Jurassic continental slope sequence: the Lamayuru unit of the Indus zone and of the Spongtag klippe;
- (3) the Cretaceous-Tertiary Kohistan-Ladakh magmatic arc, which includes the Kohistan sequence, the Ladakh batholith, the Dras unit, the Spongtag klippe, the Indus molasse unit and the Shyok zone;
- (4) the Karakorum batholith: a late Tertiary zone of granitoid magmatism and metamorphism;
- (5) a Palaeozoic-Mesozoic continental shelf and slope sequence deposited on the southern margin of an Asian continent.

The following sequence of events is tentatively proposed:

- (1) Permian-Carboniferous continental rifting;
- (2) Triassic-Jurassic collapse of continental shelf, and formation of deep (oceanic?) basin;
- (3) Cretaceous formation of Kohistan-Ladakh magmatic arc, in response to subduction from the south as ocean closed;
- (4) Late Cretaceous-Eocene emplacement of Kohistan arc and of thrust sheets of Indus zone (magmatic arc units and Lamayuru unit) southwards onto Indian continental margin, as India approached and collided with magmatic arc;
- (5) silicic phases of Ladakh batholith (Palaeocene-Eocene) and Karakorum batholith (Miocene) may be related to subduction of oceanic basin between magmatic arc and Asian margin. Alternatively, they are late- and post-collisional products;
- (6) the Shyok zone, between the Ladakh and Karakorum batholiths, was emplaced to the south in Oligocene or Miocene time;
- (7) final collision between India, the magmatic arc and Asia in Oligocene-Miocene time was followed by continued crustal shortening which disrupted thrust units.

A/468. Angiolini, L., 1995a. Permian Brachiopods from Karakorum. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

Large collections of Permian brachiopods were assembled during four Italian expeditions (1986, 1991, 1992) on the Pakistan side of Karakorum. The first three expeditions visited the Upper Hunza valley and its laterals, Chapursan valley, Abgarch valley and Shimshal valley. The last expedition was led in the western termination of the Karakorum, in the Chitral-Baroghil-Karambar sector.

Permian brachiopods from western Karakorum (Baroghil pass) were first collected by Hayden (1915) and described by Reed (1925). A small collection of Permian brachiopods from Upper Hunza valley, collected by Desio (1962), was described by Fantini Sestini (1965).

Five brachiopod assemblages have been recognized, from the Asselian-Sakmariafl to the Murgabian-Midian. The first association, named Trigonotreta lyonsensis-Punctospirifer afghanus assemblage, has been collected in the Asselian-Early Sakmarian Gircha Fm. of Upper Hunza Valley. The second assemblage, Hunzina electa-Cleiothyridina ailakensis association, characterizes the Sakmariafl Lupghar Formation, Mb. 1 of Upper Hunza valley and the Sakmarian Lashkargaz Fm., Mb. 1 of Baroghil-Lashkargaz area (Chitral). The third assemblage, with Orthothetina convergens-Aldina hexilis as index-species, is Bolorian in age and it has been collected at the top of Lashkargaz Formation, Mb. 2 of Lashkargaz (Chitral). The fourth association, Waagenochoncha (Gruntochoncha) macrotubercolata-Callytharrella sinensis assemblage, is Kubergaridian in age and characterizes the Panjshah Formation, Mb. 1 of Upper Hunza Valley and the Lashkargaz Fm., Mb. 4 of Baroghil-Lashkargaz area. Finally the youngest association, named Stenoscisma armenica-Chapursania tatianae assemblage, has been collected in the Panjshah Formation, Mb. 2 of Upper Hunza Valley and it is Late Murgabian-Midian in age.

The evolution of the assemblages testifies for a warming of the climate conditions, due to the northward drifting of the Karakorum block during the Permian. Furthermore the youngest assemblages show a greater number of endemic taxa than the oldest ones which have species in common with W Australia, SE Pamir, Afghanistan and NW Tibet faunas.

A/472. Angiolini, L., 2001. Permian brachiopods from Karakorum (Pakistan) part. III. *Rivista Italiana de Paleontologia e Stratigrafia* 107(3), 307-344.

Late Wordian (Guadalupian) brachiopods from Member 2 of the Panjshah Formation in the Karakorum (N Pakistan) are described. The brachiopod assemblage, dated by the associated fusulinids and conodonts, consists of 29 genera (3 of which are questionable and 1 unidentifiable) of the orders Productida, Orthida, Rhynchonellida, Athyridida,

Spiriferida and Terebratulida. Hunzininae, a new subfamily of the Spiriferellidae is proposed; it includes *Darbandia* n. gen., with type species *D. vagabunda* n. sp. and *Elivina chapursani* n. sp. A third new species is assigned to the genus *Anchorhynchia* of the family Wellerellidae: *A. cimmerica* n. sp.

A quantitative biostratigraphic analysis demonstrates two major faunal changes in the *Elivina chapursani*-*Chapursania tatianae* Assemblage Zone of the upper part of Member 2, which are not strictly linked to lithological changes. This biozone is correlated with the brachiopod faunas of the Gnishik Formation of Armenia and those of the basal Takhtabulak Formation of SE Pamir.

The faunal elements of the *Elivina chapursani*-*Chapursania tatianae* Assemblage Zone are an admixture of wide-ranging, Tethyan (particularly abundant), Gondwanan and endemic (Cimmerian) genera, representing a transitional fauna and a biostratigraphic tool for intercontinental correlation, which are particularly problematic in this time interval. The Panjshah transitional fauna demonstrates the persistence of the Transhimalayan Province of the Cimmerian Region into the late Guadalupian, which originated at the end of the Cisuralian and occupied Armenia, Central Afghanistan, Karakorum and SE Pamir. It provides also some insights into the biodiversity pattern before the mass extinction at the end of the Guadalupian, and suggests that this event was as rapid as the end-Permian mass extinction, at least in Central Asia.

Key words: Permian, Brachiopods, biostratigraphy, Karakoram.

A/473. Angiolini, L., Brunton, H., Gaetani, M. & Andra, Z., 1997. The once and future quest: The Carboniferous in Karakorum. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 5.

The quest for the Carboniferous in the sedimentary cover of N Karakorum has been one of the main goals of the Italian expeditions from 1986-96. However, it takes us 10 years to discover and its relationships with the Permian and Devonian successions are still unclear. So the term quests and the adjectives once and future are really appropriate.

In the Upper Hunza Valley, and its side valleys, the sedimentary succession starts with the terrigenous Gircha Formation, which contains Lower Permian brachiopods in its middle part. No Carboniferous fossils have been found in this formation but its base is possibly Late Carboniferous.

Westward in the Upper Yarkhun Valley (Baroghil area), crinoidal limestones with shaly intercalations have been tentatively attributed to the Early Carboniferous (Gaetani et al., 1996), due to their stratigraphic position between the Late Devonian Shogram Formation and the Gircha Formation in the Baroghil Unit. But again no well-preserved fossils have been found to prove this age assignment.

The 1996 Italian expedition investigating the region from the Chapursan Valley (Upper Hunza Valley) to Chitral was finally successful in finding Carboniferous fossils near the Karambar Pass and in the Showar Shur area (Upper Yarkhun Valley).

The newly discovered fossiliferous Carboniferous succession belongs to a tectonic unit located northward of the Baroghil Unit and stacked above it along a SW vergent thrust. Westward of the Karambar Pass, the Carboniferous succession is deformed by intensive folding and thrust stacking. Eastward, the Carboniferous succession passes to a monotonous sequence of black slates and arenites probably ranging up into the Permian. To the north, this unit is tectonically bounded by the Tash Kupruk Unit. The base of the Carboniferous succession is still unclear: In the Showar Shur gully it is truncated by a SW vergent thrust, whereas in the Karambar Pass area it is not exposed. However, west of the Karambar Pass, on the left (southern) side of the valley, a thick terrigenous succession, probably including the Carboniferous, overlies the Devonian Shogram Formation.

From the base to the top, the Carboniferous succession consists of at least 200 m of black marly limestones with thick intercalation of massive bioclastic limestones, passing upward to 100 m of black marly limestones, calcareous siltites, calcareous sandstones and hybrid limestone containing Late Carboniferous brachiopods such as *Pustula* sp., *Rhipidomella* sp., *Choristites* sp., *Martiniopsis* sp., *Spirifer* sp., *Gypospirifer* sp., and *Composita* sp. At the top, about 30-50 m of massive, cross bedded sandstones and conglomerates crop out, followed by 20-40 m of varicolored calcareous siltites, arenites and hybrid limestones containing Moscovian to Kasimovian brachiopods such as *Densepustula* sp., *Brachythyris* sp., *Rhipidomella* sp., *Septacamera dowhatensis*, and *Alispirifer middlemissi*. This mixed sedimentary succession is topped by 30-100 m of massive bioclastic limestones containing crinoids and recrystallized brachiopods and corals. A very thick (500 m?) terrigenous unit follows, chiefly consisting of dark slates and fine arenites with coarse sandstones and conglomerates which may correspond to the Gircha Formation of the Baroghil, Sost and Gujal Units. In fact on the path leading from Suinji to the Karambar Pass brachiopods similar to those of the lower Permian Gircha Formation (*Trigonotreta* sp., *Spirelytha* sp.) have been collected in the

scree. The Carboniferous brachiopods of N Karakorum are very similar to those collected in the Late Carboniferous of the Himalaya (Manang, Spiti, Tibet).

Key words: Carboniferous, Karakoram.

A/474. Angiolini, L., Brunton, H., & Zanchi, A., 1999. Late Carboniferous brachiopods from Karakorum, Pakistan. *Rivista Italiana di Paleontologia e Stratigrafia*, 105, 3-22.

Carboniferous rocks from North Karakorum display sharp lateral variations in lithology and thickness suggesting accumulation in half-grabens during continental rifting between the Karakorum block and northern Gondwana. Different Carboniferous successions, belonging to distinct tectonic units, have been detected. Thin, poorly fossiliferous successions of arenites and crinoidal limestones contrast with very thick terrigenous-carbonate successions comprising two distinct fossiliferous horizons. The lower fossiliferous horizon yielded brachiopods (*Pustula* sp., *Rhipidomella* sp., *Choristites* sp., *Martiniopsis* sp., *Afghanospirifer* sp., *Gypospirifer* sp., *Composita* sp.) of Bashkirian age. The upper fossiliferous horizon, lying about 90 m above the former, contains corals, crinoids and brachiopods (*Densepustula* cf. *losarensis*, *Dowhatania sulcata* n. sp., *Brachythyris* sp., *Rhipidomella* sp., *Septacamera dowhatensis*, *Alispirifer middlemissi*) of Moscovian to Kasimovian age. The Carboniferous brachiopods of North Karakorum are similar to those collected in the Late Carboniferous of Central Afghanistan, Himalaya (Manang, Spiti, Tibet), and Lhasa Block (Xainza area).

Key words: Carboniferous, Brachiopods, Karakoram.

A/475. Angiolini, L., Gaetani, M. & Nicora, A., 1993. The Permian succession of the Baroghil area (E Hindu Kush). Abstract Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 57-58.

During the 1992 Pakistani-Italian expedition from Chitral to Karambar a complete Paleozoic succession was discovered and analyzed. In particular the Permian part of the succession is extensively exposed in the Baroghil-ShoWar Shur area. There was the great opportunity to visit the Baroghil section, which was studied by Hayden in 1914 and then only shortly visited by Talent and Tahirkheli in 1973. The area was then strictly closed because of the Afghan war.

Three stratigraphic sections for about 2000 m in development have been measured along the Permian part of the Paleozoic succession, with at least 250 samples collected.

The Lower Permian overlies Lower Carboniferous crinoidal packstones and it is represented by a quartzarenitic to litharenitic unit, at least 600 m-thick. This unit has been named Gircha Formation because of its correlatability with the Gircha Formation of the Hunza region.

Then a mixed carbonate-terrigenous succession, several hundreds m-thick follows, named Lashkargaz Fm. It consists of four members; the first, mostly terrigenous, contains Sakinarian conodonts (*Adetognathus* thus *paralautus*) and brachiopods (*Globiella* cf. *G. rossiae*, *Elivina tibetana*, *Spirigerella* sp., *Cleiothyridina ailakensis*) at the top. The second member consists of fusulinids packstones and limestones locally crowded with oncolites, corals and gastropods. The third member is only 40-50 m-thick and consists of siltites and arenites. The fourth member chiefly consists of limestones with chert rich in fusulinids, conodonts (*Sweetognathus whitei*, *Gondolella bisselli*, *Gondolella* Cf. *G. idahoensis*, *G. intermedia*, *Anchignathodus* sp., *Iranognathus* sp.), brachiopods (*Costiferina* sp., *Marginifera* sp.), corals and bryozoans. Marly lixnestones may be present. The age of the fourth member is Artinskian to Bolorian on the basis of conodonts.

At the top of the Lashkargaz Fm., above an erosional surface, the Gharil Fm. crops out. It consists of red microconglomerates and arenites with phosphate nodules. Then a huge peritidal dolomitic formation, 700 m-thick follows. In the lower and middle part of this formation Upper Permian small foraminifers (*Daqmarita chanackiensis*, *Paraglobivalvulina* sp., *Globivalvulina* sp., *Lanqella* sp., *Climacammina* sp.) have been detected, whereas in the upper part foraminifers and algae are present and may suggest an Early Jurassic age. The Paleozoic succession is repeated at least three times within three thrust sheets, with slightly different facies in the Baroghil area. On the contrary we have poor informations about most of the Mesozoic.

In contrast to the Upper Hunza and Shimshal valleys (Karakoram), where deep-water sediments are present from the Midian upwards, in the upper Yarkhun-Karambar area the shallow water environments seems to persist throughout the Permian. Correlations may be inferred with the Helmand Block in Central Afghanistan.

A/477. Angiolini, L. & Rettori, R., 1995. *Chitralina undulata* gen. n. sp. n. (foraminifera) from the Late Permian of Karakoram (Pakistan). *Rivista Italiana de Paleontologia e Stratigrafia* 100, 477-492.

Chitralina undulata gen. n. sp. n. (Foraminifera) has been found for the first time in the Permian successions of Karakoram (Pakistan). Biostratigraphic analysis based on fusulinids, brachiopods, conodonts and small foraminifers pointed out that *Chitralina undulata* gen. n. sp. n. occurs from the Kubergandian to the Late Murgabian-Midian. Morphologically, *Chitralina undulata* gen. n. sp. n., is comparable to *Rectostipulina quadrata* Jenny-Deshusses, 1985, differing from it by means of the thickness and composition of the test and for the presence of marked longitudinal costae. The stratigraphic range of *Rectostipulina quadrata* spans the Midian-Dorashamian time-interval. The new genus *Chitralina* is a very similar to the Permian genus *Giraliarella* Crespin, differing from it by means of the absence of transverse growth constrictions. The new family *Chitralinidae* fam. n., is also described herein.

Lithostructural mapping with preliminary structural studies have been made of Mansehra, Khaki, Rihar area district Mansehra at a scale, of 1:1000. An attempt has been made to delineate the boundaries of igneous and metamorphic rocks precisely. Physiographic/Stratigraphic studies and various structural contour diagrams have been drawn to determine axis of minor folds. Orientation of joints has been determined with the help of Rose diagram. Thin sections have been studied to determine different phases of deformation. Attempt has been made to analyse the strain with Flinn's and Ramsay's plots.

On the basis of microscopic and mesoscopic analysis it has been tried to interpret the structure and macroscopic scale. On the basis of Kinematic Studies, structure of the area is interpreted.

A/482. Anwar, J., Khan, R.D. & Mehdi, S.S., 1977. Geological report on Chromite deposits, Malakand division, N.W.F.P: Internal report of Pakistan Mineral Development Corporation, 86p.

This report describes the geological investigations which indicate that chromite is occurring as disseminated, massive, layered and nodular ore in the rocks of Dargai Ultramafic Complex. The complex is constituted by dunite, harzburgite, peridotite, serpentinite and gabbro. Significant and economically important occurrences of chromite are restricted to dunite bodies in the form of intermittent layers. The layers are generally concordant to sub-horizontal and vertical layering in the host rocks. Chromite is graded as low to medium quality refractory ore containing 7.8% to 41.4% Cr₂O₃; 10.0% to 32.17% FeO, 4.2% to 31.2% TiO₂ and 6.2% to 33.6% SiO₂. Traces of Nickel and Cobalt have been confirmed in the chromite ore samples. Since these elements and other trace elements like Platinum etc. are usually associated with ultramafic rocks, therefore, there is a possibility of finding these minerals in Dargai Ultramafic Complex. Other minerals like asbestos in ultramafic rocks and quartz in schistose group are also present in the area and could be considered for exploitation. A total tonnage of all grade chromite ore has been estimated to be 580,098 tonnes which includes 290,548 tonnes of probable and 289,550 tonnes of possible reserves.

A/486. Anwar, M., Beech, M. & Dennelle, R., 1992. Preliminary study of carnivore accumulation in the Upper Siwalik of the Pabbi Hills, Punjab, Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.51.

The fossil specimens for this study come from a locality (362) in the Soan Formation in the Pabbi Hills, situated about 4 km southwest of the village Sohawa and 10 km west of Kharian, District Gujrat. The formation consists of varicoloured sandstone, silts and minor beds of conglomerate. The age of the formation ranges from 2.5 MaBP to about 1 MaBP, but the locality's age is thought to be about 1.6 MaBP. Preliminary study of the fossils recovered through surface collection and excavation of the site indicates the presence of Accipitridae, Hyaenidae, Giraffidae, Proboscidae, bidae, Rhinocerotidae and perhaps Suidae at the locality. Seventeen axial elements including six skull fragments, thirty-eight appendicular elements, and fifty five indeterminate fossil fragments constitute the surface collection while the excavated bone accumulation is represented by seventy three axial elements including six skull fragments and five teeth, seventy two appendicular elements, and thirty three indeterminate fragments. Comparison of the surface and excavated specimens indicates that surface assemblage gives a reasonable indication of the wealth of a fossil site but the surface collection is unlikely to show the full faunal variety. Several taphonomic features of the assemblage recovered from the locality suggest a biological mode of selection with negligible influence of fluvial transportation and sorting. Such features that favour the biological accumulation are the presence of punctures and striations on a few herbivore specimens, larger number of individuals but only of six to eight families, domination of limb bones over other skeletal elements, and the presence of several skeletal parts of hyaena in the

mblage. The Influence of fluvial sorting was minimal' as the mblage contains a few articulated/semi-articulated very delicate skeletal elements (e.g. Oспенis), co-occurrence of denser and lighter bones and the virtual absence of any polished/rounded bones in the assemblage. All these features are Indicative of the assemblage being accumulated in a carnivore den, probably the Crocuta den whose remains are embedded along with the hunted bones due to sudden collapse of the den.

A/490. Appel, E., Schill, E., Gautarn, P., Zeh, O., Singh, V.K. & Waldhdr, M., 1998. Block rotations along the India-Asia collision zone - Their significance on different scales detected by Magnetic Remanences. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 13-15.

The India-Eurasia collision has caused crustal deformations of enormous magnitude. Patzelt et al. (1996) presented direct palaeomagnetic evidence for a "Greater India" prior to collision (about 1500 km extent of the northern margin at 89oE, compared to the present outline). Palaeodeclinations (PD) were used to estimate the magnitude of rotational underthrusting (Klootwijk et al. 1985, Appel et al., 1991, Patzelt et al., 1996). Angles between expected and observed PDs allow the quantification of oroclinal bending. Fig. 1 shows the principle of restoring the former margin of the Indian Plate by incremental rotations. The expected PD is calculated from the apparent polar wander path assuming no relative movements at the northern margin of India. Observed PDs are brought into coincidence with the expected PD by stepwise rotations starting in the western syntaxis (pivot PI) and progressing to the east. In Fig. 1, this is demonstrated for the simple case of two segments. The extent of 'Greater India' is finally determined by a parallel displacement of both segments to the north until the palaeolatitude matches the result of Patzelt et al. (1996) at a longitude of 89oE.

The reconstruction is disturbed by local and mesoscale block rotations superposed on the regional movements. Data from NW Zaskar (Appel et al. 1995) demonstrate that systematic differences even occur within a few tens of kilometres. In the Pamir and along the Indus Yarlung suture zone (Otofui et al. 1995) PDs are strongly dependent on major faults. In order to get a reliable data base for the incremental rotation model of Fig. 1, systematic palaeomagnetic sampling is conducted to recognise and to isolate block rotations on different scales. In a first step, about 140 sites have been sampled from the Tethyan Himalaya (TH) of Spiti (NW India), Larkya and Shiar areas

(Central Nepal). The TH rarely contains primary remanences, but is well known to record a stable secondary components carried by pyrrhotite. The remanence acquisition of pyrrhotite can be related to exhumation and cooling of the Central Crystalline and represents a thermoremanence with blocking temperatures around 300°C.

A nearly one-component behaviour (pyrrhotite only) is observed in the Larkya area. A systematic local scatter appears with a mean in situ remanence of Larkya area, $D=010$, $I=54$ (12 sites, $k=9.5$, $\alpha_{95}=13.6$). In the Shiar area, the pyrrhotite to magnetite ratio is decreasing towards the east. As a preliminary result from 4 sites, the pyrrhotite component yields an in situ direction of $D=205$, $I=-12$ ($k=82.6$, $\alpha_{95}=82.6$). In Spiti, magnetite dominates the magnetic remanence. The varying content of pyrrhotite can be related to a different grade of metamorphism. The magnetite component carries a syntectonic remanence direction ($k=14.4$, 26 sites, Lower Pin Valley), whereas for the pyrrhotite component of the Upper Pin Valley a consistent in situ remanence direction of $D=006$, $I=32$ (12 sites, $k=16.9$, $\alpha_{95}=10$) is obtained. In Fig. 2, the rotations in respect to 'stable' India are shown together with earlier results.

In our further study, several other areas will be sampled, and rotations on different scales will be analysed quantitatively to evaluate a more sophisticated model of oroclinal bending and rotational underthrusting.

During the course of regional mapping of Timurgara and Dir quadrangles, the corundum bearing rocks of Timurgara were briefly examined. The general rock type of this area is amphibolite intruded at random by igneous rocks of granodiorite, diorite and ultramafic (Peridotite, serpentinite and hornblendite) nature. Quartz veins and aplite and pegmatite dykes are also common. Sparsely dispersed corundum crystals are found in amphibolite rock south-east of Timurgara (34 49 lat. 71 53 long). The corundum is opaque and fractured and hence cannot be used as a gemstone. The crystals moreover, are much too few and thus the possibility of its use as an abrasive is also ruled out.

A/507. Arbaret, L., Burg, J.P., Chaudhry, M.N., Dawood, H., Hussain, S.S. & Zeilinger, G., 1998. Different sets of anastomosing shear zones in the "Kamila Belt", Kohistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 15-17.

The Kohistan Complex (NW Pakistan) is squeezed between the Indian and Asian continental plates [1]. Among the different units identified in the Kohistan Complex, the Kamila amphibolitic belt separates the Chilas calc-alkaline gabbro-noritic complex to the north from the deeper ultramafic Jijal Complex to the south [2]. The southern part of the "Kamila Belt" is mainly composed of retrograde metagabbro and norite with locally preserved igneous layering intruded by hornblende bodies and plagioclase-quartz±amphibole rich veins. The latter comprise synmagmatic differentiation veins that display the same mineralogical components as the bulk rock. The metagabbro and norite are deformed by numerous anastomosing shear zones with variable spacing and size [2]. In this poster we describe three sets recognized during fieldwork:

Set 1 is composed of conjugate; centimetre scale discontinuous shear zones (Fig. 1) that curve the homogeneous foliation and layering without important change in grain size. The conjugate directions are both striking 130°. One plunges 40°±10° to the NE and corresponds to southwestward thrusts. Conjugate shear zones plunge 20°±10° to the SW and lay along Riedel orientations consistent with a general southwestward sense of shear along a bulk plane dipping 40° to the NE. Limited grain size reduction and measurements of the curved foliations indicate shear strain $\gamma < 5$.

Set 2 is characterised by an anastomosing pattern of mylonitic shear zones (Fig. 2) with an average thickness of 10 cm and a marked grain size reduction. They result from the lengthwise connection of set I shear zones, the conjugate directions wrapping around lenses of less deformed gabbro. These centimetres to decametre big lenses have an average shape ratio of 2.5 with their long axis plunging to the Northeast. Set 1 shear zones may occur within the lenses. The anastomosing shear zones contain leucocratic, garnet-bearing veins due to partial melting of the mylonites which, therefore, are high temperature shear zones. The anastomosing shear zones occur also in the northeastern part of the garnet granulites of the Jijal Complex (Southwest of Patan). Grain size reduction points to shear strain higher than 5 within these shear zones.

Set 3 corresponds to 10 cm up to 5 m thick shear zones which are continuous and undulate with large wavelength over 50 m (Fig. 3). Shear took place along horizontal to 30° Northeast dipping planes striking 130°. Strong grain size reduction and presence of centimetre size rotated porphyroclasts of plagioclase derived from stretched pegmatitic veins indicate shear strain of more than 10.

Intersections observed in the field show that these 3 sets were formed successively. Nucleation and growth of set 1 and set 2 shear zones along the same conjugate directions are interpreted as progressive localisation of shear deformation at various scales during southwestward thrusting. Relationships between veins and shear zones indicate

that deformation began during the waning magmatic stage of the gabbro-noritic body. Set 3 shear zones occurred later and are post-dated by east-west striking, c.45° north dipping amphibolitic sheared rocks located in the Northeast part the study area [3]. They represent the ductile continuous shearing developed during the upper to lower amphibolitic facies retrogression.

A/509. Arbaret, L., Burg, J.P., Zeilinger, G., Chaudhry, M.N., Hussain, S.S. & Dawood, H., 1999. Pre-collisional deformation in the Kohistan complex (NW Pakistan). *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 5.

The Kohistan Complex (NW Pakistan) is a paleo-island arc obducted onto India after closure of the Tethyan Ocean at ca 55 Ma (Coward *et al.*, 1986). The plutonic rocks of the lower southern part of the Kohistan Complex are comprised of calc-alkaline meta-gabbro, hornblende-gabbro and diorite laccoliths that were emplaced during the arc activity (Khan *et al.*, 1993). In the Patan area, the coarse grained Sarangar gabbro lies to the north of, and above the deeper granulitic gabbro laccolith commonly attributed to the upper part of the Jijal Complex (Figure 1). The Sarangar gabbro is intruded, to the north, by hornblende-gabbro and diorite laccoliths. We describe the structures and textures related to primary composite strain overprinted by anastomosing shear zones due to sub-horizontal continuous SW-ward shearing from sub-solidus to amphibolite facies conditions. The deformation history is dated between 101 and 83 Ma, which is, therefore, older than the arc collision.

Two anisotropy intensities of the regional strain, defined by heterogeneously distributed foliations with associated mineral lineations, were recognized. The weak one (<20%) is recorded in the core of both the granulitic and the Sarangar gabbros. In the granulitic gabbro, it is associated with NW-dipping foliations bearing a NW-plunging lineation. In the Sarangar gabbro it is associated with an E-W trending sub-vertical foliations bearing a W-plunging lineation. These fabrics correspond to the shape preferred orientation if the magmatic assemblages characterized by cumulate textures. Their difference in orientation reflects differences of magmatic flow in separate plutons.

The higher anisotropy intensities (> 20%) progressively replaces towards the laccolith boundaries the low intensity magmatic fabric by plastic deformation of plagioclase and rigid rotation of pyroxene and other mineral phases. Local S-C structures and the angular relationship between the mineral fabric and magmatic layering indicate a bulk SW-ward shear recorded in the crystallised margins of the plutons. Therefore, these low and high anisotropy fabrics are related to the magmatic emplacement of the gabbros dated between 96 and 101 Ma (Anczkiewicz and Vance, 1997).

Further shear strain localization is responsible for three successive sets of shear zones that formed in a continuum from magmatic emplacement to solid state deformation during cooling of the plutons. Set 1 is composed of two populations of discrete, 1 m long and a few centimetres wide shear zones forming a Riedel association. One consists of normal SW-ward shear zones, which represent Riedel shears R. The second is composed of NE-dipping thrust P shear zones. Stable magmatic parageneses in the most deformed centre zones, cut by millimetre-thick feldspar-rich magmatic joints, point to sub-solidus conditions.

Set 2 is the most spectacular anastomosing pattern of mylonitic, N-dipping, SW-verging reverse shear zones branching into horizontal to W-dipping, SW-verging normal shear zones. The change in attitude accommodates the asymmetric shape at all scales of rock lenses whose their long axes plunge to the Northeast. The asymmetric shape and the strongly dominant SW-vergence indicate that set 2 shear zones developed during distributed, non-coaxial deformation. Partial melting in set 2 mylonites generated quartz-plagioclase-garnet bearing segregation veins pointing to temperatures exceeding 650°C under pressures of >0.8 GPa. The minimum age for set 2 shear zones is inferred from the 87 Ma old amphibole-epidote-paragonite assemblage that has partially overprinted the granulitic assemblage in the granulitic gabbro (Treloar *et al.*, 1990).

The lower amphibolite facies set 3 shear zones are differentiated by larger strain recorded in the thicker mylonitic zones and widening of the spacing between shear zones during cooling.

These three sets formed by growth and coalescence of set 1 shear zones leading to set 2 shear zones, which in turn have evolved into set 3 shear zones.

Laccoliths forming the lowest part of the Kohistan Complex have recorded the dynamic evolution during their magmatic emplacement from sub-solidus to solid state deformation. Regionally distributed magmatic-related fabrics and subsequent sets of anastomosing shear zones occurred successively between 101 and 83 Ma during SW-ward shearing, probably imposed by subduction of the Tethys lithosphere below the Kohistan arc Complex because the collision, around 55 Ma, is significantly younger.

Key words: Deformation, Kohistan complex.

A/510. Arbaret, L., Burg, J.P., Zeilinger, G., Chaudhry, M.N., Hussain, S.S. & Dawood, H., 2000. Pre-collisional anastomosing shear zones in the Kohistan arc, NW Pakistan. Ductile strain localization commonly forms a pattern of shear zones anastomosing around lenses of less deformed rock. Initiation and development of anastomosing shear zones are studied through description of the structures and deformation history of plutonic rocks that from the lower crust of the Kohistan arc. Structures and textures developed in these rocks result from primary magmatic to solid-state regional strain, overprinted by anastomosing shear zones. The primary strain was mainly acquired during magmatic emplacement at 100-90 Ma. Strain localization took place continuously from magmatic emplacement to solid-state deformation cooling of the plutons and formed their successive sets of shear zones. Set 1 is composed of associated discrete Riedel and thrust shear zones developed above solidus conditions during southwestward thrusting. Continuous deformation from solidus to amphibolite facies conditions between 100 and 83 Ma formed the second set of shear zones. The lower amphibolite facies set 3 shear zones are differentiated by larger strains recorded in the thicker mylonitic zones and enlargement of the spacing probably represents arc-related deformation during subduction of the Tethys oceanic lithosphere below the Kohistan arc.

A/512. Argles, T., Edwards, M. & Foster, G., 1999. Structural and metamorphic constraints on the evolution of the Main Mantle Thrust, eastern margin of the Nanga Parbat-Haramosh Massif, N. Pakistan. *Terra Nostra* 99 Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 6-7.

Organic research is increasingly concerned with the early stages of mountain-building, as well as the pre-collisional configuration of orogenic regions. Recent advances in geochemical, particularly isotopic, techniques have allowed together constraints to be placed on orogenic processes, and at the same time techniques have become more discriminating. Theoretically this could result in the determination of more detailed orogenic histories. To complement these geochemical methods, however, similarly detailed and rigorous fieldwork is required.

Investigations on the evolution of the Nanga Parbat Haramosh Massif (NPHM) provide a case in point. While isotopic studies emphasized the rapid recent exhumation of the massif (e.g. Zeitler et al. 1982, 1993) other studies (e.g. Wheeler et al. 1995) recognized the importance of the polymetamorphic nature of the Indian plate rocks in particular. Neogene events in the NPHM have obscured much of its earlier evolution, but the degree of overprinting varies within the massif. Structural and metamorphic overprinting are not always concentrated in the same parts of the massif, and the different properties of basement and cover rocks results in both strain partitioning and various degrees of metamorphic reworking. The western margin is dominated by Neogene processes (e.g. the Liachar thrust, Butler and Prior 1988), whereas the eastern margin preserves many earlier Himalayan structures. Structural mapping

of the eastern margin reveals a ductile contact zone preserving many features of the original Main Mantle Thrust (MMT) which emplaced the Ladakh Island Arc (LIA) over the Indian margin in the late Cretaceous. The sequence of ductile deformation was controlled both by the contrasting rheologies of the LIA and the MMT footwall, and the changing thermal regime during subduction, collision and burial, which may have included dissipative shear heating. Preliminary P-T estimates indicate conditions during southward thrusting on the MMT of Ca. 650°C and 9.5 kbar; this thermobarometry is directly correlated with MMT thrust fabrics showing top-to-the-south shear sense (after unfolding of the syntaxial antiform).

An episode of later deformation (post-dating garnet growth) in some cover units took place at Ca. 500°C and 7.4 kbar. These estimates are from rheologically weak, staurolite-grade metasediments just west of the MMT mylonites on the eastern margin. The kinematics of these rocks are complex, with conflicting shear senses in adjacent layers. We interpret this as indicating partial overprinting of the metamorphic assemblages (and modification of the tectonic fabrics) during an episode of extensional (N-directed) shear in the footwall of the MMT. The extensional strain was partitioned into this narrow zone due to the comparative strength of adjacent units (overlying mafic MMT mylonites and underlying coarse orthogneiss, or basement paragneiss). No direct dating of this event has yet been attempted, but if there was significant exhumation of the region at this time, it could correspond to a period of cooling at around 25-16 Ma previously recognized in N. Pakistan (Treloar et al., 1989; Chamberlain et al., 1991).

The concordant fabrics and lithological boundaries on either side of the contact are only disrupted by a NW vergent, brittle thrust south of the village of Subsar (Indus Gorge) which cross-cuts the steepened MMT zone. This thrust appears to be related to the neotectonic Raikhot fault on the western margin of the massif and is interpreted as an expression of the regional tectonics at the western termination of the Himalayan arc (Seeber and Pêcher 1998). This late thrusting followed formation of the syntaxial antiform in Neogene times, and is the sole major evidence for Neotectonic activity on this segment of the eastern margin.

A/513. Argles, T., Edwards, M. & Foster, G., 2000. Synconvergent, Ductile N-Directed Shearing on the Western Margin of the Nanga Parbat Syntaxis, N. Pakistan. Abstract Volume, 15th Himalaya-Karakoram-Tibet Workshop, Chengdu (China), 128-129.

A key issue in orogenic research today is the recognition and explanation of normal faulting in the heart of collisional mountain belts. The active Himalayan system remains an ideal locality for studying this phenomenon, both as E-W synconvergent extension of the Tibetan plateau and normal motion on the South Tibetan Detachment System (STDS). However, these processes are difficult to correlate with the evolution of the northwest Himalaya, particularly the Nanga Parbat syntaxis where a Neogene tectono-thermal overprint partially obscures the early collisional history. An integrated programme of structural mapping, petrography, thermobarometry and isotopic dating is presented that places important constraints on both the early and pre-Himalayan evolution of the syntaxis. These data include evidence for synconvergent, ductile extension predating syntaxis development, and improved isotopic correlation of the tectonic units with the familiar central Himalayan thrust sheets, building on the work of Whittington et al. (1999).

Recent studies have focused on the rapid exhumation of the Nanga Parbat-Haramosh Massif (NPHM) during the last 10 Ma and the related Neogene thermal effects dominating the core of the massif (e.g. Zeitler et al. 1982, 1983). However, the degree of both structural and metamorphic Neogene overprinting varies within the massif, becoming weaker away from the summit region. In addition, the considerable variation in rock-type outside the gneissic core results in both strain partitioning and various degrees of metamorphic reworking. Thus several workers (e.g. Wheeler et al. 1995) could reconstruct elements of the early and pre-Himalayan history from field relations and mineral assemblages virtually untouched by Neogene processes. The eastern margin of the massif, in contrast to the active western margin, has remained largely unchanged during the Neogene, except for essentially passive rotation on the limb of the major syntaxial antiform. The original, ductile Main Mantle Thrust (MMT), which emplaced the Ladakh Island Arc (LIA) over the Indian margin in the Late Cretaceous, is preserved in a steepened orientation. Dextral shear sense indicators in this steep fabric can be clearly related to southward thrusting on the MMT at peak metamorphic conditions during the early Himalayan stage (600~700°C and 900~1200 Mpa) once the N-S trending syntaxial antiform is unfolded.

Detailed structural mapping and petrography has revealed distinct horizons of sinistral shear in the first few kilometers of Indian Plate rocks below the MMT (i.e. the upper most MMT footwall). Localities characterized by sinistral shear are generally in rheologically weak lithologies (e.g. mica schist), but there are some localities where an unambiguous timing relationship between sinistral and dextral shear sense indicators exists. Sinistral shear

overprints dextral in all cases, most commonly in the form of discrete, mylonite, sinistral shear zones cross-cutting dextral shear fabrics. In some cases, these sinistral shear zones are associated with leucogranite material. The sinistral shearing post-dated prograde garnet growth but is characterized by ductile behaviour and microstructures indicating temperatures above 300°C. Thermobarometry on schists re-worked during this event suggest deformation occurred at 500~500°C and 600~900 Mpa. We interpret this deformational event as an episode of N-directed, extensional shear in the footwall of the MMT (prior to the syntaxial folding).

The amphibolite grade of deformation suggest (a) that this event occurred soon after the metamorphic peak before substantial cooling or decompression, and (b) that the extension ceased before the rocks entered the greenschist field. This suggests that exhumation during this event occurred at a deeper level than previously documented, mostly greenschist-grade extension in northern Pakistan (Burg et al., 1996; Vince and Treloar 1996). Dating of the extensional fabrics is planned; at present the extensional event is bracketed by garnet growth (40-45 Ma, Foster et al. 1998) and Ar-Ar mica and hornblende cooling ages on the eastern margin (ranging from ca. 10~40 Ma, Zeitler and Chamberlain, 1991; Winslow, 1996; Whittington, 1997). Thus the extension could correlate with a period of cooling at around 25~16 Ma previously recognized in N Pakistan (Treloar et al., 1989; Chamberlain et al., 1991), tentatively related to orogen-wide extensional tectonics on the STDS; or it could have occurred at an earlier stage, and/or on a different fault, suggested in the recent model by Chemenda et al., (2000).

A/519. Arif, M., 1990. Mineral chemistry of the chromite occurrences from Shangla (Swat), N.W.F.P. and Bela, Baluchistan. M.Phil. Thesis, University of Peshawar, 166p.

The partly to wholly serpentinized ultramafic rocks of the Shangla and Bela areas contain disseminated grains and massive bodies of segregated chromite. Field, petrographic, and chemical characteristics of the segregated chromite from both the areas resemble those of podiform chromite deposits. Compared to accessory, the segregated chromites generally contain higher amounts of Cr, Mg, and lower Fe, Al and Mn. Composition also varies amongst as well as within individual grains. Such variations are much more pronounced in the accessory chromite due probably to a greater degree of re-equilibration with the associated silicates. The within-grain variation is more frequent and drastic in the Shangla chromite and mostly involves enrichment in Fe, (Mn and Ti), and depletion in Al, Mg, and Cr, leading to the development of ferritchromite and, rarely, magnetite along fractures and margins of individual grains. The composition of Bela olivine ranges from FO 89.0 to FO 91.2 in the silicate ultramafites. The very high 100 $Mg/(Mg+Fe)$ ratios of mafic minerals (olivine: 99.7; clinopyroxene: 97.1-98.0; and orthopyroxene: 96.0-96.4) in chromitites reflect an $Mg=Fe$ exchange between them and the associated chromite. The high to very high 100 $Cr/(Cr+Al)$ ratios of their chromite group the Bela rocks with the alpine peridotites of arc-related petrogenesis. The Shangla rocks display cumulus texture but contain abnormally magnesian olivine (FO 96.0-98.5). The 100 $Cr/(Cr +Al)$ ratios (56-86) of their chromite suggest a complex origin. These rocks may have formed under conditions transitional between those of arc and oceanic settings. The Shangla rocks underwent a low to ?medium-grade metamorphism as indicated by the development of talc and antigorite. This prograde metamorphic process probably also accompanied for the drastic chemical zoning of the Shangla chromite.

A/521. Arif, M., 1994b. Occurrence of maucherite in Shangla (Swat), northwestern Pakistan. Geological Bulletin, University of Peshawar 27, 131-132.

Besides zoned grains of chrome spinel, the variably altered ultramafic rocks of the Swat valley ophiolite, northwestern Pakistan, contain trace amounts of highly reflectant phases. These are mostly sulphides. However, the finely disseminated, discrete grains in some of the completely serpentinized samples from the Barkotaki village in Shangla were found to be of arsenide. The chemical composition of this latter phase is rather simple and consist almost entirely of Ni (57.33 – 59.14 at. %) and As (39.11 – 41.04 at. %), with only traces of Fe (<0.06 – 0.33 at. %), Co (0.83 – 1.02 at. %), and S (0.28 – 0.66 at. %). The calculated metal (Ni + Fe + Co + Cu) to arsenic ratio ranges from 1.406 – 1.514 and corresponds to that of maucherite (Ni_3As_2), one of the three arsenides of nickel (i.e. niccolite, maucherite and orcelite or rammelsbergite).

A/522. Arif, M., 1996. Chemical characteristics of chrome spinel in the magnesite-rich rocks from Swat, northwestern Pakistan. *Geological Bulletin, University of Peshawar* 29, 9-15.

The magnesite-rich rocks (magnesite $\pm$ talc $\pm$ quartz $\pm$ fuchsite $\pm$ tourmaline $\pm$ chlorite), which locally host emerald mineralization, contain trace to accessory amounts of disseminated grains as well as nodular segregations of chrome spinel. The spinel displays unusually high Cr/(Cr+Al) and low Mg/(Mg+Fe²⁺) ratios. A detailed investigation reveals that the present chemical characteristics of the chrome spinel are probably the result of modification related to the formation of the host rocks by a low-grade metamorphism in the presence of a CO₂-bearing fluid.

A/523. Arif, M., 2000a. Petrology and mineralogy of the Ahingaro serpentinites, Kabal (Swat), NW Pakistan: Implications for their tectonic setting and timing of emplacement. *Geological Bulletin, University of Peshawar* 33, 29-38.

A small (-6 x 1 km), lens-shaped body predominantly consisting of ultramafic rocks, occurs at the Ahingaro Banda Kandao near Kabal, Swat. This body is enclosed within the Kamila amphibolites that constitute the basal part of the intraoceanic Kohistan island arc. The ultramafic rocks are highly fractured and almost completely serpentinized. They consist of abundant fine-grained serpentine, varying amounts of a variety of bastites after orthopyroxene, veins and stringers of magnetite, invariably altered disseminated grains of chrome spinel, trace amounts of relict clinopyroxene and traces of rather sparsely disseminated granules of sulphide (pentlandite). Some of the samples also contain thin veins of calcite.

The Ahingaro serpentinites display both pseudomorphic and non-pseudomorphic textures. The serpentine predominantly consists of the lizardite and chrysotile varieties, whereas the antigorite occurs rarely. The chrysotile is mostly distributed as veins. A detailed petrographic and mineralogical comparison with the serpentinized rocks of the Indus suture melange zone suggests that the Ahingaro serpentinites most probably represent the original Tethyan lithosphere that served as a substratum or platform for the construction of the KIA. These rocks were emplaced together with the enclosing amphibolites along the Kohistan fault during post-Early Oligocene.

A/524. Arif, M., 2000b. Zincian, manganiferous chrome spinel from the Swat valley ophiolite, NW Pakistan. *Geological Bulletin, University of Peshawar* 33, 103-110.

Metamorphosed basic volcanic rocks of the Swat valley ophiolite locally contain trace to accessory amounts of disseminated chrome spinel. The grains of chrome spinel are invariably altered along margins and fractures. They, therefore, consist of low reflectance (grey) cores patches that are bordered and traversed by highly reflectant (bright) zones. Compositionally. The cores are high-Cr. almost Mg-free chromites, containing unusually high amounts of Zn and Mn, and may thus be described as a solid solution of three end-member spinel compositions, i.e. chromite, gahnite and galaxite. The bright zones of alteration lack any notable amount of Zn or Mn and range from Cr-magnetite to magnetite. Compositional and textural relationships suggest that the markedly zincian and manganoan character of the spinel grains is the result of a hydrothermal activity that took place before the magnetite-forming alteration process. The Zn-, Mn-bearing hydrothermal fluids either reacted with the parental lava prior to or during its solidification or, alternatively, invaded the host rocks after their formation leading to the addition of Zn and Mn to, and concomitant removal of Mg from the already crystallized magmatic chromite through dissolution-recrystallization.

A/525. Arif, M., 2001. The Gujar Kili area, Swat, NW Pakistan: Nickeliferous phases in the emerald-hosting rocks. Abstracts, 4th Pakistan Geological Congress, Islamabad, 1-2.

The occurrence of three different types of mélanges, namely the blueschist mélange, the greenschist mélange and the ophiolitic mélange, mark the westward continuation of the Indus suture zone in northwestern Pakistan. The ophiolitic member of this group of mélanges occurs as blocks that are distributed within the metamorphosed sedimentary rocks of the northern margin of the Indo-Pakistan plate. In addition to typical ophiolitic lithologies, e.g.

mafic-ultramafic plutonic rocks, pillow lavas and pelagic sediments, the ophiolitic *mélange* contains carbonate (magnesite and, rather rarely, dolomite)-rich assemblages, which at places, such as the Mingora and Gujar Kili areas, host emerald deposits. Abundant quartz veins, which at places constitute stockworks, have traversed these rocks. Locally, their close spatial association with serpentinized ultramafic rocks suggests that the rocks under discussion might have formed from the latter through the process of carbonate-alteration. In addition to abundant magnesite and/ or dolomite, the emerald-hosting rocks of the Gujar Kili area contain talc or quartz as an essential mineral. Besides, chrome spinel (chromite, ferritchromite and/or Cr-magnetite) is a common accessory constituent of these rocks. Some of the rocks, especially those invaded by quartz veins, contain tourmaline and/or chlorite. Furthermore, some of the magnesite rich rocks of the Gujar Kill area contain highly reflectant opaque phases, which occur in the form of very fine-grained disseminations as well as veins. A detailed investigation through chemical analyses reveals that these phases are of two types, i.e. sulphide and sulpharsenide. The former category includes pentlandite, violarite, mackinawite, pyrrhotite and pyrite. Gersdorffite and, rarely, cobaltite are the two sulpharsenides that occur in the emerald-hosting magnesite-rich rocks of the Gujar Kili area. As they locally occur as veins that cut across the host magnesite-rich rocks, the formation of these phases clearly post-dates that of the latter. Some of these phases, e.g. gersdorffite, are reported to occur as inclusions in the Swat emeralds. This clearly suggests that the hydrothermal activity that resulted in emerald mineralization in Swat is also responsible for the formation of the investigated sulphides and sulpharsenides.

A/527. Arif, M., Fallick, A.E. & Moon, C.J., 1996. The genesis of emeralds and their host rocks from Swat, northwestern Pakistan: a stable isotope investigation. *Mineralium Deposita* 31, 255-268.

Emerald deposits in Swat, northwestern Pakistan, occurring in talc-magnesite and quartz-magnesite assemblages, have been investigated through stable isotope studies. Isotopic analyses were performed on a total of seven emeralds, associated quartz (seven samples), fuchsite (three samples) and tourmaline (two samples) from the Mingora emerald mines. The oxygen isotopic composition of emeralds shows a strong enrichment in ^{18}O and is remarkably uniform at $+15.6 \pm 0.4\text{permil}$ (1sgr, $n = 7$). Each of the two components of water in emerald (channel and inclusion) has a different range of hydrogen isotopic composition: the channel waters being distinctly isotopically heavier ($\delta\text{D} = -51$ to -32permil SMOW) than the other inclusion waters ($\delta\text{D} = -96$ to -70permil SMOW). Similarly the oxygen isotopic compositions of tourmaline and fuchsite are relatively constant ($\delta^{18}\text{O} = +13$ to $+14\text{permil}$ SMOW) and show enrichment in ^{18}O . The $\delta^{18}\text{O}$ values of quartz, ranging from $+15.1$ to $+19.1\text{permil}$ SMOW, are also high ($+16.9 \pm 1.4\text{permil}$ 1sgr, $n = 7$). The mean δD of channel waters measured from emerald ($-42 \pm 6.6\text{permil}$ SMOW) and that of fluid calculated from hydrous minerals δD calculated ($-47 \pm 7.1\text{permil}$ SMOW) are consistent with both metamorphic and magmatic origin. However, the close similarity between the measured δD values of the hydroxyl hydrogen in fuchsite (-74 to -6permil SMOW) and tourmaline (-84 and -69permil SMOW) with pegmatitic muscovite and tourmaline suggests that the mineralization was probably caused by modified (^{18}O -enriched) hydrothermal solutions derived from an S-type granitic magma. The variation in the carbon and oxygen isotopic composition of magnesite, locally associated with emerald mineralization, is also very restricted ($\delta^{13}\text{C} \text{ sim } -3.2 \pm 0.7\%$, PDB; $\delta^{18}\text{O} \text{ sim } +17.9 \pm 1.27\text{permil}$ SMOW). On the basis of the isotopic composition of fluid ($\delta^{13}\text{C} \text{ ap } -1.8 \pm 0.7\text{permil}$ PDB; $\delta^{18}\text{O} \text{ ap } +13.6 \pm 1.2\text{permil}$ SMOW calculated for the 250-550 °C temperature), it is proposed that the Swat magnesites formed due to the carbonation of previously serpentinized ultramafic rocks by a CO_2 -bearing fluid of metamorphic origin.

A/528. Arif, M. & Hussain, S.T., 1992. Upper Siwalik vertebrate faunal correlation in sub-Himalayan. Abstracts, First South Asia Geological Congress, Islamabad, p.5.

The Upper Siwalik fluvial sedimentary history and paleontology of the Mangla-Samwal anticline (Azad Kashmir) have been studied, and faunal correlations are made with the Bhattani-Marwat Range in the west, Jammu Hills in the east and Pabbi Hills in the south. The rocks in this anticline are divided into the Samwal and Kakra Formations (ca. 3.4 to 1.1 Ma). The Samwal Formation was deposited by large and small river systems, whereas the conglomerates of the Kakra Formation were deposited as a result of the uplift of the Pir Panjal Range.

The study of vertebrate fossils indicates that the overall faunal composition in these areas is identical and they contain the characteristic Upper Siwalik fauna (e.g. *Equus*, *Cervus*, *Hexaprotodon* and *Elephas*). The faunal similarity also suggests that during the Plio-Pleistocene (the time for deposition of the Upper Siwaliks) these areas belonged to the same bio-province.

A/529. Arif, M. & Jan, M.Q., 1992a. Mineral chemistry of chromite and associated phases from Shangla, NW Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.5.

The partly to wholly serpentinized ultramafic rocks of the Shangla area, constituting the northern part of the Mingora ophiolitic melange, contain disseminated grains and massive bodies of segregated chromite. Field, textural, and chemical characteristics of the segregated chromite closely resemble those of podiform chromite deposits. The chemical composition of the chromite varies considerably from sample to sample with model proportion, from grain to grain within the domain of a thin section, and from core to margin within individual grains. In general, the segregated chromites are richer in Cr, Mg, but poorer in Fe, Al and Mn than the accessory chromites. The inter- and intra-granular chemical variations are much more common and drastic in the case of accessory chromite due probably to a greater degree of subsolidus re-equilibration with the associated silicates. The intragranular variation, probably a result of alteration, mostly involves enrichment in Fe, (Mn and Ti), and depletion in Al, Mg, and Cr, leading to the development of ferritchromite and, rarely, magnetite along fractures and margins of individual grains.

The Shangla rocks display cumulus texture but contain abnormally magnesian olivine (Fo₉₆-G_{98.5}). The 100Cr/(Cr+Al) ratios of their chromite suggest a complex origin. These rocks may have formed under conditions transitional between those of arc and oceanic settings. The Shangla rocks underwent a low-to medium grade metamorphism as indicated by the development of talc and antigorite. This prograde metamorphic process probably also accounted for the drastic chemical zoning of the Shangla chromite.

A/530. Arif, M. & Jan, M.Q., 1992b. Mineralogy of the Indus Suture ophiolite and an investigation of the associated mineralizations in Swat, NW Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 4-5.

The Main Mantle Thrust (MMT), which signifies collision of the Indo-Pakistan plate with the Kohistan island arc in northwestern Pakistan, is marked by the occurrence of an assorted zone of rock sequences. These consist of blueschist, greenschist and ophiolitic mélanges and are well exposed and easily accessible in the region between Mingora town and Lilauni village of the Swat valley. The ophiolitic rocks in this area constitute a discontinuous belt of mafic-ultramafic and metasedimentary units which occur as thrust sheets and lenses incorporated within the continental metasediments of the Indo-Pakistan plate. The mafic and ultramafic rocks include bodies of peridotite, metamorphosed gabbros, greenstone, metabasalt and pillow lavas. The metasedimentary rocks, comprising both calcareous and siliceous varieties, are interbedded with lavas. The quartz-rich metasediments are locally manganeseiferous.

The varying degree of alteration of the ultramafic rocks has, at places, given rise to a zonal pattern consisting of a core of least altered dunite and peridotite surrounded by a broad and extensively developed zone of partly to wholly serpentinized rocks followed by a locally developed peripheral shell of talc-magnesite lithologies. Besides hosting uneconomically small, lenticular bodies of chromite and containing disseminated grains of chrome spinel, the relatively fresh and the partly serpentinized rocks of the central and middle zones contain tiny grains of heazlewoodite, millerite and, rarely, relict pentlandite. The mineralization of Ni in the wholly serpentinized rocks is mostly in the form of an arsenide, maucherite. In contrast, the non-oxide opaque mineralization in the talc-magnesite rocks include more Fe-rich sulphide phases such as phases such as pentlandite, pyrrhotite, violarite and

secondary Ni-pyrite. Locally, the talc-magnesite rocks also contain tiny grains of gersdorffite and host emerald deposits which are being mined, notably near the Mingora town.

The non-carbonatized ultramafic rocks, apparently 'residual' peridotite in chemistry, are characterized by high to very high amounts of MgO [100MgI(Mg+Fe)=87-94] and very low to low contents of CaO (mostly less than 2.0 wt %) and Al₂O₃ (not more than 3.0 wt %). The olivine in these rocks, occurring both as veins as well as a matrix phase with serpentine and, rarely, pyroxene, is also very highly magnesian [100MgI(Mg+Fe)=89-98]. It is usually associated with abundant grains and host preferentially oriented, submicroscopic lamellae of magnetite. The grains of pyroxene, dominantly diopside, have bent and kinked cleavages, are locally spindle-shaped and usually partly to wholly bastitized. The serpentine in these rocks is almost exclusively antigorite displaying interpenetrating textures. The grains of chrome spinels are invariably zoned with dark gray Cr-rich cores surrounded by thin to fairly thick and highly reflecting rims of ferritchomite and/or magnetite containing higher amounts of NiO (up to 1.5 wt %). In contrast, chrome spinel in the talc-magnesite rocks is a high Cr chromite without any compositional zoning. Moreover, these rocks are devoid of any of the primary mafic silicates, i.e., olivine and pyroxene.

The field and mineralogical characteristics indicate that these ophiolitic rocks suffered a prograde greenschist facies metamorphism under oxidizing conditions in the presence of abundant CO₂-rich hydrous fluids. The antigorite-serpentinites and talc-magnesite assemblages, so developed, at the expense of the ultramafic rocks, represent a gradient in the H₂O and CO₂ contents of the original fluid. Although the fluids were dominantly metamorphic in origin, they probably carried a Be-rich and S- and As-bearing hydrothermal/magmatic component that, at places, gave rise to the mineralization of emerald and sulpharsenides in the talc-magnesite rocks.

A/531. Arif, M. & Jan, M.Q., 1993. Chemistry of chromite and associated phases from the Shangla ultramafic body in the Indus suture zone of Pakistan. In: Treloar, P.J. & Searle, M.P. (Eds.), Himalayan Tectonics. Geological Society London, Special Publication 74, 101-112.

The partly to wholly serpentinized ultramafic rocks of the Shangla area constitute the northern part of the Mingora ophiolitic mélange which lies along the Main Mantle Thrust (MMT) zone between the Kohistan island arc and the Indo-Pakistan plate. These rocks contain disseminated grains and massive bodies of segregated chromite. Field, textural, and chemical characteristics of the segregated chromite closely resemble those of podiform chromite deposits. The chemical composition of the chromite varies considerably from sample to sample with modal proportion, from grain to grain in the domain of a thin section, and from core to margin within individual grains. In general, the segregated chromites are richer in Cr and Mg, but poorer in Fe, Al and Mn than the accessory chromites. The inter- and intragranular chemical variations are much greater and more common in the case of accessory chromite due probably to a greater degree of subsolidus re-equilibration with the associated abundant silicate matrix. The intragranular variation, probably a result of alteration, mostly involves enrichment in Fe, Mn (and Ti), and depletion in Al, Mg and Cr, leading to the development of ferritchromite and, rarely, magnetite along fractures and margins of individual grains.

The studied rocks from the Shangla area display cumulus textures but contain abnormally magnesian olivine (Fo_{96.0-98.5}). The 100Cr/(Cr + Al) ratios of their chromite suggest a complex origin. These rocks may have formed under conditions transitional between those of arc and oceanic settings. The Shangla rocks underwent a low- to ?medium-grade metamorphism as indicated by the development of talc and antigorite. This prograde metamorphic process probably also accounted for the extreme chemical zoning of the Shangla chromite.

A/532. Arif, M. & Khattak, M.U.K., 1999. The emerald-hosting magnesite-rich rocks from Swat, NW Pakistan. Geological Bulletin, University of Peshawar 32, 63-70.

The Main Mantle Thrust melange zone in Swat contains carbonate rich rocks (Manganese ± talc ± quartz ± chrome spinel/ Cr-magnetite / ferritchromite ± fuchsite ± tourmaline ± chlorite) which locally host emerald mineralization. Detailed field and mineralogical studies suggest that these rocks were probably formed by talc carbonate alteration of the spatially associated, previously serpentinized ultramafic rocks in the area. This transformation may have taken place at 250 – 550 °C and was probably caused by CO₂ – bearing fluid released by the metamorphism of the underthrust sedimentary rocks of the Indian Plate.

A/533. Arif, M. & Moon, C.J., 1994. Occurrence, chemistry and genesis of the nickel-rich phases in the ultramafic rocks from Swat, northwestern Pakistan. *Geological Bulletin, University of Peshawar* 27, 29-41.

Trace amounts of finely disseminated Ni-rich phases, including heazlewoodite, pentlandite, millerite, godlevskite, violarite and awaruite, occur in the variably serpentinitized ultramafic rocks of the Swat valley. The mode of occurrence, textural relationships with each other and with the associated silicate and oxide phases, relative modal abundance and chemical variation; all indicate that only the pentlandite represents the original sulphide phase. The rest are derived from pentlandite by the process of alteration. The additional amount of Ni, required for the conversion of pentlandite to heazlewoodite and other Ni-richer phases, was possibly derived by the serpentinization of primary olivine.

A/534. Arif, M. & Moon, C.J., 1996a. Chemistry of tourmaline from the emerald-hosting rocks in Swat, NW Pakistan. *Geological Bulletin, University of Peshawar* 29, 81-89.

The ophiolitic emerald-hosting carbonated ultramafic rocks (magnesite + talc and / or quartz $\pm$ chrome spinel) in the Swat valley contain disseminated grains, clusters and veins of tourmaline and / or fuchsite. These late-stage hydrothermal minerals are especially abundant where the host rocks are traversed by ubiquitous veins and stockworks of quartz. Crystals of emerald, tourmaline and fuchsite also occur in the quartz veins. Besides, the metasedimentary rocks that are spatially associated with the emerald's host rocks also contain tourmaline. In contrast to that in the metasediments, tourmaline in the emerald-hosting altered ultramafic rocks and the invading quartz veins contain variable but distinctly high amounts of Cr_2O_3 , MgO and NiO, and relatively low concentration of TiO_2 . These chemical features, mode of occurrence and nature of associated phases suggest that the tourmaline may have been deposited from Si-rich, Al-, Be-, B- and K-bearing hydrothermal fluids which passed through and extracted Mg, Cr and Ni contents from the host carbonated ultramafic rocks.

A/535. Arif, M. & Moon, C.J., 1996b. The platinum-group element geochemistry of chromitites and silicate rocks from Swat, northwestern Pakistan. *Geological Bulletin, University of Peshawar* 29, 1-8.

The concentrations of the platinum-group elements (PGE) and Au were determined in a limited number of samples which represent chromitites, altered ultramafic and mafic rocks of Swat valley ophiolite. The PGE characteristics of the chromitites mostly conform to trend exhibited by the podiform chromitites. However, being sulphide-poor and containing Cr-rich chromite, the Pd content of one of the samples is anomalously high compared to similar chromitites from other areas. This enrichment in Pd is probably caused by a localized hydrothermal activity. The Ir content of the chromite-poor, altered ultramafic rocks is remarkably uniform (4ppb) and close to the values in mantle materials but their Pd (10 ± 3.7 ppb) and Au (5 ± 3.5 ppb) abundance are distinctly higher than the latter. These features of PGE and Au concentration of the host ultramafic rocks are consistent with an origin involving partial melting followed by hydrothermal alteration.

A/537. Arif, M. & Moon, C.J., 1997. Mineralogy and geochemistry of ultramafic rocks from the Indus Suture ophiolite in Swat, NW Pakistan: Petrogenetic implications. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p.9.

In the area around Mingora (Swat), the Main Mantle Thrust (MMT) is exposed in the form of a wedge-shaped complex zone containing lithologies with diverse geochemical characteristics and genetic affinities (blocks and slices of blueschist, greenschist, bodies of ultramafic rocks, mafic plutonic and volcanic rocks as well as metasediments) separated by faults of different ages. This assortment of rocks, collectively termed as the Main Mantle Thrust Mélange Group (MMTMG), is distinguished into three principal groups, each of which is itself a composite of lithologies, or a mélange -the blueschist mélange, greenschist mélange and ophiolitic mélange.

The ultramafic rocks (locally containing chromite pods), constituting a part of the ophiolitic member of the MMTMG, occur as lenticular bodies, distributed along the marginal part of the Indo-Pakistan plate. The majority of these rocks consist of abundant, fine grained serpentine, subordinate amounts of partly to completely bastitised, medium to coarse grained orthopyroxene, trace to accessory amounts of partly altered (zoned with ferritchromite and/or magnetite) chrome spinel, variable proportions of olivine, and accessory amounts of diopside. Thus the ultramafic rocks are dominantly harzburgitic in mineralogy and, therefore, the ophiolite as a whole can be classified as the harzburgite sub-type. The present petrographic characteristics and mineral-chemical composition of these rocks appear to be the result of a number of phenomena including partial melting, serpentinization, metamorphism and talc-carbonate alternation.

The only trace of the primary mineralogy are the relic (unaltered) cores of the original chrome spinel grains and the occurrence of pyroxenes. The former is Cr-rich [$\text{Cr} \# = 100 \times \text{Cr}/(\text{Cr}+\text{Al}) = -50\sim70$],

TiO_2 -poor and has more or less uniformly low Fe^{3+} content. The pyroxenes are highly magnesian and contain relatively low amounts of Al (with Al_2O_3 mostly <2.5 wt %). Consistent with these mineralogical characteristics, the bulk chemistry of the rocks is characterized by low to very low amounts of the easily fusible oxides (CaO, Al₂O₃ and TiO₂), low concentration of the moderately incompatible components (Sc, V, Cu, Zn and Ga) and high levels of the moderately to highly compatible elements (Fe, Mn, Cr, Co, Ni and Mg). These mineralogical and geochemical features suggest that the major bulk of the studied ultramafic rocks originated as a residue of the upper mantle. Geochemical comparison with residual rocks from other areas shows that, prior to their emplacement along the MMT, the studied rocks had suffered an intermediate degree (> 15 to $< 30\%$) of partial melting.

Key words: Mineralogy, geochemistry, ophiolites, Indus Suture.

A/538. Arif, M. & Moon, C.J., 1998. Parentage and evolution of magnesite-rich rocks from the Indus Suture Zone in Swat, NW Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 17-19.

The Indus-Tsangbo suture between the Indo-Pakistan plate and Kohistan-Ladakh arc assumes a broad wedge-shaped complex zone in the Lilaunai-Mingora area of Swat and contains diverse rock assemblages. This assortment of rocks, collectively known as the Indus Suture mélange group, is distinguished into three principal types of mélanges: the blueschist mélange, the greenschist mélange, and the ophiolitic mélange (Kazmi et al., 1984).

Rocks of the ophiolitic mélange occur as small to large lensoidal bodies distributed along the northern edge of the Indo-Pakistan plate. They possess well-preserved ophiolitic characteristics and consist of variably altered ultramafics, gabbros, lavas of basic to intermediate composition, and pelagic sediments including cherts as well as plagiogranites and albitites. Furthermore, carbonate-rich assemblages, which are known for producing one of the world's finest gemstone quality emeralds, form an integral part of the different occurrences of the ophiolitic rocks in the study area.

In most of the ophiolitic rock occurrences, the fine-grained, emerald-hosting carbonate-rich rocks are spatially associated with variably serpentinized ultramafic rocks. Although also present as small patches within the serpentinized rocks in some places, they mostly occur along the contact between the serpentinites and metasediments. These rocks are also traversed by abundant veins, locally producing stockworks, of quartz.

The studied rocks invariably consist of abundant magnesite and accessory to trace amounts of spinel (mostly Cr-magnetite-ferritchromite and, in some cases, Mg-poor but Cr-rich chromite) accompanied with one or more of such phases as talc, quartz and dolomite. The different relative proportion of these minerals has given rise to three major types of assemblage: (i) talc-magnesite or magnesite-talc, depending upon whether magnesite or talc is more abundant; (ii) talc-magnesite-dolomite; and (iii) quartz-magnesite. The texture of these rocks is related to the relative

proportions of the different minerals, especially the absence or presence of talc in the paragenesis. That is, whereas the talc-free or talc-poor quartz-magnesite assemblages are massive, the talc-magnesite rocks are strongly foliated. In addition to the phases, mentioned above, some of the investigated magnesite-rich rocks also contain fine-grained disseminations, veins, and/ or clusters or clots of fuchsite and/ or tourmaline. The tourmaline is a Cr-rich dravite and the fuchsite shows variable but, in most analyses, anomalously high concentration of Mg and Ni and Ni (NiO reaching up to 9 wt.%).

Most of the geochemical characteristics of the investigated lithologies are broadly similar to those of typical ultramafic rocks. More importantly, the overall ranges for most of their major, minor as well as trace elements are almost identical to those of the carbonate-free, serpentinized ultramafic rocks in the area. This is particularly true for the concentrations of Al_2O_3 , MnO, TiO_2 , Cr, Ni, Co, V, Zn, Sc as well as Ga. Therefore, it seems reasonable to assume that the investigated rocks could be the result of alteration (carbonation) of the previously serpentinized ultramafic rocks in the area. The close spatial association between the two categories of the rocks lends further support to interpretation. Furthermore, comparison in terms of modal mineralogy and mineral chemical data with broadly similar assemblages from other occurrences in the world suggest that this transformation probably took place at 250-550°C and was brought about by CO_2 -bearing metamorphic fluids.

Although most of the major and trace element contents of the investigated rocks fall within the corresponding limits for ultramafic rocks, the amount of SiO_2 in some of them is anomalously low. On the other hand, the SiO_2 content of a few of the samples is higher than most others. Besides, compared to typical ultramafic rocks, some of the rocks under discussion contain distinctly high amounts of some of the incompatible trace elements.

The distinctly high content of SiO_2 in some of the studied rocks could be due to the fact that precursors to these rocks, unlike the most others, were originally orthopyroxenites rather than peridotites or dunites. On the other hand, the abnormally low SiO_2 contents in the quartz-magnesite varieties of the studied rocks (less than 10 wt.%) cannot be attributed to original compositional differences because a type of ultramafic rocks having such a low amount of SiO_2 does not exist. The possibility for an alternative explanation that these lithologies were originally some sort of impure carbonate rocks of sedimentary parentage (e.g. siliceous dolomite) can easily be ruled out because their trace element contents (especially high amounts of Cr, Ni and Co) are typical of those occurring in ultramafic igneous rocks. The point to make here is that the low SiO_2 content in the studied rocks is probably a result of the process of carbonation. As their SiO_2 shows a strong negative correlation with the LOI values variable amounts of this component were probably removed from the rocks during the process of talc-carbonate alteration (Fig. 1).

As mentioned above, some of the studied samples, especially those representing the mining sites of emerald, contain distinctly high amounts of Be, B, Li, K, As, Pb, W, Zr, Y, Ba, Rb and/ or Sr. As the average abundance of elements like these is negligibly small in typical ultramafic rocks, their notably high values in the studied may have been the result of enrichment during later processes. The lack of a meaningful correlation of any one of these elements with the values of LOI precludes the possibility for their enrichment by one of the two main processes of alteration, i.e. serpentinization and/ or carbonation. Alternatively, the textural relations and mineralogical composition suggest that the mentioned incompatible elements may have been added to the studied rocks during a late-stage hydrothermal activity, most probably the one producing the quartz veins and associated phases, i.e. fuchsite, tourmaline and emerald.

A/540. Arif, M. & Moon, C.J., 2000. Mineralogy and geochemistry of ultramafic rocks from the Indus Suture ophiolite in Swat, NW Pakistan. Abstract Volume, 15th Himalaya- Karakoram- Tibet Workshop, Chengdu (China), 113-114.

Genetically diverse lithologies, which include blueschist, greenschist, ultramafic, mafic plutonic, e.g. gabbros, and volcanic, e.g. pillowed basalts, and metasedimentary rocks, occur as a wedge-shaped zone in the area to the north of the Mingora town in Swat, NW Pakistan. This zone of fault-bounded rock bodies and blocks is distinguished into three principal groups, each of which is itself a composite of lithologies, or a mélange- the blueschist mélange, greenschist mélange and ophiolitic mélange. All these lie along the Main Mantle Thrust (MMT)- the westward

extension of the Indus-Tsangbo Suture Zone and the locus of collision between the Indo-Pakistan Plate and the Kohistan Island-Arc- and, are therefore, collectively termed as the Main Mantle Thrust Mélange Group (MMTMG). The ultramafic rocks, locally containing chromite pods and constituting a part of the ophiolitic member of the MMTMG, occur as small to large lenticular bodies, distributed along the marginal part of the Indo-Pakistan Plate. They are invariably serpentinized to varying degrees and, therefore, consist of abundant, fine grained serpentinite which is mostly accompanied by subordinate amounts of completely bastitised, medium to coarse grained orthopyroxene, trace to accessory amounts of commonly altered (zone with ferritchromite and /or magnetite) chrome spinel, variable proportions of olivine, and accessory amounts of diopside. In other words, the ultramafic rocks are mostly harzburgitic in mineralogy and, therefore, the ophiolite as a whole can be classified as the harzburgite sub-type. Detailed field and mineralogical studies show that the present petrographic characteristics and mineral-chemical composition of these dominantly harzburgitic rocks are the result of a number of phenomena involving partial melting, serpentinization, metamorphism and talc-carbonate alteration.

Relict (unaltered) cores of the original chrome spinel grains and the occurrence of pyroxenes are the only primary mineralogical features of the studied ultramafic rocks. The former is Cr-rich [$\text{Cr} = 100\text{XCr}/(\text{Cr} + \text{Al}) = 50\sim 70$], TiO_2 -poor and has more or less uniformly low Fe content. The pyroxenes are highly magnesian and contain relatively low amounts of Al [mostly $w(\text{Al}_2\text{O}_3) < 2.5\%$] and Ti [$w(\text{TiO}_2) < 0.2\%$]. Consistent with these mineralogical characteristics, the bulk chemistry of the rocks is characterized by low to very low amounts of CaO, Al_2O_3 and TiO_2 , low concentration of the moderately incompatible components (Sc, V, Cu, Zn and Ga) and high levels of the moderately to highly compatible elements (Fe, Mn, Cr, Co, Ni and Mg) (Fig. 1). These mineralogical and geochemical features suggest that the major bulk of the studied ultramafic rocks originated as a residue of the upper mantle left after partial melting. Geochemical comparison with residual rocks from other areas shows that, prior to emplacement, the studied rocks suffered an intermediate degree ($>15\%$ to 30%) of partial melting. The emplacement of these residual rocks was accomplished during the Cretaceous-Tertiary collision between the Indo-Pakistan Plate and the Kohistan arc along the MMT.

A/541. Arif, M., Moon, C.J. & Christidis, G., 1996. Garnierites from the ultramafic rocks in Swat, northwestern Pakistan. Geological Bulletin, University of Peshawar 29, 69-79.

The serpentinized and / or carbonated ultramafic rocks of Swat valley ophiolite locally contain accessory to trace amounts of microscope to megascopically visible grains of garnierite. Such grains mostly occur in samples where the serpentinization and /or carbonation are rather pervasive and accompanied by supergene alteration. Their optical properties and chemical composition are extremely variable and differ greatly from spot to spot within individual grains which appear to be intimate mixture of different compositions. The highly variable and, in most cases, high to very high concentration of FeO (up to ~ 54 wt. %), and abnormally high CaO contents (ranging up to ~ 3 wt. %) in the chemical analyses make them distinct from the serpentine varieties of garnierites reported from other localities. Most of the garnierite grains seem to be pseudomorphic after, and contain relic patches of, pentlandite, and might have developed as a result of reaction between the 'normal' matrix serpentine or talc and the original magmatic sulfide. As their occurrence along fractures in the rocks is clear at least in some cases, their formation probably took place after the main episodes of serpentinization and carbonation and was probably brought about by the processes of weathering and supergene alteration. The association of calcite with garnierites in some of the rocks indicates that the fluid, which caused the alteration, was charged with calcium and CO_2 and this factor probably also accounted for the anomalously high values of CaO in the garnierites.

Key words: Garnierites, ophiolite, ultramafic, Swat.

A/542. Arif, M., Mulk, A., Mehmood, M.T. & Shah, S.M.H., 1999. Petrography and mechanical properties of the Mansehra granite, Hazara, Pakistan. Geological Bulletin, University of Peshawar 32, 41-49.

Rocks of granitic composition occur along the area around Mansehra (Hazara), Pakistan. These rocks are mostly used as building/ construction materials. In order to study the petrography of these rocks in detail and determine their geotechnical properties, representative samples were collected from different parts of the area. Detailed studies reveal that, compared to granitic rocks from elsewhere in northern Pakistan, the investigated rocks have very low values of compressive strength. This could be due to their older age, coarser texture, unevenness of grain size,

deformed/ metamorphosed character and weathered/ altered nature. Therefore, they cannot be recommended for use in the construction of large-scale engineering structures such as tunnels and dams. However, the compressive strength values and Cs/Ts ratio of the studied rocks are high enough for their use as building stones in the construction of railway tracks, bridges, roads, canals, drainage and embankments.

A/547. Armbruster, J., Seeber, L. & Jacob, K.H., 1978. The northwestern termination of the Himalayan Mountain Front; active tectonics from micro earthquakes. *Journal of Geophysical Research* 83, 269-282.

The seismicity of the northwestern Himalayan syntaxial bend and the geologically complex area to the west, between the Hazara thrust system (HTS) and the higher mountains of Indus-Kohistan, is examined in a wider tectonic context by using data from about 1,800 microearthquakes. The microearthquake data were obtained from a telemetered seismic network in northern Pakistan centered at Tarbela dam on the Indus River and were collected during an 11-month period prior to impounding of the Tarbela reservoir. The observed seismicity indicates that a branch of the main boundary thrust (MBT) traverses the region as a straight northwesterly extension of the Murree thrust, the mapped section of the MBT southeast of the syntaxial bend along the Kashmir Himalayas. Seismic release on this extension of the MBT, here named the Indus-Kohistan seismic zone (IKSZ), is highest in the upper 25 km of the crust and correlates with a pronounced topographic step. Deeper activity on the IKSZ extends to a depth of 70 km. Seismicity in the lower crust defines a second lineation 100 km southwest of the IKSZ and parallel to it. The syntaxial bend and the eastern HTS, microseismically virtually inactive at present but associated with recent and historical microseismicity, overprint the two northwesterly seismic lineaments. The two tectonic regimes may be simultaneously active at different depths separated by an incompetent layer. A set of steeply dipping faults, either parallel or perpendicular to the IKSZ, is active in the region between the HTS and the IKSZ. Seventeen composite fault plane solutions show a predominant pattern of either reverse or strike slip faulting with the inferred slip vectors oriented such that north-south compressional stresses are relieved. Such a stress field is compatible with the north-south convergence between the Indian and Eurasian plates inferred from plate tectonics.

A/548. Arshad, C.M., 1985-87. The geology of Parrai-Dodaheera Area, District Swat N.W.F.P. with special emphasis on mineralogy and petrology. M.Sc. Thesis, Punjab University, Lahore, 78p.

The topic of this thesis is Geology of Parrai-Dodaheera area with special emphasis on mineralogy and Petrology. The prescribed area lies in the lower Swat region. The area consists of about 35 sq. miles. It lies between latitudes $34^{\circ} 41' 30''$ to $34^{\circ} 45' 00''$ Longitude $72^{\circ} 11' 30''$ to $72^{\circ} 15' 00''$ in toposheet No.43 B/2

The area was mapped by the part through foot traverses on eight times enlarged toposheet 1:50000. Notes were taken on different units, their lithology and contact relationship, geomorphology, and also on social set up of the people. Details regarding the structure of the area i.e. folds, faults, fractures, joints, foliation and lineation were taken. Stations were marked on the map. Samples were also collected. Photographs of geological and geomorphic features were also taken. Back in Laboratory, petrographic study of the thin section was carried out by microscope.

The project area is not very rich in economic minerals. No mine is present. However, the following rocks and minerals are of economic importance. These are Marble, graphitic schist, graphite and garnet.

Key words: Petrography, petrology, structure, Swat.

A/549. Arshad, M., 1977-79. Mineralogy and Petrology of Shangla Par Area, District Swat. M.Sc. Thesis, Punjab University, Lahore.

The Shangla Par Alpurai-Bazarkot area is a part of District Swat, situated about 13 miles from Khwaza Khela eastward on Khawaza Khela-Besham road.

The area comprised of igneous and metamorphic rocks. These rocks were originally deposited in eugeosynclinal conditions are argillaceous sediments and afterwards, these rocks are metamorphosed to schists and phyllites. Some amphibolites of para nature formed as result of regional metamorphism on calcareous sediments is also suggested. Subsequently the area has been strongly disturbed and intruded by ophiolites, which have now been metamorphosed to serpentinites and talc carbonate rocks. Blue schist rocks from Topsin and Shangla illustrate typical assemblages as are taken to mark plate subduction or obduction zones of Indian and Siberian plates. These are originated by the metasomatic metamorphism. The rocks form a part of lower Swat Buner Schistose group of Paleozoic age (Martin et al, 1962). By way of certain stratigraphical reasoning, a Paleocene age was attributed to the Shangla Blueschist. The area lies on the northwestern limb of the syntaxis and therefore, the prominent strike is South West-North East.

A/551. Arshad, M. & Shams, F.A., 1983. Geology and petrology of the Shangla blueschist zone, Swat Himalaya, NWFP Pakistan. Geological Bulletin, University of Punjab 18, 25-31.

Based on detailed mapping of the Shangla zone, Swat, petrographic description is given of various lithologic units. Major and trace element analyses are reported of blueschist rocks along with discussion on their petro-tectonic importance.

Key words: Petrology, blueschist, Shangla, Swat.

A/552. Arshed, A., 1981-83. Geology and Petrology of Shewa and Shahbaz Garhi Area, District Mardan, NWFP. M.Sc. Thesis, Punjab University, Lahore, 43p.

This report covers a comprehensive study of Shewa and Shahbaz Garhi area. The principal emphasis has been on detailed geological mapping of the area on the scale of 1:8333. The rocks in the area are porphyries, quartzitic schists and dolerites.

A fairly detailed account of the Geology is being given and the report also includes a detailed account of petrography of the porphyries based on extensive sampling.

Numerous photographs and sketches have also been included to illustrate the geology of the area. In the light of field, laboratory work and previous work petrogenesis of the porphyries has been discussed at length.

A/554. Asad, A.F., 2000. Feasibility study of Limestone of Gandghar Range and Associated deposits for Cement manufacturing. M.Phil. Thesis, University of Peshawar.

Limestone is a valuable raw material, which is widely used in the chemical and construction industries throughout the world. With huge deposits of limestone in Pakistan it is immensely used as cement manufacturing. The extensive deposits of pre-Cambrian limestone are exposed in Gandghar, Cherat and Khyber ranges around the southern Peshawar basin. It is light grey in colour, medium to thick bedded and massive. The limestone of Gandghar range has been evaluated mineralogically and chemically for its use for cement manufacturing during present study. Mineralogically, the studied limestone is dominantly calcite very fine grained. Quartz as anhedral small clastic sand grains, chert and chalcedony, some carbonaceous matter is also present in the form of layers or bands. Iron leaching and some of clay minerals by mixing of various raw material in different proportions then the portland cement of desired composition can be obtained. Chemically, the studied limestone of Gandghar range are compared with that of the normal and argillaceous limestone elsewhere in the world. All the three varieties of the studied limestone (Shekhai, Utch Khattak greenish grey) have more silica than normal limestone but less than that of the argillaceous limestone. Al_2O_3 , and Fe_2O_3 are relatively high in the studied limestone as compared to that of normal limestone, MgO in the studied limestone is less as compared to that of the normal limestone and more as compared to that of argillaceous limestone, Al_2O_3 and Fe_2O_3 are relatively high in the studied limestone as compared to that of normal limestone, MgO in the studied limestone is less as compared to that of normal limestone and more as compared to that of argillaceous limestone. The CaO is high in the studied limestone as compared to that of both normal and argillaceous limestone. Total alkalies in the studied limestones are relatively as compared to that of normal limestone. The average chemical compositions of various cements manufactured in N.W.F.P. are within the ASTM limits. The studied limestone of Gandghar range is generally free of dolomitization and has no other deleterious substances. This pre-Cambrian limestone of the Gandghar range is therefore, recommended.

Key words: Limestone, cement, Gandghar Range.

A/555. Asghar, M., 2001. Geophysical investigations of landslide in Murree Hill area. M.Sc. Thesis, Quaid-i-Azam University, Islamabad, 64p.

Geophysical investigations of three landslides in Murree were carried out by using seismic refraction, electrical resistivity and radon exhalation detection methods. The seismic data was acquired employing reverse shooting scheme and Conventional and Hagedoorn methods were used for velocity modeling. The resistivity data was interpreted in terms of true resistivity of subsurface material by curve matching technique. The radon emission was determined as track densities for every detector planted on the surface in a profile. The results of all the methods employed were interpreted and correlated in the light of geology of the area, meteorological and anthropogenic factors.

The study reveals that geological structure and lithologies play a major role in the formation of thick weathering layer which when wet/moistened exerts more downslope force thus causing landslides. The thickness of weathering layer determined by seismic refraction and resistivity methods for all the three landslides are in agreement. Also the radon emission measurements have delineated the stable and unstable areas within a landslide zone. Such investigations are recommended on all the major landslides of the area prior to damage control measures.

A/558. Ashfak, M. & Wakeel, A., 1969b. The study of the joint patterns and the other structures of the Manki slate and the Attock shale. Geological Bulletin, University of Peshawar 4, 24-32.

On the basis of a comprehensive study of the structures, especially the joint patterns of the Manki Slate and the Attock Shale, the two distinct argillaceous units of the Attock Group, it has been established that there was, most probably, a considerable lapse of time between their depositions. The Manki Slate, as a result of a powerful compression from the north, was later pushed over the Attock Shale along a thrust striking E – W.

A/559. Ashok, S. & Kad, S., 1998. Initiation and Development of Northwestern Lesser Himalayan foreland basin: An Overview. Geological Bulletin, University of Peshawar 31. Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, p.173.

Excellent sections are available in Northwestern Lesser Himalayan region of India and Pakistan to document the evolution of Foreland basin that has taken place south of rising Himalayas. The present Indo-Gangetic basin is the southernmost and youngest in a series of foreland basin development which include the Siwaliks and Eocene-Oligocene i.e. mainly Murree group basins, which are the oldest, highly tectonically disrupted and most uplifted of all such basins.

The present paper attempts to understand initial stages of development of these Foreland basins spanning the first 25 m.y. of this development. It is based on investigated sequences in Dharampur-Kuniarhatti section, Dagshai type section and Subathu section in Shimla Himalayas and Kalakot, Sind-Khatuti sections in Jammu Himalayas.

The transition of a marine to continental basin is best studied in Dharampur, Dagshai and Kalakot sections. Transition is marked by a thick orthoquartzite band extending along the length of the basin delineating the transition. In most of the sections studied it is generally marine sequence below the orthoquartzite band but in Dharampur-Kumarhatti section, which makes an exception, some red beds are below this orthoquartzite band. It is generally believed, that a thick orthoquartzite layer may have been coeval with India -Asia collision and all sediments above represent initial stages of subsiding basin.

The initial stages of this subsiding basin are characterised by alteration of Sandstone and shale usually red in colour to multiple palaeosol horizons with reworked nodular beds. They are poorly fossiliferous in nature except for some organic debris along with thin shale partings. Next stage of development in the foreland basin are Kasaulis which suggest a certain degree of stability and uplift of Murrees.

A/561. Ashraf, K.M. & Ismail, M., 1984. Characteristics of alluvial aquifers of Potwar Plateau. Abstracts, First Geological Congress, Lahore, 3-4.

Potwar Plateau exists in the northern part of Punjab Province, extending from the foothills of Himalayas to Jhelum River, and covers an area of about 9000 square miles; Potwar Plateau and its adjoining drainage basins were investigated on scientific basis for groundwater exploration by Hydrogeology Directorate, WAPDA, Lahore.

Geologically, the area is folded, faulted and over-thrusted. The rocks of the area are generally sedimentary in origin and range in age from Pre-Cambrian to Recent. The unconsolidated deposits of Sub-Recent to Recent age consisting silt, sand, gravel and clay form the main groundwater reservoir of the area while the consolidated rocks are far less permeable and in general serve as barriers to movement of groundwater. The aquifer material in Potwar occurs in lenses and strings 4 to 152 feet thick, elongated along the present and abandoned river channels. For determining the aquifer characteristics of alluvial deposits aquifer tests/pumping tests were performed at selected sites in the area. The data collected during these tests were evaluated and analysed by different analytical methods for different parameters of aquifer. The coefficients of transmissivity, permeability and storage determined by these methods range from 7000 gpd/ft, 86 gpd/ft² and 5.7×10^{-5} to 218000 gpd/ft, 4100 gpd/ft² and 7×10^{-2} respectively. The specific capacity of tubewells ranges from 4.6 gpm/ft of drawdown to 489 gpm/ft of drawdown.

A/565. Ashraf, M., 1974a. Geochemistry and petrogenesis of acid minor bodies of Mansehra and Batgram area, Hazara District. Ph.D. Thesis, Punjab University, Lahore.

The acid minor bodies in the Mansehra and Batgram area were emplaced in the granitic rocks and the associated met sediments. These bodies have been identified as (1) Albitites, (2) albite-aplites/pegmatites, (3) albite-(microcline)-apilites /pegmatites, (4) albit-microcline-apilites/tit/pegmatites, (5) microcline-albiteapilites/pegmatites and (6) complex apilites/pegmatites. The first 4 types occur as independent and composite bodies in the interior-lateral zone (1750 to 5500 feet above sea level), types 4 and 5 occur in the interior-marginal zone (5000 to 9000 feet above sea level) and types 5 and 6 are present in both interior-marginal zone and marginal exterior zone (over 9000 feet sea level). Field, mineralogical and chemical evidences show that the acid minor bodies are genetically related with the granitic rocks of the area. This genetic relationship is significant due to continued enrichment of soda in the granites from Susalgali granitic gneiss (a potassic facies) to Hackle tourmaline granite and Chail sar micro granite. The enrichment of soda is due to gradual cooling and increases in vapor pressure of the complex (in tightly closed environments) more than 10 kbs, where the acidic fluids shifted toward the albite apex. From this the release in external pressure at within the interior-lateral zone gave rise to soda rich liquids being deposited in the fissures. These fissures provided

the local in pressure by the opening the metasediments during the welling up and the expansion of the granites in the diapiric and much room like structures. Therefore, as the vapour pressure decreased with further cooling, the behavior of the system was reversed gradually, meaning thereby that quantity depended on the release in $p(H_2O)$ in the three structural zones. The mineralogy and chemistry of these structural units is quite contrasting with the exception of some overlapping at places. Therefore, the present investigations show that the pegmatite residual solutions were derived from the albite rich solutions gradually with the introduction of K_2O and volatiles. This derivation is excellently exemplified by negative correlation of Na_2O and positive correlation of K_2O with SiO_2 and gradual but significant increase in the rare elements.

A/569. Ashraf, M., 1977. Geology and mineral composition of various lithologic units presents in the Kingriali Formation of the Surghar Range. Geological Bulletin, University of Punjab 14, 55-62.

Kingriali Formation of Triassic age has seven lithologic units, which can be distinctly recognized in the field on the basis of color, porosity, and compaction of the rocks. The thickness of individual units varies from 8 – 42 meters. The thickest unit is massive, white to pink colored and porous at places (sucrosic dolomite). The deposits were evaluated in the laboratory for their microscopic, chemical, differential thermal analyses (D. T. A.) and X-ray properties. The studies clearly indicate that most of the units are quite rich in dolomite mineral, (as MgO is 20 to 21% and CaO is 29 to 31%) with minor amount of Kutnoharite and ferrian dolomite.

Key words: Lithology, Kingriali Formation, Surghar Range.

A/571. Ashraf, M., 1992a. Petrogenesis of acid minor bodies of Mansehra granitic complex, Hazara Himalaya, NW Pakistan. *Kashmir Journal of Geology* 10, 1-26.

The acid minor bodies in the Mansehra and Batgram area were emplaced in the granitic rocks and the associated metasediments. These bodies have been identified as (1) Albite, (2) albite-aplites / pegmatites, (3) albite - (microcline) – aplite / pegmatites, (4) albite – microcline – aplites / pegmatites, (5) microcline – albite-aplites / pegmatites and (6) complex – aplites / pegmatites. The first 4 types occur as independent and composite bodies in the interior – lateral zone (1675m above sea level), and the types 4 and 5 occur in the interior- marginal zone (1525 to 2750 m above sea level) and types 5 and 6 are present in both interior – marginal zone and marginal – exterior zone (over 2750 m above sea level). Field, mineralogical and chemical evidences show that the acid minor bodies are genetically related with the granitic rocks of the area. This genetic relationship is significant due to continued enrichment of soda in the granites from Mansehra granitic gneiss (a potash facies) to Hake tourmaline granite and Chail Sar microgranite. The Mansehra granitic complex is itself a product of partial melting of Hazara and Lower Tanol Formations when they reached to metamorphic grade of kyanite-silliminite. The enrichment of soda is due to gradual cooling and increase in vapor pressure of the complex (in tightly closed environment) more than 10 Kb, where the acidic fluids shifted towards the albite apex. From this release in external pressure at place within the interior-lateral zone gave rise to soda rich liquids being deposited in the fissures. These fissures provided the local release in pressure by the opening of tension fissures parallel to the foliation of the granite and the metasediments during the swelling up and the expansion of the granites in the diapiric and mushroom lie structure. Therefore, as the vapor pressure decreased with further cooling the behavior of the system was reversed gradually, meaning thereby that SiO_2 and K_2O would be released along with the volatilize, and their quantity depended on the release in P (H_2O) in the three structural zones. The mineralogy and chemistry of these structural units is quite contrasting with exception of some overlapping at places. Therefore, the present investigations show that the pegmatitic residual solutions were derived from the albite rich solutions gradually with the introduction of K_2O and volatilizes. This derivation is excellently exemplified by negative correlation of Na_2O and positive correlation of K_2O with SiO_2 and also gradual but significant increase in the rare elements.

A/572. Ashraf, M., 1992b. Asymmetrically zoned complex pegmatite of Bagarian area North of Oghi, Mansehra District, Hazara Himalaya, Pakistan. *Kashmir Journal of Geology* 10, 93-104.

The Bagarian asymmetrically zoned complex pegmatite occurs associated with Mansehra granitic complex in the interior-marginal zone near Oghi subdivision of Mansehra District. This pegmatite body is the most developed zonally and is most evolved with contrasting mineral composition on both sides of the quartz core. The zones on east of core are border + wall zones with oligoclase, muscovite quartz and tourmaline; outer intermediate zone-microcline graphic granite; inner intermediate zone-subgraphic albite, quartz and muscovite. The zones on west side of quartz core are border + wall zone with albite, tourmaline, quartz and muscovite; outer intermediate zone-microcline perthite and minor muscovite; and inner intermediate zone-microcline perthite with minor quartz. Mirolitic cavity filled minerals of aqueous vapor phase are beryl columbite, samarskite Rb-rich translucent microcline, Rb and Li-rich muscovite. The Mansehra granitic magma was formed after 40% partial melting of Hazara and Lower Tanol Formation pelites, which in turn gave rise pegmatitic magmatic solution to develop Bagarian pegmatite and aqueous phase modified for mirolitic minerals. It is envisaged that 75-90% fractional crystallization of granitic rest magma was responsible for the present shape of Bagarian pegmatite.

A/575. Ashraf, M., 1995. Lagarban-Tarnawai phosphorite deposits of Abbottabad, Pakistan. Abstracts, International Symposium and Field Workshop on Phosphorites and other Industrial Minerals, Abbottabad, p.36.

Lagarban-Tarnawai phosphorite is the only sedimentary deposit known so far in Pakistan. Total reserves are of the order of about .19-million tones out of which 7.5 million-tonnes are of measured category as reported by SDA. The phosphorite occurs in the upper Sirban formation of Cambrian age, which is associated with dolomite, siltstone and red beds. The phosphorite is considered to have been deposited as a single bed within upper Sirban Formation. Subsequent repetition is due to imbrication with plunge of deposit towards north as a result of Himalayan orogeny. The repetition of the ore bodies has been identified and explored as (1) Eastern Phosphorite, (2) Lagarban South phosphorite (3) Batakna phosphorite and (4) South phosphorite. Assaying revealed that average P₂O₅, MgO, and H₂O₃ in the above mentioned ore bodies are 29%, 0.26% and 3.47%; 28.6%, 2.2% and 3.7%; 30.2%, 3.8% and 2.2%; and 29.6 %, 2.5% and 2.8% respectively. Collophane is dominant phosphate mineral with minor as dahlite. The gangue minerals are dolomite, chalcidony, opal, quartz, goethite, chlorite, pyrite, mica, clay minerals, and organic matters. The phosphorite was deposited in a relatively calm sea in Lagarban to Batakna whereas the East phosphorite was deposited in a very shallow sea with abundant wave activity.

A/576. Ashraf, M., 1997. The principle subdivisions of the Kamila amphibolites redefined in Kohistan. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p. 10.

The so called Kamila amphibolite was studied in details and was subdivided. The Kamila amphibolite in the area around Kamila-Dassu along the Indus canyon was subdivided into Dassu, Kayal, and Pattan complexes. The former Dassu is typical amphibolite formed from the metamorphism of plutonic rocks which is extremely deformed, poly-metamorphosed, epidote-garnet amphibolite banded gneiss. The metamorphic P-T conditions for Dassu are 5.5-6.5 kb and 520-580°C. The Kayal and Pattan plutonic complexes are locally metamorphosed to amphibolite with igneous hornblende and layering. The Dassu complex has limited aerial extent toward west whereas it extends beyond Thak valley in the east without Kayal and Pattan. The Pattan complex, however, is exposed intermittently westwards with outcrops near Khwazakhela, Landai, Tighak, Shahpur (Aspanr), etc. The ocean floor related tholeiitic amphibolites herein are called as Dir amphibolites which are found west of Lilunai everywhere as continuous outcrops to sporadic occurrences showing underplated relationship with calc alkaline arc related stuff like Chilas complex, Dassu, Kayal and Pattan complexes. Therefore, the Kamila amphibolite term may be disregarded and new subdivisions be followed which are different mineralogically/chemically and environmentally.

Key words: Amphibolite, Kamila, Kohistan.

A/577. Ashraf, M., 1998. Dir Amphibolite as an Ocean Floor Theolites Underplated by Kohistan Calcalkaline Rocks in N. Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 20-22.

Geological mapping of 673 km² area of Timargara-Lal Qila and Wari of District Dir NWFP was recarried out for the study of Petrology, structure, geochemistry etc. (first detail work after Chaudhry et. at., 1974 and 1974a). The area is part of the western extremity of Kohistan Island Arc, where the Mesozoic amphibolitized ocean floor of Kohistan in the south is sutured to the gneisses of Indian plate.

The amphibolites exposed in the southern and northern extreme of the mapped area were the parts of a single ocean floor under which the arc was built. These amphibolites were formed by the metamorphism of basic volcanics and pillow lavas of tholeiitic affinity. The subordinate interlayered sediments of argillaceous, arenaceous and carbonate composition were deposited on ocean floor away or near mid oceanic ridge (MOR). The concentration of metasediments in the southern exposure is relatively less and thin as compared to northern part of amphibolites where thick piles of these sediments were evident (Chaudhry et al., 1974a). The amphibolites exposed in the Dir area are different from Kamial amphibolites which were formed by the metamorphism of basic plutonic rocks like Dassu and Kayal complexes (Ashraf, 1997; Loucks et al., 1992). The Dassu complex represent the base of Kohistan Island Arc and is exposed near or around Nanga Parbat Syntaxis due to uplifting and uncovering of base rocks. Whereas Dir amphibolites represent the supra crustal material of Kohistan under which the arc was built.

The discrimination diagrams show that Dir amphibolites are basalts and of tholeiitic character, as is evident from the SiO₂ and total alkalies (Cox and Panhurst, 1979) plots. The K₂O-TiO₂-P₂O₅ diagram (after Pearce et al., 1975) plots of Dir amphibolites show mainly oceanic floor volcanic nature. In AFM diagram (after Irvine and Baragar, 1971) most of the Dir Amphibolites plot in the tholeiitic field. Similarly, trace elements plots also indicate the tholeiitic nature of Dir Amphibolites.

The plutonic rocks exposed in the area consist of norite, gabbro-norite, diorite, tonalite, trondhjemite, granite/adamellite, and quartz porphyries/aplites/pegmatites are intruded in the Dir amphibolites and were exposed due to uplifting and uncovering of amphibolites. But the presence of small and large roof pendant of amphibolite in these plutonic rocks (which previously were called xenoliths and screens of amphibolites) evident the presence of amphibolites over there.

AFM diagram for norites, gabbro-norites, diorite, tonalite, granites, adamellites, aplites and quartz porphyries display a calc alkaline nature of these rocks, Al₂O₃ Vs An reveal calc alkaline nature for the plutonic rocks in the Irvine and Baragar (1971) diagram. The Babien (1980) diagram plots Tio₂ Vs FeO/MgO for the Dir Plutonic rocks classifying them as orogenic rocks showing emplacements of plutonic magma during collision, underplating the oceanic crust of MORB nature.

Generally three types of ultramafic rocks are exposed in the mapped area. The first type of ultramafic are highly altered and metamorphosed. These ultramafic rocks are present as exotic blocks in amphibolites; the second types are those, which are present as roof pendent over the surface of some plutonic, rocks (i.e. granite adamellite and diorite). These ultramafic were emplaced in oceanic crust (amphibolites) during its development at MOR. The third type of ultramafics which are mostly hornblendites and scyelites are exposed both in amphibolites and plutonic rocks, were probably fractionated as hydrous magma and ascended to higher levels due to buoyancy acquired by their magmas as a result of residual liquid enrichment.

Structural studies shows that the rocks of Kohistan Island Arc exposed in the area are folded into northward dipping southward verging tight folds in the south (near MMT) which opens up northwards. The amphibolites has undergone at least two phases of isoclinal folding. In the first phase of recumbent or isoclinal folding S1 axial planner foliation was developed in these rocks. The first phase of deformation is probably related to the subduction of Kohistan mass under Eurasian plate. In the second phase these rocks were again folded. The second phase is probably related to the subduction of Indian plate under Kohistan. The rocks of Kohistan mass have undergone a third phase of deformation, which produced the shear zones and a retrograde metamorphism to chlorite grade.

The southern part of Dir amphibolites near MMT mostly trend EW and dips 65 to 80° northwards, which is almost parallel to the trend of MMT. In the central portion of the mapped area, the plutonic rocks trend NE to SW and their dips varies from 40° to 70° NW and SE. Most of the fold axis in plutonic sequence is parallel to each other which mostly trend NE to SW and plunges from 12 to 50°. The northern part of Dir amphibolites mostly trend NE and dips 150 to 60° SE.

A/578. Ashraf, M., Ahmad, M. & Faruqi, F.A., 1976. Jurassic bauxite and kaolinite deposit of Chhoi area, Kala Chitta Range, Punjab, Pakistan. Geological Bulletin, University of Punjab 12, 41-54.

Sedimentary reworked bauxite and kaolinite deposits have been found in the Kala Chitta area for the first time. These deposits are of Jurassic age and they occur on an erosional unconformity at the top of Triassic rocks. Due to reworking of bauxite and kaolinite from the same source area the physical appearance of these deposits is almost identical. The bauxitic zones are occasionally more compact than the kaolinite zones. The basal bed always consists of kaolinite. The alternations of bauxite and kaolinite continue upward. This cyclic deposition is conceived due to alternate deposition of kaolinite and bauxite. Moreover, the occurrence of bauxitic nodules in the kaolinite zone at places show that the whole deposit is of reworked nature and cyclic. These bauxite and kaolinite zones have been evaluated in detail by chemical, X-ray and D. T. A. methods.

A/580. Ashraf, M. & Chaudhry, M.N., 1974a. Geology of Dadar pegmatites, Mansehra area, Hazara District, Pakistan. Geological Bulletin, University of Punjab 10, 59-66.

Six complex pegmatite bodies have been located in the Dadar area. They are zoned. Most of the zones have been completely reconstituted. It is conceived that they are granite pegmatites, which have been derived from sodic solutions with gradual enrichment in potassic phase. The reconstitution occurred at pneumatolytic stage forming cleavelandite, muscovite and beryl. Replacement by tourmaline is local. In one of the pegmatites the replacement by cleavelandite is so extensive that small islands of microcline perthite are left as relicts in the intermediate zone, even the outermost zone (wall zone) has also not survived replacement.

Key words: Pegmatites, Mansehra, Hazara.

A/581. Ashraf, M. & Chaudhry, M.N., 1974b. Quartz, quartz-ilmenite and quartz-kyanite veins in the Mansehra Batgram area of Hazara District. Geological Bulletin, University of Punjab 10, 67-72.

Simple quartz, quartz-ilmenite and quartz-kyanite veins have been found in the area. Simple quartz veins occur both in the metamorphics as well as in the granites. But quartz-ilmenite and quartz-kyanite veins have only been found in the metamorphics so far. They range from mere stringer to many hundreds of feet in dimensions. They are lensoid, lenticular and lenticular branching type. They are thought to be products of hydrothermal solution and metamorphic differentiation.

Key words: Quartz-Ilmenite/Kyanite Veins, Mansehra, Hazara.

A/582. Ashraf, M. & Chaudhry, M.N., 1974c. The geochemistry and petrogenesis of albitites from Mansehra and Batgram area, Hazara District, Pakistan. Geological Bulletin, Punjab University 11, p.97.

A/583. Ashraf, M. & Chaudhry, M.N., 1976a. Geology and classification of acid minor bodies of Mansehra and Batgram area, Hazara Division, Pakistan. Geological Bulletin, University of Punjab 12, 1-16.

Seven types of acid minor bodies have been identified in the Mansehra and Batgram region of Hazara division on the basis of their mineralogical composition and structures. The acid minor bodies classified are 1) albitites, 2) aplites, 3) simple pegmatites, 4) complex pegmatites, 5) albitized or replacement bodies, 6) composite bodies and 7) quartz veins. Subclasses of these minor bodies are made possible by detailed field and microscopic studies. They are distributed in the area in such a way that each type has a direct bearing on the site where it has crystallized. Three zones have been recognized, i) Interior-lateral zone (1750-5500 feet above sea level, containing albitites, albite-aplites/pegmatites, albite-(microcline)-aplites/pegmatites), ii) interior-marginal zone 5000 to 9000 feet above sea level containing albite-microcline-aplites/pegmatites, microcline-albite-aplites/pegmatites and some complex pegmatites), and iii) marginal exterior zone (over 9000 feet above sea level; containing mainly complex pegmatites). The acid minor bodies vary in thickness from less than a centimeter to over 20 meters and in length from one to 100meters and occur as lensoid, lenticular branching, pinch and swell, patch, pod, pyroclastic, tabular bodies with regular and sharp boundaries and irregular to diffused contacts in a few cases. Internal structure of the bodies varies from one type to another. Zonation is perfect in some pegmatites. In other types the textural variation is marked from wall inwards.

Key words: Classification, acid bodies, Mansehra, Batgram, Hazara.

A/584. Ashraf, M. & Chaudhry, M.N., 1976b. The geochemistry and petrogenesis of albitites from Mansehra and Batgram area, Hazara District, Pakistan. Geological Bulletin, University of Punjab 13, 65-85.

Albitites are present in the granites and associated metamorphic rocks of the Mansehra and Batgram area. They have been classified as syenitic albitites of three distinct types: 1) pegmatitic albitites, 2) medium-grained albitites and 3) fine-grained albitites, the two former being associated with the granites and the latter with the metamorphic rocks. The albitites occur as streaks stringers and 1 – 10m wide and 5 – 70m long bodies. They occur either independently or as composite bodies and are associated with albite-aplites and albite-(microcline) aplites. The shape of these bodies is tabular to lensoid, showing usually sharp contact relationships with the granite and metamorphics. Mineralogically these rocks are usually formed of albite with quartz, muscovite, rutile, sphene, chlorite and apatite; zircon, tourmaline and magnetite may also be present. Chemically they contain SiO₂ 66-67 %, Al₂O₃ 19-21%, Na₂O 9-11%, K₂O 0.2 – 0.7%. The origin of these rocks is evaluated in the light of recent experimental work in the granitic system at 4 to 10 Kbs and it has been suggested that at a water vapor pressure 10 Kbs the granitic system shifts towards albite, thereby forming albititic solutions whose deposition and crystallization took place in fissures of the host rocks with gradual cooling of the system.

Key words: Geochemistry, petrogenesis, albitite, Mansehra.

A/585. Ashraf, M. & Chaudhry, M.N., 1976c. Origin of chessboard albite present in the acid minor bodies of Mansehra and Batgram area, Hazara Division, Pakistan. Geological Bulletin, University of Punjab 13, 93-98.

Primary chessboard albite is widely developed in the albitites and albite-aplites/pegmatites. Replacement and stress or deformation is also postulated for the development of chessboard albite on a minor scale. Exsolution chessboard albite is found only in a few complex pegmatites in the outer intermediate zone. Exsolution is shown by microcline.

A/586. Ashraf, M. & Chaudhry, M.N., 1977a. A discovery of carbonatite from Malakand. Geological Bulletin, Punjab University 14, 89-90.

Carbonate rocks carrying vermiculite and iron oxides were reported by Fayyaz and Shafiq from near the village of Silai Patti which is 19 miles from Dargai (in the Malakand Agency) on the Dargai Bajaur road. The

authors studied the area and carried out laboratory studies on the rocks and concluded that the rocks were carbonatite bodies. Following is a brief description of the occurrence.

The carbonatites occur as dykes, sills and ring type bodies in the pelitic-psammitic schists of possibly Pre-Cambrian age (The dykes and sills are from 50' x 10 feet to 300' x 60 feet). The pelitic rocks have been thrust against calcareous and quartzitic rocks of Cambrian age intruded by granites (Chaudhry et al. 1976, E.C.L. 1977).

The rocks are composed of calcite, arfvedsonite, siderite, ilmenite/magnetite, vermiculite, apatite, chlorite and some feldspar. The minerals show uneven distribution and local segregation. The rocks are coarse grained and from porphyritic to subporphyritic. Calcite is the main mineral and ranges from 50 to 90% in most cases. However, where Fe-Ti oxides or vermiculite increase in amount the amount of calcite may fall below 50%. Some siderite crystals are also present.

Vermiculite occurs unevenly distributed and ranges in size from 1 mm to 3 mm and occasionally upto 8 cm in size. Fe-Ti oxides (magnetite/ilmenite) are generally below 5% however, at a few places they may be as high as 50% as pods and lenses). These oxides occur from subhedral to anhedral crystals. Arfvedsonite ranges from 2 to 25% of the rock. It forms subhedral to euhedral crystal. Apatite ranges from 2 to 12%. It occurs as subhedral to anhedral crystals. It may be partly enclosed by the carbonates. Vermiculite and amphibole at places alter to chlorite. K-Feldspar ranges from 0 to 5%. It occurs as randomly distributed crystals.

Key words: Carbonatite, Hazara.

A/587. Ashraf, M. & Chaudhry, M.N., 1977b. A chromium muscovite bearing zoned complex aplite from hill Khwar, Batgram area Hazara Division, NWFP, Pakistan. Geological Bulletin, University of Punjab 14, 39-44.

A chromium muscovite bearing zoned complex aplite has been reported for the first time from the Batgram area of Hazara Division. The aplite, which occurs in the pelitic metamorphics close to the contact of the granite gneiss, shows two well-developed zones i.e., an intermediate zone and a core. One chemical analysis, one spectrographic analysis and one modal analysis of each of the zone along with their normative composition is presented. One analysis of chromium muscovite is also presented. Both the zones contain chromium muscovite but the core is distinctly rich in this mineral. The intermediate zone contains 800ppm and the core contains 1000ppm chromium. The relative enrichment in chromium in such a body is attributed to contamination with the host metamorphics.

Key words: Muscovite, Hill Khwar, Batgram, Hazara.

A/588. Ashraf, M. & Chaudhry, M.N., 1980. Clayey bauxite and clay deposits of Kotli District, Azad Kashmir. Contribution to the Geology of Pakistan 1, 87-112.

Bauxite and underlying fireclay deposits occur over an erosional unconformity of possibly post Mesozoic age in the two big inliers of Kotli District, Azad Kashmir. Thickness of the bauxite so far noted is highly variable, being at a maximum in Nikial area (upto 2.4 m thick). The thickness of clay ranges from 0.6 to 2.5 m. Irregularities in thickness are mainly erosional/depositional. Dip of the deposits generally varies between 10^0 to 20^0 . Mineralogically the bauxite consists of boehmite, gibbsite, kaolinite, quartz/chalcedony, haematite/limonite, pyrite, carbonaceous matter and chlorite. The fireclay consists of major kaolinite and minor gibbsite, boehmite, quartz/chalcedony, haematite/limonite, pyrite, carbonaceous matter, calcite, chlorite and tourmaline (studied by microscopic, D. T.A. and X-ray methods).

Chemically the bauxite rocks contain Al_2O_3 (X=49.8B, S= 7.08), SiO_2 (X= 27.93, S= 8.10), Fe_2O_3 (X= 4.87, S= 4.96). The fireclay Rocks contain Al_2O_3 (X= ~8.47, S= 9.34). SiO_2 (X= 41.54, S= 9.34) and Fe_2O_3 (X= 2.68, S= 3.27).

The results of spectrochemical studies are also presented.

Industrial studies show that the silica content is difficult to reduce by physical processing methods. Soda-lime sinter process and/or pechiney acid process may be applicable for the ore. Bricks were prepared using four samples of fireclay of Kotli mixed with plastic clay from Mianwali. A mixture containing 35% plastic clay gave better results compared to a mixture with 25% plastic clay. The crushing strength of the former was higher than the latter. The proved and inferred reserves of the bauxitic ore are of the order of 2.722 million tons and 5.577 million tons respectively. And that of the fireclay are 3.228 and 21.177 million tons respectively.

Mining of the exposed deposits along with fireclay deposits will be possible by open cast/quarrying method. The working face be laid out in steps. The bauxite step will be leading by 15 feet.

A/591. Ashraf, M. & Chaudhry, M.N., 1985. Crystalline graphite deposits of Agra-Silai Pattai area Malakand Agency, NWFP, Pakistan. Kashmir Journal of Geology 3, 1-12.

The crystalline graphite occurs in Agra-Silai Pattai are at a distance of 32 to 40 km by truckable road from Dargai railway station. The graphite is a part of the pelitic-psammitic rocks of the area. Important graphite bearing rocks occur in Silai-Patti, Haspur South, Haspur North, Agra and Rang Dheri localities. The thickness varies from about 5m to 52m and the deposits extend intermittently over a length of 8 km. The petrographic study showed that graphite and predominant grain size upto 0.25mm. While flakes more than 0.5 to 1mm were rare. The crystalline graphite contents in the rock are 19.32, 18.32, 21.70 and 17.53% on average in the localities mentioned above.

The dominant gangue minerals in the rock are quartz ($X=31.8$ to 40.79), muscovite ($X=23.01$ to 35.83), geothite/limonite/haematite ($X=7.43$ to 9.57), boehmite ($X=1.19$ to 4.10), and minor andalusite, pyrite, feldspar, clay, magnetite, epidote, chlorite, tremolite, sillimanite etc. The ore microscopy and X-ray studies confirm the presence of crystalline graphites.

Chemically the graphite rocks contain carbon ($X=14.99$ to 17.82), amorphous carbon ($X=1.41$ to 1.80), SiO_2 ($X=50.78$ to 54.15), Al_2O_3 ($X=12.48$ to 14.113), Fe_2O_3 ($X=7.20$ to 7.39), FeO ($X=0.60$ to 0.87), MgO ($X=1.27$ to 2.02), CaO ($X=0.29$ to 1.13), Na_2O ($X=0.63$ to 0.81), K_2O ($X=2.43$ to 3.08), H_2O ($X=0.99$ to 1.22).

Textural relations suggest that graphite may be released as particles passing about 70 BBS mesh. This limits the recovery of flakes of appropriate size which would have otherwise produced flakes in appreciable quantities. However, optimum liberation of graphite was found to be between 200 to 250 BBS mesh for achieving better flotation. Reserves of inferred category are 16.10 million tonnes which include 2.94 million tonnes of indicated category.

A/592. Ashraf, M. & Chaudhry, M.N., 1986. Plate tectonic and mineralization associated with alkaline province, N.W.F.P., Pakistan. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, 1-2.

Nepheline syenite and associated alkaline rocks are known from north western part of Pakistan as an alkaline igneous province trending WSW-ENE. Important exposures so far known are at Loe Shilman, Warsak, Malakand, Shewa, Koga and Tarbela. The distribution of the alkaline magmatism in a narrow belt suggest a zone of crustal weakness during late Eocene/Oligocene in the Indian block and was caused by the influence of compression. Butt Chaudhry and Ashraf (1980) proposed that while the leading edge of the Indian plate was being collided with Asian

block, compressional features were produced within the zone of deformation a complimentary zone of tension was created within Indian block. These tensional opening provided sites for intrusion of highly alkaline magmas.

The economically important alkaline magmatism is seen in Koga area as medium to coarse grained nepheline syenite, sodalite nepheline syenite, foyaites, litchfieldite and carbonatites. The first four rocks are prone to beneficiation to produce a product useful for the manufacture of colourless glass and quality ceramic wares. The carbonatites are quite interesting as they contain Ce (0.07%), Sr (0.9 to 2.46%), Y (0.005%), Ba (0.09%). Apatite contents are quite interesting as it is about 15 & 18% in two samples of carbonatites, 5 and 6% in fenite and lamprophyres.

Interesting occurrences of carbonatites are found by Ashraf and Chaudhary (1977) in Malakand. They occur as composite bodies having Nb (100-300 ppm), Sr (0.3%), V (0.01%), Y (100 to 200 ppm), Zr (0.01%), Sc (traces) La (400 ppm) and Yt (3 to 5 ppm). P₂O₅ in the six samples studied is 6 to 12%. Loe Shilman is also very interesting deposit regarding trace/rare earth elements and phosphate contents.

A/593. Ashraf, M. & Chaudhry, M.N., 1987. A Cambrian unconformity represented by Galdanina Formation in Abbottabad District, NWFP, Pakistan. *Kashmir Journal of Geology* 5, 43-49.

In Abbottabad District Galdanian Formation is formed at the top of Abbottabad Formation. The Upper Abbottabad Formation contains marine phosphorite deposit which laterally changes over to turbidite phosphorite bed associated with Galdanian variegated beds and to Galdanian continental deposits. It is evident from such lithologies that in Upper Abbottabad times the geological environments were such that deep sea conditions were lacking. However, the continental to shelf environments were dominating. In the deeper shelf conditions normal inorganic precipitation of phosphorite was in progress whereas bauxitization and lateritization was occurring continuously on projections (small islands) above sea level. The intervening zones between continental projections and sea conditions contained reddish to brown red siltstone, brownish red cherty dolomite, reddish cherty siltstone or chertstone and overlain fine-grained quartzose siltstone.

The present study, therefore, envisages that phosphorite is facies equivalent of Galdanian Formation whereas Hazira Formation is definitely younger than both of them and is possibly not related to Galdanian Formation.

Key words: Unconformity, Galdanina Formation, Cambrian, Abbottabad.

A/594. Ashraf, M., Chaudhry, M.N. & Baloch, I.H., 1991. Sedimentary petrology of Lagarban phosphorite, Northern Pakistan. *Kashmir Journal of Geology* 8 & 9, 25-38.

The Lagarban phosphorite of Cambrian age occurs in the Hazara District of Northern Pakistan in the upper dolomite member of the Sarban Formation. The geology is complicated by imbricate reverse faults which run more or less parallel to the regional strike and separate the phosphorite into the different structural blocks of Lagarban phosphorite, Bataknaala phosphorite, East phosphorite, South phosphorite and Middle phosphorite. The displacement along the imbricate faults appears to be large, because the rocks of different facies of phosphorite have been brought into juxtaposition. The faults separate the East phosphorite of shallow water marine facies from the western phosphorite of open-marine facies. This is confirmed by petrographic study of the two major types. The former type shows evidence of reworking of the phosphate and associated sediments, whereas the latter type is represented by undisturbed, normal deposition of phosphate oolites and associated dolomite.

A/598. Ashraf, M., Chaudhry, M.N. & Hussain, S.S., 1980. General geology and economic significance of the Lahore granite and rocks of southern ophiolite belt in Allai Kohistan area. *Geological Bulletin, University of Peshawar* 13, 207-213.

Geological mapping of the toposheets (43 ^B/₁₃ and ^F/₁) carried out shows the following rock units in Besham-Kohistan and Allai areas: (1) Granitic rocks: Lahore granite and associated Shang granite gneiss and Mansehra (Susalgali) granite gneiss (2) Metamorphics: Thakot group, Tanawal group, Salkhala series, Hazara type slates and dolomitic rocks and amphibolites (garnet amphibolite and normal ortho-amphibolites) (3) Jijal ultramafics: dunite/peridotites and pyroxenites. Economic mineral deposits found so far are magnetite (in skarns, hornblendites and ultramafics), sphalerite/galena (in skarns, veins and altered granite), chromite (in dunites/peridotites and pyroxenites) and molybdenite (in silicified skarns, altered, altered granites and pegmatites). Anomalous values of Sn, W, Bi, Cd and Mn mineralization have been found in skarns, altered and silicified Lahore granite. The skarn type mineralization appears to be associated with the Precambrian Lahore granite rocks, which have intruded into the rocks equivalent to Salkhalas. This granite is unconformably overlain by Hazara type slates and Abbottabad Formation (dolomitic).

Two very important structural features have been noted in the area. They are one older thrust separating Thakot group and associated Lahore granitic rocks and Tanawal group and associated Mansehra granite gneiss. The other very major thrust is the Main Mantle Thrust bringing ophiolite/amphibolite rocks onto Lahore granite, Thakot group, Tanawal group, Mansehra granite gneiss and the Salkhalas.

Key words: Granites, economic geology, ophiolites, Lahore, Allai Kohistan.

Nepheline syenite and associated alkaline rocks are known from northwestern part of Pakistan as alkaline igneous province trending WSW-ENE. Important exposures so far known are at Loe Shilman, Warsak, Malakand, Shewa, Koga and Tarbela. The distribution of the alkaline magmatism in a narrow belt suggests a zone of crustal weakness during late Eocene/Oligocene in the Indian block and was caused by the influence of compression. Butt, Chaudhry, and Ashraf (1980) proposed that while the leading edge of the Indian plate was being collided with Asian block, compressional features were produced within the zone of deformation, a complimentary zone of tension was created within Indian block. These tensional opening provided sites for intrusion of highly alkaline magmas.

The economically important alkaline magmatism is seen in Koga area as medium to coarse-grained nepheline syenites, sodalite nepheline syenites, foyaite, litchfieldites and carbonatites. The first four rocks are prone to beneficiation to produce a produce useful for the manufacture of colorless glass and quality ceramic wires. The carbonatites are quite interesting as they contain Ce (0.07%) Sr (0.9 to 2.46%), Y (0.005%), Ba (0.09%). The P₂O₅ contents are quite interesting as they range from 15 & 18% in two samples of carbonatites, 5 and 6% in fenite and lamprophyres.

Interesting occurrences of carbonatites were found by Ashraf and Chaudhry (1977) in Malakand. They occurs as composite bodies having Nb (100-300 ppm) Sr (0.3%) V (0.01%), Y (100-200 ppm), Zr (0.01%), Sc (traces), La (400 ppm) and Yt (3-5 ppm) P₂O₅ in the six samples studied is 5 to 11%. Loe Shilman is also very interesting deposit regarding rare earth elements and phosphate contents.

Key words: Mineralization, alkaline rocks, carbonatites, NWFP.

A/600. Ashraf, M., Chaudhry, M.N. & Hussain, S.S., 1994. Geology of the lead - zinc-molybdenum, copper and iron skarns of Besham area Kohistan, NWFP, Pakistan. *Kashmir Journal of Geology* 11 & 12, pp. 1-27.

At the leading edge of Indo-Pak plate magnetite, sphalerite, galena, chalcopryrite, molybdenite etc. bearing skarn mineralizations occur in the Besham group of rocks. Geologically the Besham group of rocks consists of psammites, pelitic psammites, pure to impure carbonates, graphitic pelites and Lahor basement granitic complex including small to large acid pegmatite bodies. Exotic small ultrabasic to basic metamorphosed intrusions are also found at places. Base-metal mineralization has been found in rocks of carbonate character i.e. they are pure carbonate to impure carbonate rocks. In the former magnetite is the dominant replacive mineral as grain, streaks, patches, lenses etc. with overall contents of 12 to 96%. The impure carbonate rocks formed well-developed skarn mineralogy with sphalerite and galena as major base-metal minerals with contents of 1 to 15% along with molybdenite at places.

It is envisaged that magmatic solutions evolving from Lahor granitic complex and its derivatives were responsible for the development of skarn mineralogy and base-metal precipitation in three stages. The stage I was magnetite carbonate skarn. The stage II was for the formation of dense base-metals, developing in impure carbonate rocks with skarn minerals like pyroxene (CPX), amphibole, calcite/dolomite, pyrite/pyrrhotite, garnet, epidote, pyrolusite/puenselite etc. This is overlapped by silicification of stage II mineralogy (surrounding metasediments and apophyses of granite, as patches lenses and lenticular bodies increasing the base - metal contents in them. The stage III is subsequently developed from stage II as vein formation.

A/601. Ashraf, M., Chaudhry, M.N. & Malik, R.H., 1984. Bituminous/anthracitic coal of Kotli District, Azad Kashmir. Abstracts, First Geological Congress, Lahore, 54-55.

Consult the following account.

Key words: Coal, Kotli, Azad Kashmir.

A/602. Ashraf, M., Chaudhry, M.N. & Malik, R.H., 1986. Bituminous and anthracitic coal of Kotli District, Azad Kashmir. *Kashmir Journal of Geology* 4, 1-12.

Coal occurs at two horizons within Patala Formation in the Kotli anticline (a continuation of Riasi anticline in Jammu). Most commonly the coal lies over the bauxite as in Sawar, Tattapani, Dondili and Karela. The second horizon occurs within the carbonaceous shales about 9 to 15m above bauxite bed as in Kamroti, Barmoch, Bangang and Nikial. The exposed thickness of individual seams ranges from 0.02 to 1.0m which in underground working is from 1.0 to 2.2m in thickness.

Petrographic studies of coal show the presence of carbonaceous matter (X=63), Clay (X=30.14), quartz (X=2.79) haematite/limonite (X=2.53), carbonate (X=0.12), and muscovite/sericite (X=0.24). Carbonaceous shale has the same minerals as in coal but in quite different proportions. Chemical studies of the coal indicate a wide range of variation. The coal samples can be classified as high fixed carbon (max. 86.75%) to low fixed carbon (35.31%), low volatile matter (7.25 to 13.56%) low ash (down to 3%) and high ash (26 to 49%) Coal.

Washability study on coal samples shows that using sink/float, heavy media separation and flotation techniques on different size fractions such as 25X4 mm, 4X0.5 mm and less than 0.5 mm reduced ash from 34% to 21% and sulphur from 3.4% to 1.2%. This shows that coal is amenable to cleaning to a limited extent as ash forming mineral matter is uniformly and finely disseminated in the coal. Some coal samples collected from Balmi, Sohra Seri, Kamroti, Bangang and Kandel are low in ash (3.32% to 14.61%) and high in fixed carbon (51.56 to 86.75%). These coals can be blended with clean coal from other localities of Kotli to obtain a product containing 14 to 16% ash. Such a coal blend may be used for cooking purposes. The Kotli coal is of bituminous to anthracitic variety having decidedly better rank than any of the coal deposits found in Pakistan so far. The numerous coal exposures all along the strike on both limbs of eroded anticline are encouraging and are indications of the occurrence of large coal deposits.

A/603. Ashraf, M., Chaudhry, M.N. & Qureishi, K.A., 1983. Stratigraphy of Kotli area of Azad Kashmir and its correlation with standard Type areas of Pakistan. *Kashmir Journal of Geology* 1, 19-30.

In Kotli area, rocks, Precambrian to Pleistocene age have been found and studied. The Precambrian rock formation is, Dogra Slate which has been reported by author for the first time in Nail Nala. Cambrian rocks are correlated with Abbottabad Group (consisting of basal boulder bed and overlain by thick sequence of Sirban dolomite/quartzite). In this area apart from Cambrian (Abbottabad Group) all the formation of Paleozoic and Mesozoic are missing. Either they were not deposited or were weathered to form bauxite/laterite-representing an unconformity of a big gap. In the Tertiary period Patala Formation, Margalla Hill limestone, Murree Formation and rocks of Siwalik Group were deposited. Section measurements were done to establish the stratigraphy etc.

A/605. Ashraf, M. & Hamood, O., 1997. Tectonic reinterpretation constraints of the Western most Kohistan complex in Timargara, Dir District, Pakistan. *Geological Bulletin, University of Peshawar*, 30, 311-323.

No detailed tectonic and structural studies were carried out in the western most extremity of the Kohistan area. People have been concentrating mostly along Indus canyon and Swat valley for geotectonic, structural, petrological and geochronological studies. Present investigation is the first study to thoroughly work out tectonic reinterpretation constraints of the western most Kohistan complex particularly in Timargara quadrangle and adjoining area of Warai consisting of 673 sq.km. The concept of underplating for the emplacement of major plutonic complexes is advocated in this area as well, as was also found out in Swat and Indus canyons, i.e., the Balambat norite and Timargara gabbro-norite which are different from Chilas complex magma type underplated the Dir tholeiitic amphibolites. These plutonic rock types are more evolved than those of main Chilas complex. The latter underplated Dassu metaplutonic complex of Kamila amphibolites. The Kamila amphibolites are further subdivided into Kamila group metaplutonic calc-alkaline amphibolites and Dir metavolcanic tholeiitic amphibolites or precisely as Kamila amphibolites and Dir amphibolites which are advocated to be adopted due to their different provenances.

Key words: Tectonics, Kohistan complex, Timargara, Dir.

A/606. Ashraf, M., Hamood, O. & Khan, H., 1999. Structural geology of the western extremity of the Kohistan Island Arc in Dir area, NWFP. *Geological Bulletin, Punjab University* 33 & 34, 71-81.

Structural studies show that the rock of Kohistan island arc exposed in the area are folded into northwards dipping southwards verging tight folds in the south (near MMT) which opens up northwards. The amphibolite have undergone at least IWO phases of isoclinal folding. In the first phase recumbent or isoclinal folding S1, axial planar foliation was developed in these rocks. The first phase of deformation is probably related to the subduction of Kohistan Island Arc under Eurasian plate. In the second phase these rocks were again folded. The rock of Kohistan Island Arc has undergone a third phase of deformation which produced the shear zones resulting into retrograde metamorphic chlorite grade rocks. That is related most probably to the collision of India plate with Kohistan complex. The southern part of the Dir amphibolite near MMT mostly trend EW and dips 65' to 80' northwards which is almost parallel to the trend of MMT. In the central portion of the mapped area the plutonic rocks trend NE to SW and their dips varies from 40' to 70' NW and SE. Most of the fold axes in the plutonic sequences are parallel to each other which mostly trend NE to SW and plunges from 12' to 50'. The northern part of the Dir amphibolites mostly NE and dips 150 to 60' SE.

A/607. Ashraf, M., Haq, R., Qureshi, M.H. & Faruqi, F.A., 1971. Magnesite occurrence in Hazara District. *Pakistan Journal of Scientific and Industrial Research* 14, 538-541.

Magnesite occurs as three lens-like bodies near Sherwan (Hazara) in the Abbottabad Formation of Upper Paleozoic system. Total length of two outcrops is around 900 ft and width about 150 ft. The third outcrop is 150 ft. long and 20 ft wide. The deposit is probably hydrothermally metasomatized type. The properties of the magnesites were determined by utilizing microscopic, chemical, X-ray diffraction and differential thermal techniques.

The conclusion drawn from the results obtained is that ores are fairly rich in magnesite with some minor impurities such as calcite, hematite, clay, siderite, quartz and limonite.

A/608. Ashraf, M. & Hussain, K. 1994. Economic geology and mineralogy of PGE-Au in dunite of Chilas, northern area-Pakistan. Abstracts, Second SEGMRITE International Conference on the Export Oriented Development of Mineral Resources and Mineral Based Industries, 20-21.

Platinum group elements (PGE)-gold (Au)-copper (Cu) occur in dunite rocks of Thurli and Chilas in northern area of Pakistan. Dunite rocks in Thurli are dominantly fresh olivine rich from 93-98%. The impurities are CPX 2 to 5%, chromite/magnetite 1 to 2% and sulphides like covellite, chalcopyrite, bomite, pentlandite, chalcocite and pyrrhotite containing PGE and Au from 0.2 to 2%. The olivine is dominantly forsterite (Fo 85-92%). In a 50m dunite zone near Thurli Cu is about 0.4%, Ni 0.2%, PGE + Au 800 ppb to 2800 ppb. The POE minerals are moncheite, michenerite and merenskyite with electrum and tetra-aurocuprite as Ag, Au and Au.Cu alloys. Texturally dunite in Chilas area is very compact to moderately compact with grain size of about 0.3 to 2mm. The valuable POE+Au+Cu+Ni bearing minerals of Thurli dunite can be liberated by crushing the dunite rocks down to 0.3 to 1.0mm size. With the removal of valuables, the tailings obtained are pure forsterite sand. The size of such deposit near Thurli is about 30 million tonnes and the one that is pure compact forsterite is 50 million tonnes near Chilas.

Key words: Economic geology, platinum-group mineralization, dunite, Chilas Complex.

A/609. Ashraf, M. & Hussain, S.S., 1983. Chromite occurrences in Indus Suture ophiolites of Jijal, Kohistan, Pakistan. In: Sinha, K.A. (Ed.), *Contemporary Geoscientific Researches in Himalaya* 2, 129-132. Singh, Dehra Dun, India.

A/610. Ashraf, M., Khan, M.A. & Asghar, I., 1999. Geotechnical properties of Balambat norite, Panjkora diorite and hornblendite of Timargara area, Dir District, NWFP. *Geological Bulletin, Punjab University* 33 & 34, 149-156.

Gabbro-norite, norite, diorite and hornblendite occur as very large to large deposits in the Kohistan Island Arc of Timargara area Dir district. These rocks are very fresh and compact at many places. Texturally Balambat norite and Panjkora diorite are fine to medium grained whereas hornblendite are medium to coarse grained. The rocks were tested to know their geotechnical properties for usefulness as building material and as polished dimension stones/slabs. The tests carried out are like absorption of water, soundness, compression/crushing strength. Absorption value of norite is 0.59% maximum, of diorite is 1.01%, and that of hornblendite is 0.98%, soundness value for fine losses is 0.83%, 1.05% and 1.05% respectively for sieve size 35". Unconfined compressive strength is 8644, 6483 and 6915 PSI respectively. These rocks take good to very good polish and are thus useful as decorative stones and for building purposes.

Key words: Geotechnical, norite, diorite, hornblendite, Dir.

A/611. Ashraf, M. & Khan, M.S., 1992. General geology & stratigraphy of Muzaffarabad and Poonch area in Azad Jammu & Kashmir. Abstracts, First South Asia Geological Congress, Islamabad, p.51.

General Geology and stratigraphy of the Poonch and Muzaffarabad areas are quite interesting due to fact that various formations in Hazara, Azad Kashmir and occupied Kashmir are continuous in Precambrian to Cambrian & Tertiary Time and discontinuous during rest of the Paleozoic and Mesozoic times. From this it appear that there were definitely some stratigraphic barriers in those areas but they were not as reported by Ghazanfar and Chaudhry (1987) the three stratigraphic provinces. In our view the three regions had same geological environments during Precambrian times, depositing Sharda/Salkhala sediments overlain by Hazara/Dogra Slates and Tanol quartzites and pelites. The Cambrian conditions remained similar as well in all the three areas by depositing dolomites, limestone etc of Abbottabad Formation, with Tanakki unconformity at base. In all the three stratigraphic areas, during Late Cambrian times unconformity is seen in Hazara in the form of Galdanian Formation, (Ashraf et al. 1983), with subsequent non-deposition till the formation of Datta/Sarnanuk Formation of Jurassic and further Cretaceous formations. But there are no such formations even upto Late Cretaceous times in the Muzaffarabad -Kotli basin. That is, a pre-Tertiary unconformity is regionally present in Hazara, Kashmir, Potwar & Salt Range. Whereas in Kahuta-Pir Panjal Range Gondwana Formation of Carboniferous age occurs and are not seen in other two basins. Panjal Group of rocks consisting of pyroclasts and lava flow occur as rift related submarine to aerial rocks in both Kahuta and Muzaffarabad areas with Triassic sediments at places. And lastly there was only one basin/geosyncline forming Paleocene to Lower Miocene rocks everywhere.

Key words: Stratigraphy, Poonch, Muzaffarabad, Azad Kashmir.

A/612. Ashraf, M., Khan, M.S., Awan, M.A., Yasir, A., Warraich, M.Y., Khan, A. & Awan, M.S., 1991. Geology and petrology of Jijal and Pattan layered ultramafic-mafic complexes in the vicinity of Jijal, Duber and Pashto, NWFP, Pakistan. *Kashmir Journal of Geology* 8 & 9, 193-196.

The project area covers about 300 km² located in the vicinity of Jijal, Duber and Pashto (Fig. 1) in Districts of Kohistan and Mansehra. Geological mapping was carried out of the area on a scale 1:50,000 of toposheet No. 43A/12, 43A/16, 43E/4 and 43F/1 of Survey of Pakistan.

The geological sequence of Jijal complex consists of ultramafic and mafic cumulates. The ultramafic cumulates are divided into dunite, wehrlite, websterite, garnet-pyroxenite and garnet-hornblendite whereas mafic cumulates are garnet gabbro. The geological sequence of Pattan complex also consists of ultramafic and mafic cumulates, the ultramafic cumulates are chromite, dunite and (meta)-wehrlite, whereas mafic cumulates are divided into two pyroxene gabbro and two pyroxene quartz-diorite.

Previously, the metamorphosed mafic complexes of the Kohistan island arc have been lumped together as an undifferentiated mass called Kamila amphibolite. Now, the Kamila amphibolite has been divided into three complexes i.e., Dassu complex, Kayal complex and Pattan complex. The Dassu complex is the oldest pluton which is polymetamorphosed, isoclinally folded and banded amphibolite augen gneiss that grades from metatonalite at its top downward to melanocratic garnet amphibolite at its base some 5 to 6 km down section. Dassu complex is underplated by the Kayal complex, has a metamorphosed agmatitic intrusive breccia at its roof and grades downward from moderately banded metadiorite gneiss in its upper part to melanocratic garnet-amphibolite at its base. Again Kayal complex is being underplated by the Pattan complex which is least metamorphosed partly to greenschist facies. The Pattan complex is underplated by Jijal complex.

Field evidences suggest that the Pattan complex was emplaced along the pre-existing metamorphosed Kayal cumulate complex. The top of the Pattan complex is marked by a spectacular, intrusive, polymictagmatite breccia. In Duber and NW of Duber the Pattan complex is overthrust on to the Jijal complex. While in Pattan area and SE of Pattan, there is a faulted (strike slip) contact between Pattan complex and Jijal complex.

The Jijal complex is the southern most, layered ultramafic-mafic cumulate complex of the Kohistan tectonic province, the Main Mantle Thrust (MMT) is the southern boundary of the Jijal complex, which in turn is the southern boundary of Kohistan arc complex. The Main Mantle Thrust (MMT) and Duber thrust wedges out Jijal complex NW of Duber near Charri, on the other hand Main Mantle Thrust and Pattan fault (strike slip fault) wedges out the Jijal complex on the eastern side near Pashto.

A/615. Ashraf, M., Loucks, R.R., & Awan, M.A., 1989. Serpentinization of cumulate ultramafites and development of Heazlewoodite-Pentlandite-Awaruite-Magnetite and Pentlandite-Chalcopyrite-Pyrrhotite association in Alpurai and Khishora, Swat, Pakistan. Kashmir Journal of Geology 6 & 7, 8-18.

Ultramafics of Alpurai and Khishora areas of Swat District have been found to occur as cumulates. These ultramafic bodies occur along the Main Mantle Thrust which marks the part of the suture zone between the Asina and Indo-Pakistan plates. The present study elaborates the classification of ultramafics of the two areas, their chemico-mineralogical composition, distribution of minor elements, ore microscopy and electron microprobe composition of some sulfides. The Alpurai rocks are found to be, stratigraphically upward, harzburgites, olivine websterite, wehrlite, dunite, wehrlite, websterites, dunite and ilmenite. All these members are altered variably to serpentine minerals. The Kishora rocks are dominantly a part of an ultramafic mantle tectonite i.e., a harzburgite which is overlain by dunite. All these rocks are pervasively serpentinized. In both Alpurai and Kishora areas nickel mineralization is present in two distinct ore mineral assemblages as heazlewoodite-awaruite-pentlandite-magnetite and pentlandite-chalcopyrite-pyrrhotite-pyrite associations respectively. These associations appear to have developed from hydrothermal alteration of ultramafic rocks by the introduction of water, sulfur and or carbon dioxide. The Ni values found in the ultramafic rocks appear to be low i.e. 1500-2000 ppm. But most of Ni is in the form of nickel sulfides and alloy.

A/616. Ashraf, M. & Malik, M.I., 1983. Prospects and development of phosphate deposits of Lagarban area Abbottabad, Pakistan. Kashmir Journal of Geology 1, 77-82.

Sedimentary Phosphorite of Lagarban is 7.831 million tonnes as in-situ rock and is 5.093 million tonnes recoverable reserves from East, Batakna, Southern and Lagarban South Phosphorite. 840 tonnes can be mined per day. The undiluted ore contain 28.55 to 30.20 % P₂O₅ in the four ore bodies. Mineralogically the ore consists of collophane with minor dahllite as phosphorite minerals. The other ubiquitous to accessory minerals are dolomites, chalcedony, chert, quartz, goethite, pyrite, chlorite, clay, mica, organic matter etc. It is that variation in grade and the proportion of impurities is a function of original sedimentary variations, and the amount and nature of contamination and dilution during and after the deformation are by physical & chemical mechanisms. The beneficiation of the ore is possible by HMS and acid leaching methods but the proposition appears expensive. However, ROM blending with Jordan ore may be viable after some more plant trials and tests.

A/619. Ashraf, R., 1989. Electrical resistivity survey for groundwater investigations in an area between Quaid-i-Azam University and Murree Road with special emphasis on anisotropy. M.Sc. Thesis, Quaid-i-Azam University, Islamabad, 35p.

Surface electrical resistivity measurements were made at 20 geophysical observation stations in an area between Quaid-e-Azam University and Murree Road (longitudes 73° 7' 48" to 73° 10' 40" E and latitude 33° 43' 55" to 33° 46' 33" N), Islamabad in order to delineate the suitable ground water aquifer zones using Schlumberger electrode configuration keeping the maximum current electrode spacing $AB/2 = 200$ meter with ABEM Terrameter. The interpretative results deduced various subsurface geological units named as clay, compact clay, gravels + clay + silt sand with minor amount of clay or silt, boulders (moist & dry).

For ground water investigation, the field resistivity data was interpreted by partial curve matching technique to obtain the interpreted electrical and geological sections in the form of vertical electrical and geological columns for each resistivity station. Besides, four geological sections have also been prepared. An anisotropic contour map has also been prepared to see the isotropic and anisotropic regions in the study area.

The combined interpretative results of all these maps indicate layers of permeable formations at various depths, but these formations are not good aquifers as the recharging mainly depends upon weather condition of the area, especially rain. The anisotropic contour map shows 3 anisotropic zones with a maximum anisotropy of 1.5. This anisotropy shows a good contrast in lithology which is due to boulder and compact clay.

A/620. Asif, M., Habib, M. & Jan, M.Q., 1985. Ultramafic and mafic rocks of Thurlly Gah and their relationship to the Chilas Complex, North Pakistan. *Geological Bulletin, Peshawar University* 18, 83-102.

Detailed field and petrographic studies in Thurlly area substantiate the idea of a two-fold subdivision of the Chilas Complex. Much of the area is occupied by the association of "Main Norites" with subordinate pyroxenites and anorthosites displaying only local layering. Apparently intrusive into these is the association of ultramafic-mafic rocks occurring principally in a 2.5x1 km lensoid body. These possess well-developed sedimentary features, especially layering and comprise dunite, peridotites, pyroxenites, troctolite, norite, anorthosite, and olivine/pyroxene pegmatites, there are distinct differences in the mineralogy of the two associations, especially in the composition of plagioclase and oxide minerals. It is suggested that the ultramafic-mafic association was derived from a picritic magma emplaced in the floor of crystallizing (main) noritic magma. There is a strong concordance in the planar structures of the two associations and the crystallization of the ultramafic mafic rocks apparently preceded all deformational events.

A/622. Asim, M., Karim, A. & Khan, M.H., 1999. Geology of Shamoza area in Lower Dir District, NWFP, Pakistan. Geological Bulletin, University of Peshawar 32, 51-55.

Rocks of the Main Mantle Thrust and associated suites have been investigated in a 100 km² area in southwestern Dir district. Field investigations and thin section study reveal that the succession of rock units from south to north is that of the Indian plate rocks, ophiolitic mélange zone, and Kohistan arc terrane. The Indian plate rocks comprise granitic gneisses along with minor calcareous schists and phyllites. The ophiolitic mélange zone, which is reported for the first time from the area, mainly comprises serpentinized dunite, talc-carbonate schist and crystalline limestone blocks in a matrix of phyllite and minor graphitic schist. The arc terrane is represented by amphibolites, intruded by quartz porphyries and tonalites in a number of places.

A/623. Asim, M., Majid, M. & Shah, M.T., 2000a. Geology, geochemistry and tectonic setting of ophiolitic rocks from the Waziristan ophiolite complex, NW Pakistan. *Geologica* 5, 109-132.

The Waziristan Ophiolite Complex occupies about 5000 km (super 2) area in a north-south elongated belt in the north and South Waziristan Agencies. It demarcates the spatial disposition of the suture zone between the Indian plate and the Afghan block in the Waziristan area. The complex consists of a chaotically arranged stack of thrust slices. Section(s) showing a complete sequence is not preserved but all members of a typical ophiolite are separately present in the area. Basic volcanics, ultramafics and jasperites within the ophiolite belt respectively contain copper, chromite and manganese. A 40 km (super 2) area near Boya, west of Miranshah in the North Waziristan Agency was selected for detailed study. Dominant rocks of the study area include basic lavas, ultramafics and gabbros with subordinate amounts of mafic dikes, granites, and pelagic sediments. Representative samples were studied in thin sections and analyzed for major elements. The major elements data of the studied rocks have been interpreted to reveal the tectonic environment at the time of generation and emplacement of the ophiolite sequence. The petrochemical indices of the mafic volcanics, in particular, correspond to a transitional character (from tholeiitic to calc-alkaline) developed in an island arc environment in general and MORB in little. The geochemical parameters substantiates the assumed prevalence of the arc-related structures in the Waziristan section of the suture zone before collision of the Indian plate and the Afghan block. On the basis of geological and geochemical signatures of the constituent rocks, it is suggested that the WOC was formed in supra subduction zone setting probably by marginal basin or back-arc basin rifting and was later on obducted on to the Indo-Pakistan plate.

A/625. Asim, M., Majid, M. & Shah, M.T., 2001. Mineral chemistry and origin of ophiolitic rocks from the Waziristan complex, NW. Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.1.

The Waziristan ophiolite complex demarcates the spatial disposition of the suture zone between the Indian plate and the Afghan block in the Waziristan area. The complex is located along the western margin of the Indian plate and consists of a chaotically arranged stack of thrust slices. Section(s) showing a complete sequence is not preserved but

all members of a typical ophiolite are separately present in the area. Dominant rocks include basic lavas, ultramafics, gabbros, dikes, granites, and pelagic sediments. Major minerals (pyroxene, spinel, serpentine and plagioclase) within the rocks were analyzed using Jeol Superprobe Micro-analyser. Pyroxenes from basalts, apparently crystallized at temperatures above 1000°C, plot in the field of volcanic arc basalts and ocean floor basalts. Pyroxene and chromite data have been further interpreted to reveal the tectonic environment at the time of generation and emplacement of the ophiolite sequence. The pyroxene data show a transitional character (from tholeiitic to calc-alkaline) and ocean floor to island arc type environment. Chromite data, with moderate to high Cr#, also exhibit oceanic (abyssal) to arc affinities. The chemical data on pyroxene and chromite suggest a complex origin for the Waziristan ophiolite such as oceanic+island arc, back arc or infant arc.

A/626. Aslam, A. & Kaneda, H., 1993. Mineralogical study of the Kakul phosphorite deposit, Abbottabad District. *Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad*, 7, 17-33.

The present study has been carried out as a research exercise to improve and evaluate the analytical precision of the XRD and Microscopic techniques. The XRD and Microscopic investigation of the Abbottabad phosphorite ore deposit shows considerably important information related to ore mineralization and mineral resource.

The following mineral species have been identified by means of the XRD analysis; dolomite, ferroan dolomite, calcite, quartz, hematite, hydroxyapatite and fluorapatite. On the basis of XRD, volume and weight percentages of constituent minerals of ores have been determined. The volume percentage data shows that the carbonaceous minerals in the studied area consist mostly of ferroan-dolomite. Relatively large amounts of ferroan-dolomite occur within phosphorite ore beds and in the associated rocks. In particular, the ores from the northwestern sites (Q site in Figure 1) are rich in ferroan-dolomite, which occupy 24.5 volume % of all specimen. The volume % relationship among carbonate minerals, quartz and apatite minerals shows that ore samples from the Q site are relatively rich in carbonaceous minerals compared to quartz. The ore grade of the Q site is higher than the Kakul mine site. It is considered that ferroan dolomite and large amounts of carbonaceous minerals are associated with ore formation. The weight percent analysis has been performed on the basis of standard calibration method, and belongs to the technique of quantitative analysis. The data shows that the carbonaceous minerals / quartz weight values are quite different in the two sample sites. The carbonaceous minerals / quartz ratios vary from 0 to 0.5 for the mine site and on the contrary, range from 1.04 to 19.6 for the Q site. This suggests that the ore at the mine site is relatively rich in quartz. This result is identical with the data of volume percent analysis. Microscopic observation gives more useful information about the mineralogy and mode of occurrence of minerals. A major ores forming phosphorite mineral is cellophane which is an aggregate of amorphous P-bearing hydrous phases. The collophane often occurs in a host dolomite mass filling the interstices and cavities. The massive phosphorite ores show the following two distinctions with respect: to the minerals occurring along grain boundaries of collophane. One is that the cement is composed mostly of calcite, and another is that the cement is predominantly quartz. The former occurrence is from the Q-site, while the latter from the mine site. This occurrence under the microscope is concordant to the XRD results. It is concluded that carbonaceous minerals, in particular ferroan-dolomite and the carbonate/quartz ratio plays an important role in ore formation. In order to make clear the ore genesis and to evaluate the ore resources, mineralogical and geochemical studies are essential.

Silica sand, feldspar, nepheline syenite, limestone and dolomite are the principal naturally occurring industrial minerals that are used in the glass industry. This paper describes briefly their occurrence, formation, mineralogy, physical and chemical characteristics and their utilization in the glass industry. Physical and chemical characteristics of these minerals suited to the glass industry have also been discussed. Since silica sand is the main and important constituent of all commercial glasses, samples of sand from all commercially exploited deposits were collected and chemical analyses of raw as well as washed samples, including grain size distribution and some other properties, have been determined and compared. Similarly, chemical and physical properties of some other minerals collected from different parts of Pakistan have been determined and discussed with particular reference to their use in the glass industry.

A study of marble deposits of the North West Frontier Province of Pakistan has been carried out in the years 1983 and 1984 primarily to update the previous work on this commodity and also to additionally investigate some of the new and the little known occurrences.

The marble deposits in the area under study are mostly associated with metasedimentary rocks of varying age and composition, displaying a wide array of colour shades and grain sizes. The marble from most of these deposits has a pleasing appearance, takes good polish and meets the standard specifications for specific gravity, water absorption, flexural strength and other physical properties.

A/650. Atudorei, V., Baud, A. & Sharp, Z.D., 1995. Late Permian and early Triassic carbon isotope and sequence stratigraphy of the northern Indian margin. *Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETCH Zurich) Switzerland*.

The Northern part of Great-India was subjected to an early rifting phase in the late Paleozoic, just at the end of the large scale Gondwanian glaciation. The beginning of the rifting processes is marked by large hiatuses and discontinuities (paraconformities) between the early or middle Paleozoic sedimentary succession and the discontinuous middle-late Permian Panjal Traps and transgressive sediments. The North Indian passive margin consists of the present High and Lower Himalaya and a small part of the Indian craton and its sedimentary cover (from Zaskar, Chamba and Kashmir synclinoria to the Salt Range), and belongs to an upper plate separated from a lower plate (Ladakh and Karakoram continental crust with their former sedimentary cover) at the end of the Permian (Baud et al., 1989). The Permian rift shoulder is partly located in the N Lahul-Kashmir Himalaya and part of it in the underthrust Lower Himalaya. The rim basin (landward of the shoulder) is developed in the Potwar-Salt Range area.

From rifting to drifting stages (early late Permian to early Triassic time) the sedimentary evolution is characterised by three transgressive-regressive (T-R) second order cycles. These overlie the Panjal Traps plateau basalts, which were deposited during the Murgabian time on the broad rift shoulder.

Profiles of inorganic carbon and oxygen stable isotopes were studied in marine carbonates from the Himalayan province (Guryul Ravine and Palgham, Kashmir; Salt Range, Pakistan; Thini Chu Valley, Kali Gandaki, Nepal).

The first T-R cycle (upper Murgabian to lower Dzulfian) is fully developed on the rim basin and consists of the transgression and the growth of the Wargal shallow carbonate platform. On the rift shoulder, this T-R cycle is present only in Kashmir with the sandy limestone of the Member A and B of the Zewan Formation. Positive $\delta^{13}\text{C}$

values (+2-4‰) occur within this first T-R cycle. In Central Nepal, stratigraphic indications are too scarce as to the age of the Thini Chu Group.

The second T-R cycle (Dzulfian-lower Changhsingian) corresponds to a sudden terrigenous influx occurring both on the rift side and on the land side. A shallow water mixed carbonate-clastic ramp is developed in the rim basin (Chhidru Formation) and overlies the Wargal shallow carbonate platform. To the north, the submerged part of the shoulder develops an offshore mixed clastic carbonate deltaic complex, the upper Zewan Formation (Member C and D). Positive $\delta^{13}\text{C}$ values (+2-4‰) occur for both areas, but a large shift of about 3‰ is recorded with the regressive phase of this cycle. This important negative excursion is documented worldwide. It is thought to be due to the oxidation and removal of the light organic carbon stored on the emerging continental shelf, after the huge regression marked by the Permian-Triassic boundary. On the emerged part of the shoulder, the marine Kuling sandstones and shales are transgressing on older sediments. This T-R cycle, with the marine submersion of the shoulder, indicates the beginning of the thermal subsidence and the transition to the drifting stage.

The third T-R cycle belongs to the Lower Triassic and is characterized by an important change in sedimentation. The age of the first transgressive sediments is still in dispute; it is either latest Permian or earliest Triassic (age of the lowest *Otoceras* zone and the problems of reworking during transgression). The first transgressive sediments consist of high energy dolomitic grainstone with glauconite and reworked quartzarenite (Lower Katwai Member) in the Salt Range area, of thin bedded *Claraia* limestones and shales with "Permian brachiopods" overlain by black shale with ammonoid lenses in Kashmir (Member E1 and E2 of the Khunamuh Formation) and of high condensed nodular limestone (*Otoceras* beds) in the Tethys Himalaya (Panjang member).

At the Kashmir sections, the negative excursion of $\delta^{13}\text{C}$ continue in the Early Induan *Otoceras* zone and the lowest value (-4‰) is reached in the overlying *Ophiceras* zone. Above the low $\delta^{13}\text{C}$ value samples in the *Ophiceras* zone, we note a progressive rise in the $\delta^{13}\text{C}$ values at the base of the overlying *Vishnuites* zone (late Induan).

For the Thini Chu Valley profile, samples from the Panjang member (sensu Hatleberg & Clark, 1984) and the lower part of Tamba Kurkur Formation show negative values ($\delta^{13}\text{C} = -0.5 \pm 0.7\%$) with no significant trend suggesting a lower Induan age and make possible the correlation with the E Member of the Khunamuh Formation from the Kashmir sections.

A generalisation of the pelagic limestone deposition corresponding to the maximum flooding surface is realised at the beginning of the late Induan time with the Lower Ceratite Limestone in the proximal part of the margin (Salt Range) and thin, condensed Limestones and shales in the distal part.

It is interesting to note that the $\delta^{13}\text{C}$ values for the Kali Gandaki and Kashmir sections are very low comparative with Salt Range section and others Tethyan sections, ranging from -9‰ to -12‰ (v.PDB). These low values can be explained by the thermal metamorphism process that affected the Kashmir and Nepal sections, documented by the high Color Alteration Index of conodonts (Wang, 1990; Garzanti et al. 1994). For the limestones from the base of Tamba Kurkur Formation (Kali Gandaki section) anomalous values of $-20 \pm 3\%$ occur. There is no correlation between carbon or oxygen values and the different types of carbonate cement.

A/652. Auden, J.B., 1934. Notes on the Biafo Glacier in Baltistan. Himalayan Journal 6, 67-76.

Godwin Austen, of the Survey of India, made the original survey of the Hispar and Biafo glaciers in 1860-1 (Survey Maps 42 P, 43 M), but did not reach their upper neve fields. He marked the Biafo as running almost due NW.-SE. In 1892 Martin Conway (now Lord Conway) made the first complete traverse of the two glaciers, starting from Hispar village, crossing the Hispar pass, and descending the Biafo to Askole. In his map the orientation of the Biafo glacier is more nearly NNW-SSE.

The Workmans visited the Biafo glacier twice, in 1899 and in 1908. The orientation of the glacier, as determined by them, corresponds more closely with that originally given by Godwin Austen. Neither Conway nor the Workmans were able to explore the snowfield or neve, called by the former Snow Lake, and on the modern map the Basin of the Biafo Glacier. The Workmans found snow conditions in this flat area too unpleasant.

On the 5th June we motored from Srinagar in heavy rain to Pahlgam, hoping to cross by Astanmarg and Amarnath to the Gamru valley, just below Machhoi (Map 43 N). The snow-line was found to be as low as 10,000 feet, and the Pahlgam coolies were unwilling to go over Astanmarg under such abnormal conditions. On the 6th we therefore motored back to Srinagar and on to Woyil bridge, marching the same day to Gund. The Leh route was followed over the Zoji La as far as the suspension bridge below Kargil (43 N, 52 B). We then branched down the Shingo river, dismissing our ponies at Olthing, and taking on men from there onwards at every stage. From Parkutta (43 M) we left early with excellent coolies for the ferry across the combined Shyok and Indus rivers. Across the ferry the Kiris coolies took us on to Narh. From Narh to Shigar is a short march. By taking this route one is saved a day, since the long detour through Skardu is avoided. Shigar was reached on the 16th. There was still too much snow on the south-west side of the Skoro La for that pass to be easily negotiable, so the longer route along the Shigar and Braldu rivers was followed. We hoped to reach Askole on the 20th, but were held up three miles from that village by late afternoon flooding of the streams, due to rapid melting of the glaciers by which they are fed.

There is little of interest along the route from Dras to Askole. The valley sides were barren and hot, and the apricots near the villages as yet unripe. We were unfortunately not told of the aquamarine mine at Dusso until arrival at Askole. At Chongo there is a series of hot springs which deposit extensive mounds of tufa. We bathed, buoyed up in bliss by effervescent bubbles of sulphuretted hydrogen. The temperature of the water in one spring was 98° F. De Filippi mentions it as 120° in 1909.

The 21st was spent at Askole collecting coolies. Besides the pukka coolies for transport, others were required for carrying up ata, and, after Camp 4, wood as well. After several hours of bickering, Gregory managed, with the help of some conjuring tricks with magnets and corks, to make them decide on a wage of Rs. 1 /1 per day, and a daily ration of 1 seer of ata. For economy we had not brought boots, except for the coolie mate or sirdar and one or two others. Apart from the factors actually responsible for the failure of the trip, this lack of boots would have eventually led to great difficulties, since the local paboos stand up very badly to wet snow conditions. In a good year it would not be necessary to provide boots for all the coolies, but solely for those taking part in the actual survey of the Snow Lake and in any climbing of the adjacent peaks. Under good conditions the glacier itself should be dry enough for the transport coolies to use their paboos.

A/656. Auden, J.B., 1938b. Resume of geological results, Shaksgam Expedition, 1937. Himalayan Journal 10, 40-48.

The area described in this account occupies about 2,000 square miles and is situated on both sides of the Karakoram Range, extending northwards up to the Yarkand river at approximately latitude 36° 22' N. It is included partly within the provisional issues of Survey of India J-inch maps 42 p, 43 m, and 52 a. Most of our time was spent in the area covered by the as yet unpublished map 51 d. The visit was made in the company of E. Shipton (leader), H. W. Tilman, and M. A. Spender. I wish to record my thanks to Shipton for the invitation to join his expedition and for the well-planned arrangements that were made throughout. Spender and I had little of the worry connected with coolies and the distribution of food supplies, and were spared the monotony of relaying, which Shipton and Tilman

unselfishly supervised. Moreover, when mountaineering difficulties did occur, it was often their experience and skill which allowed us to carry out our programme.

It is true that geological work would have been easier and more detailed if I could have been relieved of carrying a rucksack loaded with personal and survey equipment, and had there been no necessity of keeping rigidly to a timetable. For reasons of economy, however, it was imperative to cut down the porters to the absolute minimum, and the rapid flooding of the rivers in July necessitated our being on the Indian side of the Shaksgam by a settled date. The flooding of the rivers, both daily in the afternoons, and seasonal as the summer progressed, became for us the chief bogey. Indeed, it was a fortunate spell of cloudy and snowy weather at the beginning of July which, by lessening the melting of the glaciers and lowering the Shaksgam, allowed us ever to return across this river. When I reached the Shaksgam with Lhakpa and Mahadi on the 28th June, after crossing the Aghil col, we were somewhat dismayed at the expanse of water, and had fears of all of us having to go north again, over the Aghil pass, with food exhausted, and the prospect of an uncertain welcome by Yarkandis below Bazar Dara.

Apart from the reconnaissance map of Professor Desio, which included the Panmah and Sarpo Laggo valleys and part of the Shaksgam, there were no topographical data upon which to base a geological map. Geological sketch plans were made throughout the expedition, and it is hoped to adapt these to the topographical map on which Spender has been working since our return. Spender tirelessly carried out the main survey, based on K2peak, 28,250 feet, while Shipton and I used a light 3-inch theodolite, belonging to the Royal Geographical Society and fitted with a Leica photographic attachment, to fill in details of areas he was not able to visit. These included the K2 glacier, surveyed by Shipton, and the lower Shaksgam valley and Nobande Sobande glacier, done by myself. Spender has the more difficult and exacting task of incorporating these results in the general map.

A/666. Awan, M.A., 1989a. Application of the olivine spinel and two pyroxene geothermometer to the Dargai ultramafic complex Pakistan. Kashmir Journal of Geology 6 & 7, 51-56.

Seven olivine-spinel and two pyroxene geothermometers were applied to the Dargai Ultramafic Complex, Pakistan. Using olivine-spinel geothermometer, the temperatures were estimated between 675 °C-825 °C whereas the temperatures fall between 900 °C – 950 °C when pyroxene data were plotted on pyroxene quadrilateral. This discrepancy is attributed more likely due to various degree of re-equilibration in two thermometers.

A/667. Awan, M.A., 1989b. Metamorphism of the obducted Dargai ophiolite, Pakistan. Kashmir Journal of Geology 6 & 7, 57-60.

The secondary minerals in the rocks of the Dargai Complex resulted through polymetamorphism. Field petrologic, and geochemical studies show that the complex passed through hydrothermal metamorphism at the mid oceanic ridges. A retrograde metamorphic event is discerned from the gabbroic mineral assemblages. The syn-tectonic metamorphism involved the obduction of the Dargai Complex which produced the dynamothermal effects in the underlying metasediments. The presence of antigorite and garnet mica schist near the southern (lower) boundary contact is related to dynamothermal metamorphism.

Key words: Metamorphism, geochemistry, ophiolites, Dargai, Malakand.

A/668. Awan, M.A., 1992. Petrotectonic interpretation of the Dargai ultramafics complex Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.52.

Field observation support the interpretation that the Dargai ultramafic complex is an ophiolite. These include (i) lack of major thermal effects at margins ii) absence of lamination in tectonites, and iii) fault contact, not intrusive contact with structurally underlying rocks.

It is proposed here for the first time that Dargai Klippe is sitting on the Main Mantle Thrust (MMT). The trace of the MMT in the surrounding area is missing due to extensive erosion below the MMT into Indian Plate rocks. The southern boundary fault of the Dargai complex is the trace of the MMT while the northern boundary fault is related to post -Eocene southward thrusting.

Petrologic data also support the contention that the Dargai complex is a supra-subduction zone ophiolite that constitutes part of the fore-arc shelf of oceanic crust in front of the Kohistan Island Arc. Petrochemical discriminant diagrams show that its lithologies have compositions corresponding to Oceanic Ridge Crust.

Key words: Petrology, tectonics, ultramafics, Dargai, MMT, Malakand.

A/669. Awan, M.A., 2000. A petrologic approach origin of the Dargai ultramafic-mafic complex of Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, p.120.

The Dargai Ultramafic-Mafic Complex occupies fore-arc position with respect to Kohistan Island Arc. The chemistry of ultramafic Tectonite and a Ultramafic cumulates represent the differentiated nature of the Dargai Complex which is marked by presence of more Mg. rich olivine in Tectonites than in Ultramafic cumulates.

Major and trace elements data of the rocks from the Dargai complex are plotted in a number of discriminant diagrams, which show:

- i) Whole rock ppm Ba versus wt % SiO₂ indicates mid oceanic ridge affinity.
- ii) Al/Ti from pyroxenes of the Dargai complex also indicates ophiolitic nature.
- iii) Cr ppm versus TiO₂ Wt % of the Dargai ultramafic represents its formation at supra-subduction stage.

The Dargai complex is quite distinct from Jijal and Chilas complexes as increase of K₂O Wt % with respect to Na₂O Wt % confirm it fore-arc position from the Shangla subduction trench.

Key words: Petrology, ophiolite, Malakand.

A/670. Awan, M.A., Khawaja, A.A. & Jadoon, I.A.K., 1991. Strike-slip faulting along the western boundary of Indian Plate, in Pakistan. Kashmir Journal of Geology 8 & 9, 117-120.

In northern and western part of Pakistan some strike-slip faults are considered lateral ramps of thrust sheets. However, in this area, systems of strike-slip Riedel R and R' shears is expected to develop due to a dominant component of simple shear along the western transform boundary of the Indian plate. The majority of strike-slip faults trend between N-S and NNW-SEE, close to the expected orientation of R shears. A few strike almost parallel to the expected orientation of R' shears. Faults close to R shears show sinistral and those to R' shears show dextral sense of displacement.

Both the orientation and sense of displacement suggest that the majority of these strike-slip faults are secondary Riedel shears, developed in response to plate scale sinistral simple shear, along the Chaman transform fault.

A/671. Awan, M.S., 1988-90. The geology and petrology of Jijal and Pattan layered ultramafics-mafic complexes in the vicinity of Jijal & Duber with special emphasis on petrogenesis of these complexes. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 90p.

The project area covers about 368 sq. Km. located in the vicinity of Jijal & Duber, District Kohistan. The work has involved geological mapping of the area on a scale of 1:50,000 of toposheet No. 43 A/16 of Survey of Pakistan. This thesis deals with the geology, petrography and petrogenesis of the Jijal and Pattan complexes in particular and the relation of these complexes with other complexes of Kohistan Arc complex has also been discussed.

The geological sequence of Jijal complex consists of ultramafic and mafic cumulates. The ultramafic cumulates are divided into dunite, wehrlite, websterite, garnet-pyroxenite and garnet-hornblendite, whereas mafic cumulates are garnet gabbro. The geological sequence of Pattan complex also consist of ultramafic and mafic cumulates. The ultramafic cumulates are chromite, dunite and (meta) wehrlite, whereas mafic cumulates are divided into two pyroxene gabbro and two pyroxene-quartz-diorite.

Field evidences suggest that Pattan complex was emplaced along pre-existing metamorphosed kayal cumulate complex. The top of the Pattan complex is marked by a spectacular, intrusive polymagmatic breccia. In Duber and NW of Duber Pattan complex is overthrust onto the Jijal complex, which is also a layered cumulate complex. While in Pattan area and SE of Pattan there is a faulted (strike slip) contact between Pattan complex and Jijal complex.

The Jijal complex is southern most, layered ultramafic-mafic cumulate complex of the Kohistan-Ladakh tectonic province. The Main Mantle Thrust (MMT) is the southern boundary of the Jijal complex, which interns is the southern boundary of Kohistan Arc complex. The Main Mantle Thrust (MMT) Duber Thrust Fault wedges out Jijal complex NW of Duber near Chert. On the other hand Main Mantle Thrust and Pattan Fault (strike slip fault) wedges out the Jijal complex on the eastern side near Pashto. The Jijal and Pattan complexes are generated by precipitation from subduction generated, hydrous, low K, picritic high Mg tholeiitic magmas and there is a strong possibility of finding economic metallic mineral deposits with in these layered cumulate complexes.

Key words: Petrology, Jijal, Pattan, Kohistan.

A/672. Awan, M.Z., 1999-2000. Geological mapping of Kohala-Muzaffarabad area with special emphasis on rock failure due to shale undercutting and road widening along Muzaffarabad-Kohala Road. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 61p.

The slopes along Muzaffarabad-Kohala roadways are highly disturbed during most part of year due to differential weathering conditions. Along the road at left bank of river Jhelum Murree Formation is exposed. Murree Formation consists of alternate bedding of Shale, Sandstone, Mudstone, Claystone, Silty clay and Silt. The rocks are differently weathered and tectonically highly disturbed due to Main Boundary Thrust (MBT). The Shales and Claystone are highly weathered, erodible during severe weathering conditions and undercut due to differential weathering, undercutting of sandstone, mudstone, claystone and siltstone results in rockfall, rockslide, rock toppling and wedge failure in the area. The area is divided into the stable and unstable zones to prevent undercutting, which induced failure. The rate of undercutting is measured. Ten sites were located along Muzaffarabad-Kohala located road for evaluation. The sites consist of road cut for road widening shale, mudstone, claystone, and siltstone undercutting. The sites were selected because the road was undercut by blasting and shale was undercut by differential weathering.

The amount of each site was carefully measured along the entire length of the cut information regarding the data of road cut was collected from Highway Department record. The measured rate of undercutting at road cut and the age of cut were used to estimate the rate of shale undercutting since the time of excavation. Samples of the undercutting units were collected from each site and tested for slake durability and Atterberg limits. The results suggest the shale undercutting can be remediated by grouting or installing bericles to prevent rockfall, rockslide and toppling failure.

A/673. Awan, T.R., 1986-88. Geology and petrology of the Eastern Chilas calc-alkaline complex in the vicinity of Chilas (District Diamir) with special emphasis on petrogenesis of the rock units. M.Sc. Thesis University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 105p.

A geological map of 301 sq. km. between Pain Ges Gah Helor Gah in the north of the Indus River and Thurlly Gah in the south in Chilas area is presented at the scale of 1:25,000 on toposheet No's 43 E/15, 43 I/9 and 43 I/7 issued by the survey of Pakistan.

Most of the project area lies in the vicinity of the north side of the eastern Chilas Complex. The exposed sequence of rocks in the project area is a part of the northern limb of the Chilas Complex, where ultramafic rocks occur in the core of the anticline and is overlain by norite, gabbro-norite and diorites. This is capped by metadiorites of Early Jurassic age which is a part of Kamila Amphibolite.

Field and petrographic study show that the rocks of the Chilas Complex are formed with in a separate magma chamber and igneous in nature. There is younger silt like leuco dioritic pluton emplaced in metadiorite. The leuco diorite hosts a small ultramafic body which has probably been formed by a magmatic protrusion of ultramafic composition and is not related to ultramafic rocks in core of the Chilas Complex.

A/678. Ayub, M., Yusaf, M., Lodhi, S.A.K. & Ashraf, M., 1993. Geology and utilization of pegmatitic albitites and aplites of Mansehra Area, NWFP as indigenous raw materials for pottery wares. Pakistan Journal of Scientific and Industrial Research 36(10), 397-00.

Various samples of pegmatitic albitites and aplites were collected from Mansehra area NWFP of Pakistan. It was found that only pegmatitic albitites, albitite aplites and albitite-microcline aplites were the rocks suitable for making pottery wares. For this purpose petrographic and chemical analysis were carried out. The crushed samples were used for the purpose of making porcelain bodies as well for glazes to be used on their respective bodies; the presence of small quantity of TiO_2 and Fe_2O_3 was successfully used to impart cream to orange cream color to both bodies and glazes. The studies were carried out to replace conventional feldspar totally and quartz partially.

A/680. Azam, M., 1983-85. Biostratigraphy of the Jhalar-the Kala Chitta Range, Attock District. M.Sc. Thesis, Punjab University, Lahore, 91p.

A geological map of the Jhalar area -the Kala Chitta Range, on a scale of 1" to 0.789 mile or 1:50,000 and covering an area of 16.43 square miles has been prepared to discuss the stratigraphy and micropaleontology of the area. An attempt has been made to discuss the importance of foraminiferal content of these rock units, for determining the

depositional pattern and age, the geological sequence of the Kala Chitta Range with a view to recognize the continuity or unique aspects of the lithostratigraphic units in the adjoining area.

The various geological events that occur in the area and their geological implications have also been discussed. In the Kala Chitta Range there are some eighteen lithostratigraphic units but the area under discussion comprises ten lithostratigraphic units mostly of marine environments and with non-marine units.

A/681. Aziz, M.A., 1968. Structure and geology of Ghari Habibullah, Taranna Area, Hazara. M.Sc. Thesis, Punjab University, Lahore, 77p.

A. B. Wynne was the first pioneer (1887-89) to work in this area followed by Middlemiss (1890-93). But the first complete map ever produced of the region including the project area was by D. N. Wadia on a 1" = 16 miles scale. Both D.N. Wadia and Middlemiss had included pisolitic formation of Rinjata in their Eocene (Geology of India PP 336) and Nummulitic (although he did that for convenience sake). This pisolitic formation is placed in cretaceous. This work is first of its nature in the subject area so far as details and accuracy is concerned.

Although repeated phases of orogenesis had to great, extent blurred the picture, a try has been made to give a clearer picture of the events that took place in the Geological past. Detailed study has revealed the presence of different sets of faults which have been differentiated on the basis of age, trend and direction of movement. Different behaviour of sedimentaries and metamorphics to the deformational forces has come to light. Presence of Syringoporoid corals is noted for the first time and the age of Kakul dolomites assigned. A close study of Talhatta metaconglomerates and quartzites is given.

Metamorphics of the area are found to grade from slates through phyllites to Biotite schist grade and described. Probable age of injection of acidic fluid in the Balakot Injection Gneisses and the probable reasons for injection only in these rocks are discussed. Reasons for no evidences of metamorphism in Kakul dolomite and younger sedimentaries of the area are discussed. An appendix is included to give the microscopic mineral determination & features of structural importance of various rocks.

A/682. Aziz, N., 1994. The study of groundwater contamination of the Sihala Industrial Triangle Islamabad with a special emphasis on physiochemical, hydrochemical, biochemical and flow net analysis. M.Sc. Thesis, Quaid-i-Azam University, Islamabad, 74p.

This physiochemical, hydrochemical, and biochemical studies of groundwater aquifer of Sihala Industrial Triangle were made. Water sample collected randomly from thirty two preexisting dug wells/tube wells were analyzed in N.I.H. Laboratory. Chemical data was projected graphically on stiff pattern and trilinear piper diagrams using U.S.G.S Software. HC-GRAM. The STIFF PATTERN diagrams thus developed for each dug well/tube well are projected on location map to visualize the distribution of ground water chemistry. Bivariate statistical analysis were applied on scattered data points of TDS (total dissolved solids) and coliform bacteria h +ve and -ve growth of F. Coliforms to study their relationship. The equipotential line map was prepared to develop the flow net. Two plumes of contamination were marked in flow net map. Results indicate that study area has better groundwater on basis of physiochemical analysis and poor quality of groundwater on basis of Hydrochemical and biochemical analysis. Soan River behaves like an effluent stream.

Approximately 15 miles² of Tandiani-Bins Gali area in the form of a rectangle on the Northwest side of Abbottabad has been mapped at a scale 1:10,000. It is a mountainous humid region with fairly high relief. The stratigraphic sequence ranges from Pre-Cambrian Hazara slates to the Lockhart Limestone of Paleocene age. The structure of the area is in the form of a major synclorium, which is interrupted and deformed by high angle thrust faults. Over 50 thin sections were studied under the microscope and detailed petrography and petrogenesis are included.

A/686. Azizullah, 1997a. Lithostratigraphy and depositional system of Siwalik of Shinghar-Surghar Range, Thatti Nasrati-Shanawah area, District Karak, Pakistan. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, 11-13.

The Himalayan molasse sediments, the Siwalik Group, Pliocene to Pleistocene (in Trans-Indus) in the Thatti-Nasrati and Shanawah area were studied in order to understand the nature, origin and conditions of deposition.

The Siwalik Group is comprised of four formations i.e. Chinji, Nagri, Dhok Pathan and Soan Formation. The Rawalpindi Group is absent in this area. The Chinji Formation unconformably overlies the Mitha Khatak Formation (Fig-i). The Chinji Formation consists of maroon and reddish brown colour shale and subordinate sandstone horizons. The thickness of the Chinji Formation varies from 160m to 1400m. The Nagri Formation is marked by thick sequence of massive sandstone with lot of paleochannels. Shales are absent or present as thin patches. The thickness of the Nagri Formation varies from 1050m to 2075m. The Dhok Pathan Formation exhibits excellent development of cyclic deposition of alternate shale and sandstone sequence. The thickness of this formation varies from 950m to 1200m. The Soan Formation may be divided into Tatrot and Pinjor stages. The sandstones and shales of different colours are present here. A portion of Pinjor stage is absent in some area. The lower portion of Pinjor and Tatrot are represented by 300-500m thick sequence.

The study of lateral and vertical accretion deposits, presence of scouring, channel abandonment behaviour, facies occurrences and channel fill of the Siwalik Group show that it is mainly deposited by braided river system. The Siwalik Group of the Shinghar-Surghar range was deposited from 12 M.a. to 0.5 M.a. as compared to the Siwaliks of the Potwar Plateau, where these molassic sediments begun to be deposited prior to 15 Ma. The sedimentation rate of the Siwalik Group was generally higher in the Trans-Indus ranges than that of the Potwar Plateau area. The entire molasse sequence covering the time span of 12 M.a. to 0.5 M.a. is conformable. There was no tectonic activity except subsidence of basin till folding begun about 0.5 Ma. which stopped the Siwaliks sedimentation in the study area. These molassic sediments were deposited by high velocity streams as indicated by the presence of pebbles, cobbles and boulders. Poor sorting, angular to subangular rock fragments show immature nature of sediments.

The study area is covered by toposheet No.3 8 P/1 and 38 0/4, the latitudes and longitudes of the study area are as follows.

A.	71°03" / 32°48"	D.	71°15" / 33°00"
B.	71°03" / 33°00"	E.	71°09" / 32°57"
C.	71°15" / 30°05"	F.	71°09" / 32°41"

The area is mapped on 1:10,000 scale. The study area is 225 Sq. Km. it is accessible by jeepable roads both from Thatti-Nasrati as well as Isa Khel.

Three geological cross-sections were measured at suitable intervals for studying vertical and horizontal variations and stratigraphic correlation.

Detailed sedimentological studies were carried out on the rocks of the Siwalik Group exposed in the study area. All the four formations namely the Chinji, Nagri, Dhok Pathan and Soan Formation are well exposed.

In these studies, in general, the facies models presented by Miall (1977, 78, 85&88) have been utilized. General criteria for distinguishing, comparing and contrasting braided and meandering rivers presented by Miall have been used. Additional criteria have also been used for the Siwalik Group in order to distinguish between braided and meandering river systems. Observations of important sedimentological features in the area were made. This study helped in defining the fluvial facies and interpreting the conditions of deposition. It further helped to design the

hydrodynamic conditions during sedimentation. The rate of sedimentation depends strongly on the relief of the source area as well as subsidence of the basin during deposition. The relief in turn in the active collisional mountain ranges, depends strongly on factors like uplift and exhumation, which in turn depends upon the rate of convergence as well as total crustal shortening. Crustal shortening is accommodated by folding and thrust piling. Series of napes development in the collisional mountain ranges sometimes in a piggy-back fashion. During process of uplift and exhumation, successively deeper structural levels are exposed through tectonic erosion and denudation. Thrusting alone cannot explain the exposure of deeper crustal levels. This is only possible through a combination of thrusting and exhumation. Another mechanism which can expose deeper levels is the tectonic collapse and gravity structures in the mountain fold belts. Successive phases of uplift and exhumation are excellently reflected in the Siwalik molassic detritus of the foreland basin. The vertical sequences in these deposits have faithfully recorded the effects of successive uplift and exhumation phases.

A/687. Azizullah, 1997b. Petrotectonic framework of the Siwalik group of Shinghar Range with special reference to its petrography. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p.11.

No petrological/petrotectonic account from Thatti Nasrati Shava-Shanawah area (Shinghar Range) for the Siwalik Group with reference to its petrotectonic framework has yet been published. It was therefore, important to carry our detailed petrological/petrotectonic studies in order to understand the nature, origin and condition of deposition of Siwaliks in this area.

In the past, it was generally considered that the Siwaliks were deposited by the mighty Siwalik River (ancestral Indus). But subsequent studies have indicated that Siwaliks show great lithological as well as petrographic diversity. Siwaliks of different areas have been derived from different source of regions. Therefore, it was important to trace the sources of Siwalik sediments in this region and to relate them to an evolving petroTECTONIC framework.

Correlation of Siwaliks on the basis of gross lithological variation (sandstone/shale ratio) has not proved very satisfactory. Similarly, faunal correlation is not always possible, because the distribution of fossils is not uniform. So it was planned to correlate the Siwaliks of the area on the basis of petrographic studies. It has now enabled the author to build a better picture and develop a better understanding of the stratigraphy and sedimentation of the study area.

Petrotectonic studies require a thorough understanding of the tectono-stratigraphic evolution of the hinterland as well as the nature of detritus shed by them both in time and space. The focus of sedimentation and the basin geometry undergo changes concomitant with changes in the source regions.

In order to understand the dynamics of the tectono-stratigraphic evolution of the source areas and changing sedimentary pattern, lithologies and the composition of the sediments, and integrated scenario has been presented.

A/688. Azizullah, 2001. Nuclear fuel potential of the Surghar Range, Bannu basin. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.13.

The collision of Kohistan island arc with Eurasian plate occurred at about 90-100 Ma. resulting in an Andean type of margin. At 40 to 65 Ma. the Indian plate collided with the Eurasian plate sandwiching the island arc. As a result of this collision the Himalayan molassic sediments started to deposit in S-shaped foredeep. Depositional environment was changed from marine to continental. Except for an arid red-bed paleoclimate represented by the Chinji Formation, the semi-arid and sub-tropical environments dominated during this period. Under these tectonic and paleoclimatic conditions in the foredeep basin, a paleo Siwalik drainage was developed and a thick fluvial sequence was deposited. Within this sequence the Dhok Pathan Formation controls the general distribution of the sandstone type uranium mineralization in Pakistan.

The sandstone type uranium mineralization discovered till today is mainly distributed in the east-west trend in the Dina-Kallar Kahar-Chakrala (Potwar Plateau) and in the north-south trend in Thatti Nasrati, Shanawah, Isa Khel and Simu Killi (Bannu Basin) and also in similar trend in Baghalchur, Rakhuchur, Nagar Nai and Rajanpur areas (the eastern flank of Sulaiman Range). Although uranium potential of these rocks is confirmed, however, the uranium resources so far discovered are not commensurate with the widespread mineralization phenomena observed on the outcropping area. It is therefore essential to understand the regional uranium mineralization in its true perspective.

B/4. Badgley, C., Bartels, W.S., Morgan, M.E., Behrensmeyer, A.K. & Raza, S.M., 1995. Taphonomy of vertebrate assemblages from the Paleogene of northwestern Wyoming and the Neogene of northern Pakistan. *Paleogeography, Paleoclimatology, Paleoecology*, 155, 157-180.

We compare the taphonomy of vertebrate assemblages from two long continental records—the early Paleogene of the Bighorn Basin, Wyoming, and the Neogene Siwalik sequence of northern Pakistan. Both sequences contain a similar array of fluvial facies, and the abundance of these facies differs among formations. We document environments of preservation of vertebrate localities over time to determine comparability of fossil assemblages within and between sequences. Changes in sample size and species richness are noted to reveal potential sampling effects on patterns of faunal turnover. Preservation history determined the environment, sample size, quality of specimens, taxonomic composition, and spatial and temporal resolution of fossil assemblages and thereby the quality of the fossil record and its suitability for further analyses.

In both sequences, changes in prevailing taphonomic processes reflect changes in lithofacies and habitat distribution. Correlated changes are found in fossil productivity, species richness, and faunal composition. Both sequences contain some episodes of apparent faunal change in which appearances and disappearances of rare taxa can be attributed principally to changes in sample size. The Paleogene record has high taxonomic resolution (i.e., to genus or species) for most mammalian fossil remains. Temporal and spatial averaging of Paleogene fossil assemblages changes with lithofacies. The Neogene record has higher taxonomic resolution for remains of small mammals (<2 kg) than of large mammals. All formations have several fossiliferous facies, with moderate to high degrees of temporal averaging and low to high degrees of spatial averaging.

Different preservational circumstances impose different constraints on paleoecological and evolutionary analyses. The best opportunities for paleocommunity reconstruction are provided by high taxonomic resolution, large samples, and varied environments of preservation. These circumstances are found in limited portions of each record. The best opportunities for documenting evolution within lineages and species-replacement patterns are provided by high taxonomic resolution, high temporal resolution, and consistent preservational context. These taphonomic attributes pertain to the more common Paleogene mammals, particularly from the rich paleosol localities of the Willwood Formation, and to the more common Neogene small mammals from abandoned-channel fills of the Siwalik record.

B/5. Badgley, C. & Behrensmeyer, A.K., 1980. Paleoeocology, middle Siwalik sediments and faunas of Northern Pakistan. *Paleogeography, Paleoclimatology, Paleoecology* 30, 133-155.

The Siwalik deposits of northern Pakistan are distinctive for their excellent sedimentary record and Neogene mammal faunas that include a family of homonoids, the Ramapithecidae. A 160-m interval was chosen from 3500 m of local section for study of lateral lithofacies variation, microstratigraphy and taphonomy of selected fossil localities. Field data consists of: (1) stratigraphic sections that span 30 km of lateral exposure, (2) microstratigraphic sections of fossil localities in presentative depositional environments, and (3) taphonomic sampling of a subset of these localities. These data form the basis for landscape, habitat, and community reconstruction. The physiography of the paleoenvironment was determined by braided and meandering river channels. Lateral distribution of channel and floodplain deposits suggests that a mosaic of vegetation types covered the entire drainage basin, including constantly renewed plant succession along channel margins and more stable associations on floodplains. Vertebrate fossils occur in three major depositional settings: channel-lags, channel-margin swales, and floodplain land surfaces. Most collected fossils come from channel-lag conglomerates. The predominant taphonomic influence on the overall fossil assemblage from this interval has been fluvial transport and sorting resulting in a sampling bias toward medium-sized taxa. However, rank abundances from the fossil samples may be valid for these taxa. Fluvial processes probably harvested bones from all habitats present, but no habitat associations of major taxa are detectable. A relatively high species richness of small to medium ungulate herbivores suggests the presence of diverse vegetation types that probably included forest, woodland, and grassland. The ramapithecids were uncommon, medium-sized members of this community.

B/6. Badgley, C. & Behrensmeyer, A.K., 1995. Two long geological records of continental ecosystems. *Palaeogeography, Palaeoclimatology, Palaeoecology* 115, 1-11.

The early Paleogene continental sequence of northwestern Wyoming and south central Montana (USA) and the Neogene Siwalik sequence of northern Pakistan are exceptionally long, fossiliferous, and well studied in terms of geology, paleontology, mammalian evolution, paleoeocology, and paleoclimatology. Each record spans about 15 myr of alluvial deposition in a foreland basin. The fluvial systems differed in size, drainage of floodplains, and change in alluvial architecture through time. Both sequences preserved abundant paleosols, which are a source of paleoclimatic signals in stable isotopes from soil carbonates. Fossil collections from both records are dominated by vertebrate remains and especially by mammals; the Paleogene sequence also preserved abundant floral remains. Patterns of vertebrate preservation differed markedly between the two sequences, placing inherent limitations on paleoeocological reconstruction and on the scope of evolutionary studies of mammalian linkages.

In this introductory paper, we summarize the major similarities and differences in geologic setting, chronology and time resolution, and mammalian faunal composition of these two long sequences. Finally, we present a brief overview of the organization of papers in this special issue.

Key Words: Continental ecosystems, Montana, siwaliks, Himalaya.

B/7. Badgley, C. & Tauxe, L., 1990. Paleomagnetic stratigraphy and time in sediments: Studies in alluvial Siwalik rocks of Pakistan. *Journal of Geology*. 98(4), 457-477.

Sediments may acquire magnetic remanence upon deposition and shortly after deposition. Hence, the paleomagnetic record of sedimentary rocks may provide a chronostratigraphic framework for rates and patterns of depositional and post-depositional processes over time scales intermediate between those of modern observation and those of the dated geologic record. Two applications of high-resolution magneto- stratigraphy in Miocene, alluvial rocks of Pakistan illustrate this point. (1) Transition stratigraphy-the dense sampling of a magnetic reversal-of correlated sections in the Dhok Pathan Formation revealed high variability in sediment accumulation rates (over several thousand to 10,000 yr), time-transgressive strata representing a paleosol and a floodplain marsh, and a pervasive post-depositional record mainly from pedogenesis. (2) Lateral tracing of paleomagnetic reversal boundaries in the Chinji Formation revealed a secular change in sediment accumulation rate and evidence for increased accumulation rate associated with extensive sandstones and the time-transgressive nature of certain sandstone units. Both studies demonstrate the significant lateral component to accumulation of lithological units, indicating that individual strata

may embody considerably greater time spans in their lateral extent than in any vertical transect. Hence, stratigraphic completeness should be evaluated in the lateral as well as the vertical dimension.

Key words: Palaeomagnetism, stratigraphy, siwaliks, Potwar.

B/8. Badshah, M.S., 1975. Geology of lower Gandao with main emphasis on silica sand. FATA DC, Record, 1, 32p.

The geology and various sedimentary rocks of the Gandao area in Mohmand Agency are described. The main emphasis has been laid on promising silica sand deposits.

Key words: Mineral deposits, silica sand, Mohmand Agency.

B/9. Badshah, M.S., 1979a. Geology of Bajaur and northern part of Mohmand. Geological Bulletin, University of Peshawar 11, 163-179.

Geological investigation in about 1000 sq. km of area in Bajaur and Ambhar Utmarkhel reveal that the area falls in the western tip of Kohistan with the Main Mantle thrust (MMT) running roughly east-west, following the course of Bajaur Khwar. The area is overlain by the tectonic slices, which moved from NW to SE.

The area exposes igneous and metamorphic rocks. Nawagai limestone of (?) Silurian-Devonian age lies to the south-west. The pelitic sediments include amphibolites, epidote chlorite schists, phyllitic schists, piemontite schists, talc carbonate schists, graphite schists and slates. Extensive distribution of garnet schists is observed in the Shamoza area, lying to the south-east.

The igneous masses comprise granites and diorites; ultrabasic and volcanic rocks. The granitic and dioritic rocks are not considered to be comagmatic. The intrusion of diorites started sometimes in the Late Cretaceous, while the whole magmatism ended with the last phase of granitic stocks and dykes in Middle Eocene. The late Upper Cretaceous to Eocene-Oligocene ultrabasic phases of serpentinite, peridotite and pyroxenite / hornblende lie "interbedded" with the metasediments. Eocene to Oligocene rocks of andesitic, rhyolitic and tuffaceous composition are also present.

Poor mineralization of copper, promising mineralization of manganese, soapstone and chromite along with large deposits of marbles are the noteworthy prospects in the area.

Key words: Petrography, MMT, Bajaur, Mohmand, Kohistan Arc.

B/10. Badshah, M.S., 1979b. Soapstone deposits of Daradar Valley, Kurram Agency. Federally Administered Tribal Areas Development Corporation, Information Release 11, 17p.

B/14. Badshah, M.S., Gnos, E., Jan, M.Q. & Afridi, M.I., 2000. Stratigraphic and tectonic evolution of the northwestern Indian plate and Kabul Block. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 467-475.

A 1:500 000 scale geological map covering large parts of the northwest Pakistan-southeast Afghanistan borders region between 31-34°N and 69-71°E has been completed. The map covers the tribal area of Kurram and of North and Waziristan in Pakistan, where the map is based on unpublished data of the Federally Administered Tribal Areas Development Corporation. The map area comprises Precambrian crystalline rocks of the Indian and Kabul blocks, Permian to Quaternary sedimentary rocks, and the Late Cretaceous-Palaeocene Kabul-Altimur and Zhob-Waziristan-Khost ophiolite complexes. The Himalayan collision resulted in extrusion of the Kabul Block along the Chaman Fault system and formation of the Katawaz Basin which was filled with clastic deposits of the 'Early-Indus' fan. Ongoing contractional tectonics led to southward thrusting of the Spinghar Indian crystalline basement over the Miocene Murree Formation. New names and type sections are proposed for six units in the Spinghar and South Waziristan. These units are the Daradar Dolomite, Spinghar Quartzite, Sikaram Series, Makai Limestone, Wana Schist and Kaniguram Slates.

Key words: Stratigraphy, tectonic evolution, Indian plate, Kabul block, Waziristan.

B/16. Baig, M.A. & Faruqi, F.A., 1984. Industrial minerals for whiteware industry. Abstract Volume, First Pakistan Geological Congress, Lahore, 32p.

There are several occurrences of raw material, e.g., china clay, feldspar, that can be used in the manufacture of ceramics. This account gives some details of the raw material for ceramic industry.

Key words: Economic geology, industrial minerals.

B/17. Baig, M.A.A., 1967. Important economic minerals of Pakistan. Geological Bulletin, Sindh University, Jamshoro 3 (4), 18-27.

This is one of several such compilations by different authors. It gives a summary of the more important economic minerals discovered by 1967 in Pakistan.

Key words: Economic geology, mineral deposits.

B/18. Baig, M.A.A., 1970. Geological bibliography of Salt Range, Sulaiman Range, Potwar and Hazara areas. Sindh University, Geology Department, Jamshoro, Pakistan, 40p.

This document lists many of the publications on the three areas up to 1969. Those of Hazara and Siwaliks of the Salt Range are included in the present work.

Key words: Salt Range, Sulaiman Range, Potwar, Hazara.

B/19. Baig, M.A.S., 1984. Some observations about change of fluvial pattern in Cis-Indus and Trans-Indus exposures of Dhok-Patan Formation. Abstract volume, First Pakistan Geological Congress, Lahore, 46-47.

The paleocurrent measurements in the Dhok Pathan Formation at different parts of the Cis-Indus and Trans-Indus Siwalik exposures indicate different directions of paleoflow. The stream systems responsible for the deposition of Dhok-Pathan Formation in the Cis-Indus part of Potwar were flowing towards east while those which caused deposition of similar sediments in the Trans-Indus Potwar as well as in Sub-Suleman Ranges flew due south.

The Paleomagnetism data collected at Chinji and Khisor Range indicate a difference of about 5 million years in the depositional age of Chinji Formation sediments at both these places. This observation confirms the difference in depositional systems for Siwalik exposures in Cis-Indus and Trans-Indus areas. It is evident from this data that the fluvial systems responsible for the deposition of Dhok Pathan Formation were flowing due east similar to the present day Ganges and Yamuna river systems. Late, due to some structural disturbance, this flow changed and the river started flowing due south, parallel to the present day Indus river system, thus indicating two different depositional basins.

Key words: Sedimentology, siwaliks, Potwar, Salt Range.

B/20. Baig, M.A.S. & Pervaiz, K., 1995. Remobilized uranium mineralization: A record episodal uplift of frontal fold-thrust belt, NW Himalaya. Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, 18-19.

Salt Range-Potwar and Bannu basin were developed during the last phase of the Himalayan orogeny which is still active. The mechanism of uranium ore formation in Bannu Basin and Salt Range potwar suggests leaching of the Siwalik Molasse rock and its subsequent reprecipitation along the water table due to change in physio chemical conditions. An analysis of the uranium ore formation process indicates presence of ghost (depleted) ore bodies in the oxidized zone. These radioactive haloes represent paleo water tables which were developed due to episodal uplift. At least four such upheaval episodes have been registered in the Siwalik rocks of Bannu separated by periods of relative stability. This process seems to be still active.

Key words: Uranium mineralization, structural geology, Himalayan fold-thrust belt.

B/21. Baig, M.G., 1992-94. Geology and structure of Barian area, Hazara, Northwest Himalaya and sedimentology of Early Cretaceous Lumshiwal Formation and Early Eocene Chorgali Formation. M.Sc. Thesis, Punjab University, Lahore, 251p.

It is a study of the geology and structure of the Barian area (50 sq. km) along with sedimentological study of the Early Eocene Chorgali Formation and Early Cretaceous Lumshiwal Formation.

A large-scale geologic map of Barian area as (1: 10,000) is presented. The area comprises sedimentary rocks from Middle Jurassic to Early Miocene age, tectonically forming a part of the Lesser Himalayan sequence in the Galiat Area Hazara. The Palaeogene and older sequence is mainly limestone and shales of shallow massive shelf facies. The overlying Neogene rocks are gypsiferous marls, limestone and shale of supratidal to sabkha facies in the lower sandstone, shale molasse of Murree Formation in the upper part. Structurally the area comprises NE-SW trending cylindrical to double plunging folds constituting anticlinoria and synclinoria. The folded sequence is disturbed by numerous reverse faults. However small number of normal faults also exist. Faults are either dip slip or oblique slip and except for the MBT involves a maximum displacement of a few hundred meters. MBT is the major tectonic discontinuity of regional significance. At Darya Gali the thrust is high angle feature dipping to the northwest with opposing dips in the rocks on the two sides. A fault-related escarpment accompanies the surface expression of MBT and much degradation accompanied by land sliding.

Chorgali Formation has been divided into 3 facies and 20 microfacies. Basic microfacies, which repeat, are wackestone microfacies, shale microfacies, mudstone microfacies, and dolomite mudstone facies, calcareous shale microfacies and arenaceous dolomite microfacies.

XRD analysis shows that illite is the predominant clay mineral of shale. Other essential minerals are chlorite, kaolinite, quartz and smectite. Chorgali Formation represents open shelf subtidal to lagoonal environment. In lower part deposition appears to be cyclic with periods of clastic influx alternating with little clastic influx. Fossils present

are mostly broken and probably transported from high energy environment. Shale horizons were deposited in quite subtidal zone but not below 70m due to paucity of pelagic fauna. In upper part of the section dolomites are interbedded with shale. They also show cyclic deposition. Dolomites were probably initially deposited as mudstones in deeper part of shelf. They lack of pelagic fauna and evaporites. Dolomitization appears secondary. Non-ferroan microcrystalline calcite appears biological in origin.

Key words: Structure, sedimentology, Hazara, Himalaya.

B/22. Baig, M.I., 1997. Utilizing geothermal waters. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 2p.

This review paper briefly describes geothermal manifestations in form of warm and hot water springs both in northern mountains and in southern regions of Pakistan. The basic data on the thermal springs in Pakistan mainly comes from second half of the last century. It was compiled later almost independently by Waring (1965) and Bakr (1965). Later isolated work has appeared since independence. Areas of potential geothermal resource identified are northern mountain regions of the country, northern Baluchistan and Dadu in Sind. There are large number of manifestations reported: to mention a few, a number of springs in Garam Chashma in Chitral, along Astore river. Tatta Pani in Azad Jammu & Kashmir, Kohlu in Baluchistan and a number of springs in Dadu including super heated stream Issuing at Lakhra in Sind. Reservoir temperature calculated by workers at Murtza Abad in Hunza range 114-296°C, at Tatta Pani near Chilas. 130-239°C. In south, the super heated stream at Lakhra and the other more than 15 springs in Dadu be studied to determine potential underground source of energy in that load center of Pakistan.

This potential geothermal energy source is non-depleting and is non polluting. Its utilization can lessen the risk of depleting perishable source (oil, gas and coal) and to an extent we can avoid the danger of polluting our environment. While super heated steam is being utilized world over in production of electric power, the low enthalpy waters have been used for centuries for recreation, baths and as health spas for their curative effects (hydrotherapy), injuries, joint pains and cutaneous diseases. These waters are being used elsewhere for warming houses, heating green houses for larger productively in agriculture, poultry farming and fish breeding and even air conditioning. Natural reserves are generators of economic growth. A lot needs to be done to explore and harness this source of energy in the country. Plans need to be developed to collect reliable data to utilize this energy resource as a contribution to the development and in improving quality of life of those areas.

B/24. Baig, M.S., 1989. New occurrence of blueschist from Shin-Kamer and Marin areas of Allai-Kohistan, Northwest Himalaya, Pakistan. Kashmir Journal of Geology 6 & 7, 103-108.

In Allai-Kohistan, the Indus Suture Zone is represented by the Allai melanges. The Allai melanges constitute the Baleja ophiolitic melange, Shin-Kamer blueschist melange, and Matai greenschist melange. The Bela ophiolitic melange, Shin-Kamer blueschist melange, and Matai greenschist melange represents the Neotethys oceanic crust, Neothys trench, and island arc affinities respectively.

New in situ blueschist occurrence have been found from the Shin-Kamer blueschist melange, near the Shin-Kamer and Marin areas of Allai-Kohistan. The Shin-Kamer blueschist is composed of glaucophane, epidote, chlorite, quartz, white mica, with small amount of calcite and plagioclase. The mineral assemblage, suggest blueschist facies P-T conditions of about 380-450 °C and pressure of about 7-8 kbar.

In the blueschist melange, the high-pressure blueschist facie metamorphism is overprinted by the low-pressure greenschist facies metamorphism. During the greenschist facies metamorphism, the actinolite (rims around glaucophane), chlorite, and white mica overprinted the blueschist assemblages. Similar change from high-pressure to low-pressure metamorphic conditions also occurred in the Indus Suture Zone of Ladakh and Shangla areas of the Northwest Himalaya. The transition from blueschist to greenschist facies metamorphism in the Indus Suture Zone

can be relate to tectonic decompression along the Neotethys trench zone or due to a separate tectonic event related to melange emplacement.

Key words: Blueshists, melange, Allai-Kohistan, Indus Suture, Himalaya.

B/25. Baig, M.S., 1990. Structure and geochronology of Pre-Himalayan and Himalayan orogenic events in the Northwest Himalaya, Pakistan, with special reference to the Besham area. Ph.D. Thesis. Oregon State University, Corvallis, U.S.A. 300p.

Details of structural studies, geochronology (including large number of ^{40}Ar - ^{39}Ar dates) and tectonics of the Besham and neighbouring areas are presented in this thesis. The information has been published in a series of papers, including the following one and others listed here.

Key words: Geochronology, tectonics, Swat, Hazara, Himalaya.

B/26. Baig, M.S., 1991. Geochronology of pre-Himalayan and Himalayan Tectonic events, Northwest Himalaya, Pakistan. *Kashmir Journal of Geology* 8 & 9, 197.

In the northwest Himalaya of Pakistan, metamorphism, deformation and plutonism are the result of collision between the Indo-Pakistan and Asian plates. The timing of pre-Himalayan orogenic events remain uncertain, due to strong, pervasive Himalayan overprinting.

This study presents new field, structural and metamorphic date together with $^{40}\text{Ar}/^{39}\text{Ar}$ isotopic age data on hornblende, muscovite, biotite and K-feldspar for Besham, Mansehra, Swat and Hazara areas of northern Pakistan. These data provide the first detailed record of Early Proterozoic to Late Paleozoic events in the northwest Himalaya and combine with prior U/Pb, Rb/Sr, and fission track data record an orogenic history from the Early Proterozoic to Cenozoic. The Early Proterozoic orogenic events in the Besham basement complex occurred at (A) $2,031 \pm 6$ to $1,997 \pm 8$ Ma, (B) $1,950 \pm 3$ Ma, and (C) $1,887 \pm 5$ to $1,865 \pm 3$ Ma. These were followed by sodic granite intrusion at $1,517 \pm 3$ Ma.

Subsequently, flysch of the Kurmang, Gandaf, Manki, Hazara, Dakhner, Dogra and Simla formations was deposited unconformably on the basement rocks of the Indo-Pakistan plate. These units are unconformably overlain by the molasse of the Tanawal and Manglaur formations. The area underwent metamorphism and deformation at 664 to 625 Ma, and volcanism and plutonism at 850 to 600 Ma (Hazaran orogeny or Pan-African orogeny). Later metamorphism and deformation at $> 466 \pm$ Ma and plutonism at 550 to 450 Ma record an Early Paleozoic orogeny. This tectonic event is marked by the development of Cambro-Ordovician unconformity in the Himalaya. Alkaline magmatism (315 ± 15 to 297 ± 4 Ma), sodic granites ($> 272 \pm 1$ Ma), mafic Panjal volcanism (284 ± 4 to 262 ± 1 Ma) and metamorphism (333 ± 1 Ma), occurred during early rifting of the Cimmerian microcontinent from Gondwana. The early Himalayan metamorphism and deformation in northern Pakistan occurred between 70 to 64 Ma. The Late Cretaceous to Early Paleocene deformation and metamorphism is related to melange emplacement along the northwestern margin of the Indo-Pakistan plate. This tectonic event is marked by the widespread development of Paleocene unconformity in the Himalaya. $^{40}\text{Ar}/^{39}\text{Ar}$ dates of 51 to 36 Ma, 36 to 30 Ma, 30 to 24 Ma from shear zones, date successive shearing and thrusting and 24 to 5 Ma fission track dates show unroofing and tectonic erosion, during the development of the Indus syntaxis. The presence of active faults, seismicity and newly recognized 1600 m of uplifted Indus River terrace, show that the Indus syntaxis is an active feature, which has an uplift rate of about 1 mm/year since 5.2 Ma.

Key words: Geochronology, tectonics, Swat, Hazara, Himalaya.

B/27. Baig, M.S., 1992. New occurrences of blueschist from Indus Suture Zone of Allai-Kohistan, Northwest Himalaya, Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.6.

In northern Pakistan, the Indus suture zone marks the collision boundary between the Indo-Pakistan plate and the Kohistan island arc. The Late Cretaceous blueschists have been reported from the Topsis and Shangla areas of the Indus suture zone.

This paper reports new blueschists occurrences from the ShinKamer and Marin area of the Indus suture zone of Allai-Kohistan. The blueschist is composed of glaucophane, epidote, chlorite,

quartz, white mica a minor plagioclase and calcite. The mineral assemblage suggests blueschist facies P-T conditions of about 7-8 kbars and 380-459 C. The new microprobe data on the blue amphibole show the rims of calcic amphibole (actinolite) around the cores of sodic amphibole (glaucophane). The presence of actinolite rims around the cores of glaucophane shows that the high-pressure blueschist facies metamorphism is overprinted by the low-pressure greenschist facies metamorphism. The change from the blueschist to greenschist facies metamorphism can be related to tectonic decompression or melange emplacement along the Indus suture zone of Allai-Kohistan.

Key words: Metamorphism, blueschist, Indus suture zone, Allai-Kohistan.

B/28. Baig, M.S., 2000. Precambrian polyphase pre-Himalayan deformation and metamorphism in the Indian plate, Indus syntaxis, North-West Himalaya Pakistan: $\text{Ar}^{40}/\text{Ar}^{39}$ constraints. Abstracts, Third South Asia Geological Congress, Lahore, 53-54.

South of Indus suture zone in northern Pakistan near the village of Besham, the Precambrian Besham Block rocks of the Indian plate in the core of the Indus syntaxis preserve polyphase pre-Himalayan deformation and metamorphism through the Tertiary Himalayan metamorphism. The Indus syntaxis is the basement-cored antiformal hinterland syntaxis similar to the Nanga-Parbat syntaxis. The Besham Block is separated from lower greenschist to upper amphibolite facies Precambrian to Mesozoic metasedimentary and metaigneous rocks of the Mansehra Block to the East and Swat Block to the West by high-angle oblique slip Thakot and Puran Faults respectively. The Besham block consists of Late Archaean to Middle Proterozoic metasediments, amphibolites, sodic granite gneisses and tourmaline-bearing graphic sodic granites of the Besham Basement Complex (BBC) and Late Proterozoic lower greenschist facies cover metasediments of the Karora Group (KG). The BBC is unconformably overlain by the KG. The BBC and KG rocks are intruded by Palaeozoic peraluminous sodic granites. The polyphase pre-Himalayan deformation, metamorphism and plutonism in BBC occurred before the deposition of the KG. The field evidence for pre-Himalayan metamorphism and deformation includes the truncation of gneissic fabric of the BBC at the base of the KG, the presence of BBC metasedimentary and metaigneous gneissic clasts in the phyllitic fabric of the basal metaconglomerate of the KG and the major change in metamorphic grade from amphibolite facies to lower greenschist facies across the KG unconformity. The field, fabric, petrographic and $\text{Ar}^{40}/\text{Ar}^{39}$ studies show three phases of pre-Karora group deformation (D1, D2 and D3), metamorphism (M_{B1} , M_{B2} and M_{B3}), fabric development (S_{B1} , S_{B2} and S_{B3}) and folding (F_{B1} , F_{B2} and F_{B3}). Early S_{B1} fabric related to M_{B1} upper amphibolite facies metamorphism is preserved as intrafolial fabric in sheath folds. S_{B1} fabric yields minimum age of 2031 - 1998 Ma (Hb Ar/Ar dates) for M_{B1} metamorphism. S_{B2} upper amphibolite facies penetrative gneissic to schistose fabric is axial planar to NS-striking, small scale tight to isoclinal folds. S_{B2} fabric yields minimum age of 1950 Ma (Hb Ar/Ar dates) for M_{B2} metamorphism. The epidote amphibolite facies S_{B3} spaced fabric is axial planar to N-S-striking tight to isoclinal folds, those deform S_{B2} fabric. S_{B3} fabric yields age of 1887-1865 Ma (Hb Ar/Ar dates) for M_{B3} metamorphism.

The Early Proterozoic polyphase deformation and metamorphism in BBC is postdated by 1500 Ma tourmaline-bearing graphic sodic granites. All of these deformational, metamorphic and plutonic events predated the unconformable deposition of the Late Proterozoic KG. The lower greenschist facies (up to biotite grade) D_{IV} deformation forms S_{K1} and S_{B4} fabrics in the KG and BBC respectively. S_{K1} occurs as relict fabric in intrafolial folds and microlithons and S_{B4} occurs as spaced fabric and actinolite rims around hornblendes. S_{K1} and S_{B4} fabrics predate the intrusions of 500 Ma and 272 Ma sodic granites. The Tertiary Himalayan deformation in the Besham block occurred at 66-64 Ma, 50-40 Ma and 36-26 Ma.

Key words: Metamorphism, deformation, Precambrian, Swat, Hazara, Himalaya.

B/29. Baig, M.S. & Lawrence, R.D., 1987. Precambrian to Early Paleozoic orogenesis in the Himalaya. *Kashmir Journal of Geology* 5, 1-22.

Precambrian to Paleozoic Himalayan rocks are metamorphosed from lower greenschist facies in the south to amphibolite, and granulite facies in the north. Two or possibly three, metamorphic episodes are preserved in the Precambrian shelf and platform sediments of the northern margin of Gondwana in the Indo-Pakistan plate. At least one metamorphic episode appears to be Precambrian to early Cambrian in age and significantly predates Himalayan metamorphism.

The late Precambrian to early Cambrian tectonism is evidenced by the presence of an angular unconformity, between the late Precambrian and early Cambrian rocks in Hazara, Kotli Azad Kashmir, and the Nepal Himalaya.

The unconformity is marked, by a basal conglomerate, which is composed of clasts of metamorphic rocks that are derived from the underlying Precambrian basement rocks of the Indo-Pakistan plate. The late Precambrian to early Cambrian tectonism is here designated the Hazaran orogeny, because it is well evidenced in the Hazara Himalaya of Pakistan. In the Hazara area, the early Cambrian Tanakki basal conglomerate of the Abbottabad Group above the angular unconformity is unmetamorphosed, whereas the underlying Precambrian Hazara Formation is metamorphosed to lower greenschist facies. The Tanakki conglomerate has cleaved metamorphic clast derived from the underlying Hazara Formation but the matrix of the unit is unclesaved. The Hazara Formation is deformed and has growth of new mica along, the axial plane cleavage, which is truncated by the Tanakki conglomerate. This confirms that the Precambrian metamorphism and tectonic occurred before the deposition of early Cambrian Tanakki conglomerate.

During the Hazaran orogeny, 600-900 Ma plutonic and volcanic rocks intruded into and extruded onto the Precambrian basement rocks of the Indo-Pakistan plate and predate the late Precambrian to early Cambrian unconformity. Somewhat after the Hazaran orogeny, 500-600 Ma peraluminous granites, with initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of 0.7102-0.7190, intruded the Precambrian as well as earliest Paleozoic rocks. The high initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios suggest that these plutons were derived by antaxis from the basement rocks of the Indo-Pakistan plate. The 500-600 Ma plutons of the Indo-Pakistan plate may be late Hazaran or post-Hazaran orogenic phase of the Hazaran orogeny. The Hazaran orogeny in the Himalaya occurred before the Permo-Triassic breakup of Gondwana and may correlate with the Pan-African, Batkalian, Cadomian, Katangan, and Assyntic orogenies of Africa and Europe.

Key words: Precambrian, Paleozoic, orogenies, Himalaya.

B/30. Baig, M.S., Lawrence, R.D. & Snee, L.W., 1988. Evidence for late Precambrian to early Cambrian orogeny in the northwest Himalaya, Pakistan. *Geological Magazine*, 125, 83-86.

An angular unconformity below Cambrian rocks is present in the northwest Himalaya in the Hazara district, Pakistan. Low-grade metamorphism and folding with axial planar cleavage present in Precambrian rocks below the unconformity, but not in those above it, confirm orogenic deformation at this time. This is the first clear evidence for such a deformation episode and it may be referred to locally as the Hazaran orogeny. Anatectic peraluminous granites of the Himalaya are of only slightly younger age and may be related to this orogenic episode.

B/33. Baig, M.S. & Snee, L.W., 1991. A Discovery of Late Archean to Early Proterozoic Komatiite from the Northwestern Margin of the Indian Plate, Besham area, Northwest Himalaya Pakistan. *Kashmir Journal of Geology* 8 & 9, 19-24.

In northern Pakistan, near the village of Besham, the Besham block of Indian plate is exposed in the core of the Indus syntaxis. This basement block is separated from low-to high-grade Precambrian to Mesozoic metamorphic

rocks to the east and west by high-angle ramp faults and from low-grade to unmetamorphosed sedimentary rocks to the south by thrust faults. The Besham block consists of epidote-amphibolite to upper amphibolite facies Late Archean to Middle Proterozoic cover sediments of the Karora group.

Precambrian komatiites are known from the basement rocks of the southern Indian plate. No komatiites have previously been reported from the Indian basement. Early Proterozoic komatiites from the Besham basement complex of the Besham area, northwest Himalaya, Pakistan. It is the first report of komatiites from the northwest basement rocks of the Indian plate. An amphibolite from the Besham basement complex is herein characterized as an alumina depleted basaltic komatiite on the basis of high SiO_2 (55%), high MgO (15.94 %), $<0.5\%$ K_2O (0.24%), $<0.9\%$ TiO_2 (0.25 %), low Fe/Mg ratio (0.89) at given Al_2O_3 (3.77%) and $>\text{CaO/Al}_2\text{O}_3$ ratio (3.45).

Precambrian komatiites are commonly associated with the rift-related extensional environments. The presence of Late Archean to Early Proterozoic mafic komatiites in the Besham basement occurred during the rifting of Indian plate.

Key words: Komatiite, Precambrian, Late Archean, Besham, Indian Plate.

B/34. Baig, M.S. & Snee, L.W., 1997. Precambrian tectonics of the Indian plate, Indus syntaxis region, Northwest Himalaya, Pakistan: $\text{Ar}^{40}/^{39}\text{Ar}$. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 117-118.

In the northwest Himalaya of Pakistan, metamorphism and deformation are the result of collision between the Indian and Asian plates. The presence, timing and significance of pre-Himalayan orogenic events have previously been uncertain, due to the pervasive high-grade Himalayan tectonic overprint which apparently obscures any prior record (Baig and Lawrence, 1987; Baig and others, 1988). The study of the Indus syntaxis of northern Pakistan has discovered earlier pre-Himalayan events, which are dateable due to weaker Himalayan metamorphic overprinting (Baig and Snee, 1989; Baig and others, 1989, 1992; Baig; Treloar and Rex, 1990). New field, structural, metamorphic and stratigraphic data together with $^{40}\text{Ar}/^{39}\text{Ar}$ isotopic age data on hornblende and muscovite are presented for the basement and cover rocks of the Indian plate near Besham and Hazara areas. These data reveal a lengthy pre-Himalayan orogenic history initiated at least in the Early Proterozoic and /or in the Late Archean.

The newly recognized Besham basement complex of the Indian plate, in the core of the Indus syntaxis, consists of multiply-intruded epidote-amphibolite- to upper amphibolite-facies metasediments of the Besham group. $^{40}\text{Ar}/^{39}\text{Ar}$ dating of Indian basement rocks (Baig, 1990) confirms the following Precambrian events:

Archean to Early Proterozoic Besham group shallow water pre-to syn-rift sedimentation and associated mafic and komatiitic volcanism, mafic dike intrusions, Darwaza Sar potassic and Lahor sodic granite intrusion, upper amphibolite-facies metamorphism at $>2,000$ Ma ($^{40}\text{Ar}/^{39}\text{Ar}$ hornblende dates), upper amphibolite-facies metamorphism at $1,950 \pm 3$ Ma ($^{40}\text{Ar}/^{39}\text{Ar}$ hornblende dates), hornblende-biotite granodiorite and granite intrusions, mafic dike intrusions and epidote-amphibolite-facies metamorphism at $1,887 \pm 3$ Ma ($^{40}\text{Ar}/^{39}\text{Ar}$ hornblende dates). Proterozoic by tourmaline-bearing sodic granitic granites at 1,500 Ma ($^{40}\text{Ar}/^{39}\text{Ar}$ hornblende dates). The 2,000-1,500 Ma orogenic events define the Early to Middle Proterozoic Besham orogeny.

The Late Proterozoic syn- to post-rift Karora group was deposited subsequently with a breakup unconformity on the Archean to Middle Proterozoic Besham basement complex. It is composed of Amlo conglomerate Formation, Kurmang Formation and Kandoana Formation (Baig, 1990). The shallow water turbidite Kurmang Formation and its facies equivalent Manki, Dakhner, Hazara, Landikotal, Simla, Dogra, Phe and Salt Range formations show syn-rift sedimentation and associated local mafic Dogra and Khewra volcanisms. The Amlo conglomerate Formation marks the breakup unconformity at the base of this widespread unit in the northwest Himalaya. The Kurmang and Manki formations are conformably succeeded by post-rift shallow water carbonates of the Kandoana and Shahkot formations respectively.

The Eocambrian or Latest Proterozoic Hazaran orogeny initiated at 650 ± 25 Ma ($^{40}\text{Ar}/^{39}\text{Ar}$ sericite dates). The Hazaran orogeny uplifted and eroded the Precambrian basement and cover rocks of the southern Indian shield and deposited the Eocambrian Hazaran clastic molasse of the Tanawal and Manglaur formations north Panjal thrust in a pre-Himalayan subsiding Hazaran foreland basin. The Hazaran orogeny predated the unconformable deposition of the Early Cambrian fossil-bearing sedimentary strata in the northwest Himalaya of Pakistan. The Eocambrian Hazaran or Pan-African orogeny caused the amalgamation of Gondwana as a super continent.

Key words: Precambrian, tectonics, geochronology, Indian Plate, Himalaya.

B/35. Baig, M.S., Snee, L.W., Fortune, R.J.L. & Lawrence, R.D., 1989. Timing of Pre-Himalayan orogenic event in the Northwest Himalaya: $^{40}\text{Ar}/^{39}\text{Ar}$ Constraints. *Kashmir Journal of Geology* 6 & 7, 29-40.

In the Northwest Himalaya, pre-Himalayan metamorphism and deformation is present, which is postulated by early Paleozoic peraluminous granites. The early Paleozoic granites and the Precambrian basement rocks of the Indo-Pakistan plate were metamorphosed and deformed, during the pervasive high-grade Himalayan metamorphism and deformation, which caused uncertainty in the recognition of the timing of the pre-Himalayan metamorphism and deformation.

Field criteria such as intrusive age relationship of meta-igneous plutons, relative ages of deformation phases, overprinting of gneissic fabric by weak younger fabric, and an angular unconformity, can provide relative ages for the pre-Himalayan and Himalayan metamorphism and deformation. However, such data do not constrain the absolute timing of metamorphism and deformation, which must be constrain by isotopic dates. The new $^{40}\text{Ar}/^{39}\text{Ar}$ dating of the Precambrian basement rocks of the northwest Himalaya of Pakistan, confirms five pre-Himalaya metamorphic events. These metamorphic events occurred at $>2,000 \pm 6$ Ma, $>1,950 \pm 3$ Ma, $1,865 \pm 3$ Ma to $1,887 \pm 5$ Ma, 650 ± 2 Ma, and $> 466 \pm 2$ Ma. The 600-900 Ma plutonic, volcanic, metamorphic, and deformational events are related to the Hazara orogeny. The 550-450 Ma peraluminous granites and $> 466 \pm 2$ Ma metamorphism in the Himalaya, record a separate Cambro-Ordovician orogenic event. This orogenic event correlates with the Pan-Paleozoic orogenic events on the Indo-Pakistan plate occurred before the Permo-Triassic breakup of Gondwana.

B/37. Baig, Z.M., 1996. Environmental geochemistry of water, rock and soil of Gadoon and surrounding area, District Swabi, N.W.F.P., Pakistan. M.Phil. Thesis, University of Peshawar, 165p.

Elements like carbon, hydrogen and oxygen are considered as an essence for living organisms, while the trace elements have both benevolent and harmful effects to living organism upto certain limits. Environmental geochemistry is one of the science that deals with the interaction of the pollutants in our daily life. These pollutants may be either contributed by anthropogenic or natural processes or both. A wide range of industrialization throughout the country is flourishing on one side but poor management in this sector is polluting the water and soil with the toxic effluents that are coming from these industries. In Gadoon and surrounding areas natural and anthropogenic pollution is effecting the quality of water by adding pollutants such as SO_4 , NO_3 and trace metals like Cd, Cu, and Pb.

In the present study thirty-five samples of water (both surface and groundwater) and twenty-six sample of soil, from Gadoon and surrounding areas, were analyzed for different parameters. The most alarming issue of the study area is the higher concentration of sulfate and nitrate contents in the drinking water of Gandaf, and Biasak, where the concentration of SO_4 in the drinking water exceeds 1700 and 1525 mg/l respectively. The US-EPA & WHO recommended a permissible limit of 250 mg/l in drinking water. The source of this high concentration in the drinking water of the area is the contamination through the rocks of the Salkhala Formation. The rocks of the Salkhala Formation are enriched in sulfide minerals like pyrite. Sulfate as a pollutant is causing diarrhea, dehydration and gastrointestinal problems in the people of the area. The concentrations of NO_3 in the Gandaf and Miani wells also exceed 946 and 286 mg/l respectively. The US-EPA's permissible limit for nitrate is considered to be 10 mg/l. The higher concentration of nitrates in water is due to agricultural pollution (i.e. fertilizers and human feces. etc.). This enormous increase of nitrate in drinking water is due to the mixing of animal manure in the soil. Ultimately, this manure makes its way to water, due to the run-off from cultivated and fertilized field. In infants, nitrate contaminated water cause a disease called methemoglobinemia, a type of blood disorder in which red blood cells cannot carry oxygen.

B/42. Bajwa, M.A., 1995. Shallow seismic reflection surveying for mapping the weathered layer velocity and lithology correlation in Attock District. M.Sc. Thesis, Quaid-i-Azam University, Islamabad, 35p.

Shallow Seismic Refraction Survey was carried out to map the low velocity weathered zone in Attock District for the completion of M.Sc. dissertation. For this purpose five parallel profiles were laid. Overall 52 Seismic spread were shot using reverse shooting technique. After plotting the observed refraction travel times, in the travel time versus distance graph, velocities V0, V1 and depth Ho were calculated.

The values thus obtained have been used to prepare isovelocity (Vo) map, isovelocity, (V1) map and isopach (Ho) map. Hawkin's method was also used for comparative study. Integrating the available geological information along with interpreted velocity depth picture, a relationship between velocity and lithology has been established. The low velocity of weathered layer ranging from 400 m/sec to 1100 m/sec, which shows unconsolidated material of alluvial deposits comprising of sand and clay. The high velocity of sub-weathered layer ranging from 1400m/sec to 3200 m/sec indicates the combination of sandstone, shale, clay and wet sand. The thickness of weathered layer varies from 2m to 8m in the project area.

Key words: Seismic reflection, Attock.

B/43. Bajwa, M.S., 1970. Geology and petrology of Swat Hornblendic Complex in the Chargah–Khawza Khela Area, Swat. M.Sc. Thesis, Punjab University, Lahore.

The geology and petrography of this area of the Kohistan magmatic arc is described. The principal rocks include amphibolites, metagabbros and their associates.

B/44. Bajwa, M.S., 1984. Petrology of Siwalik rocks of Chakri-Chauntra area, Attock and Rawalpindi Districts, Punjab, Pakistan. *Kashmir Journal of Geology* 2, 93-102.

A sequence nearly 3000 meters thick of the Siwalik Group of Late Cenozoic age is exposed in the Chauntra quadrangle, in Attock and Rawalpindi Districts. For the purpose of petrological studies, the sequence has been differentiated into Lower, Middle and Upper Siwaliks. The sandstones and clays of these sub groups have been studied lithologically, petrographically and chemically. The petrographical evidences suggest that sediments of the Siwalik Group were derived from igneous, metamorphic and sedimentary rocks of the adjacent Himalayan region and were deposited in a shallow fast sinking basin, after their short and rapid transportations.

Key words: Petrology, siwaliks, Attock, Rawalpindi.

B/45. Bajwa, M.S., 1997. Geochemical study of the detrital almandites of Murree and Siwalik Formations from Potwar, Pakistan. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, p.139.

The detrital almandites (garnets) of Murree and Siwalik formations of Miocene to Pleistocene ages, from Rawalpindi and Jhelum areas, eastern Potwar, Pakistan, were chemically analysed with the help of EPMA (Electron Probe Micro Analyser), at Kyoto, University, Japan. The data of more than three hundred almandites were plotted on Mg-Fe-Mn and Mg-(Fe+Mn)-Ca triangles. The distribution of the data points, based on Mg, Fe, Mn and Ca molecular percentage ratios in both the triangles showed a marked difference between Murree and the Siwalik strata. Some differences in the chemical trends of the garnets from the Lower, Middle and Upper Siwalik formations can also be seen in Mg-Fe-Mn triangles, but no such difference could be noted in the second type. It is evident that most of the garnets of Murree Formation have been concentrated in the high Fe, high Mn zones as compared to that of Middle and Upper Siwaliks, which have taken positions in the high Fe and high Mg areas. Whereas, the data of Lower Siwaliks are distributed almost equally in the zones of high Fe, low Mg and low Mn, but the trend towards Mn is a little higher. However, some evidences suggest that the almandite garnets of Murree Formation have been derived from low grade metamorphic rocks, those of Lower Siwaliks from medium and high grade, and Middle and Upper Siwaliks from high grade rocks from a source area situated in northern Pakistan.

Key words: Geochemistry, Murree Formation, siwaliks, Potwar.

B/46. Bajwa, M.S. & Akhtar, M., 1988. Preliminary bibliography of Siwalik rocks of Pakistan. Geological Survey of Pakistan, Information Release 343.

The Siwalik molasse heavy mineral assemblages also include garnet. There are many places in the north-west Himalaya where metamorphic and igneous rocks contain garnet, the source of for the Siwaliks. The analyzed garnets range from Fe-rich compositions to those having substantial amounts of Ca and/or Mg.

Key words: Geochemistry, garnet, Murree Formation, Siwalik Formation.

B/48. Bajwa, Z.A., 1991-93. Geology of Dubran Area District Haripur with microfacies study of Langrial Algal limestone. M.Sc. Thesis, Punjab University, Lahore, 127p.

Geological mapping of some 64-km² area around Dubran in District Haripur has been carried out at the scale 1:12500. The geomorphology, soils, stratigraphy and structure have been described. Stratigraphically a Mesozoic-Tertiary sedimentary cover is overlying a Precambrian to Eo-Cambrian basement of Hazara Group now

metamorphosed in the lower greenschist facies. Numerous faults, high angle north dipping Nathiagali Thrust is the main fault that passes through the area and has thrust the Precambrian Hazara Slates over the younger sedimentary sequence. Dubran syncline lying on top of a major anticlinorium makes an interesting structure.

B/58. Balme, B.E., 1970. Palynology of Permian and Triassic Strata in the Salt Range and Surghar Range, West Pakistan. In: Kummel, B. & Teichert, C. (Eds.), *Stratigraphic Boundary Problems: Permian and Triassic of West Pakistan*. Geology Department University of Kansas, Special Publication 4, 305-454.

This paper deals with the palynological examination of 57 samples of sediments, six of which came from a single locality in the Surghar Range, and the remainder from eight localities in the Salt Range, West Pakistan. The material ranges in age from Lower Permian (Artinskian) to Middle Triassic, but most of the samples are from the uppermost Permian and Lower Triassic.

Seventy-nine species of spores and pollen grains, 23 of which are new, have been described and illustrated. *Sirneonoshota* (type species: *S. khlonovae* sp. nov.) and *Paravittatina* (type species: *Decussatis!Jorites lucifer* Bharadwaj and Salujha) have been instituted as new form genera.

Implications of the palynological data are discussed in relation to biostratigraphy and the plant geography of late Paleozoic and early Mesozoic times. They provide evidence for sweeping floral changes in the Salt Range area, coincident with the Permian-Triassic boundary, and for further extensive modifications during the late Scythian. Spore and pollen assemblages from the Late Permian Chhidru Formation appear to have derived from a transitional flora, but to have much in common with those from strata of similar age in Madagascar. Triassic assemblages both in their composition and succession closely resemble those from the Perth Basin, Western Australia.

Key words: Palynology, Permian, Triassic, Surghar Range, Salt range.

B/59. Baloch, I.H., 1986. A mineralogical study of the industrial utilization of bauxitic clays of Nawa area, Kala Chitta Range, Attock District, Pakistan. *Acta Mineralogica Pakistanica* 2, 144-152.

This paper gives a detailed account of the mineralogy of the Bauxite clays of Nawa area from the Datta formation of early Jurassic age exposed in the Kala Chitta Range, Pakistan. The mineralogic studies show that the Kaolinite, diaspora and boehmite are the essential minerals, while chlorite, anatase, rutile, quartz and haematite are accessories. A brief account of the chemistry, phase transformation and detailed description of industrial utilization is also presented. Three grades of clays are found: one can be used as a high grade refractory, the second for ceramics and the third for common bricks.

Key words: Mineralogy, clays, economic geology, Kala Chitta Range, Attock.

B/60. Baloch, I.H., 1997. Petrogenesis of alkaline igneous province of Pakistan. Geological Bulletin, Punjab University 31 & 32, 169-176.

The Alkaline Igneous Province of Northwest Pakistan (AiPNP) extends from Loe-Shilman in the West to Tarbela in the East for a distance of about 150 Km. There are at least two distinct periods of magmatic / volcanic activity in the alkaline province. One is Permo- Carboniferous in age and is related to the break up of Gondwana land through Intra continental rifting.

The second activity is Tertiary in age. This is related to bending of Indian Plate during subduction. This bending caused tension and rifting. Tectonically the alkaline province falls in two Himalayan subdivisions: (a) Tarbela, Kogu, Ulla, Babaji, Ambela and Loe Shilman falls in the Lesser Himalaya South of the Main Central Thrust and (b) Sillai Patti and Jambil fall in the Higher Himalaya North of the MCT. It may therefore be concluded that alkaline province is not restricted to the Lesser Himalaya alone.

Key words: Petrology, alkaline rocks.

B/61. Baloch, I.H., 2001. The age of the carbonate cover to the basement of higher Himalayan crystalline. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.45.

The cover rocks of the Higher Himalayan Crystalline (HHC) in Swat are composed of a basal pelitic-psammitic unit overlain by a thick sequence of carbonates and calc-pelites. This cover has variously been considered as Pre-Cambrian or Triassic. Most of the workers have correlated this cover with Lesser Himalayan carbonates variously known as Bampokha group, Tursak marbles, Khasala Formation etc. The Lesser Himalayan carbonates have in turn been considered as Triassic/Jurassic to Siluro-Devonian.

The units equated with HHC cover rocks have been intruded at various places by Babaji syenite, Sills, dykes and minor apophyses of Babaji syenite intrude the rocks of Tursak/Bampokha/Khasala formations. Clear-cut hornfelsing in pelitic horizons has been identified at a number of places. Babaji Syenite has been dated as Carboniferous by U/Pb, Ar/Ar and Rb/Sr methods. The country rocks are therefore Pre-Carboniferous. If these rocks are correlated with HHC pelite/carbonate cover, then the HHC cover is older than Carboniferous.

Key words: Alkaline rocks, carbonates, stratigraphy, Swat.

B/62. Baloch, I.H., Ahmed, N., Mateen, A., Chaudhry, M.N. & Ghazanfar, M., 1999. K-Rb relations in the Koga Ijolite-feldspathoidal syenite complex, Buner Swat, Pakistan: Their bearing on the petrogenesis and comparison with similar alkaline undersaturated magma series of the world. Pakistan Journal of Geology 10 & 11, 20-33.

The Ambela granitic complex contains a range of alkaline rocks, including syenite, ijolite and carbonatite. This paper describes these alkaline rocks and uses geochemistry in drawing conclusions regarding their origin and comparison with other such rocks from other parts of the world.

B/63. Baloch, I.H. & Chaudhry, M.N., 1991. Occurrence, geology, petrology and industrial applications of More Khun barite deposits of Northern Areas of Pakistan. Geological Bulletin, Punjab University 26, 71-73.

The Mor Khun barite deposit is a hydrothermal replacement deposit which occurs within Gujhal Dolomite close to the contact of Gircha Formation. It is exposed intermittently for hundreds of metres. The deposit is snow white and very pure with a specific gravity between 4.3 and 4.4. Chemical and physical characteristics of this deposit indicate a number of industrial applications.

Key words: Economic geology, barite, Northern Areas.

B/64. Baloch, I.H., Chaudhry, M.N. & Mateen, A., 2000. The mineral chemistry of the Koga undersaturated alkaline complex, Buner, Swat, North Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, 130-131.

Mineral Chemistry of feldspathoids, feldspars, sodium pyroxenes and biotite-annite-siderophyllite series coupled with petrochemistry of the Koga Alkaline igneous complex has been studied and interpreted to understand the crystallization history of the undersaturated magma in the region.

The Koga feldspathoidal complex is comprised of feldspathoidal syenites, foyaites, melanite nepheline syenite, alkali syenites and sodalite-cancrinite rich pegmatites. The pegmatites are minor. The feldspathoidal syenites formed at pressure of < 5 kbar. These rocks comprised essentially of feldspar and feldspathoids. Pyroxene, biotite magnetite, garnet, sphene, apatite and zircon are minor to accessory minerals. The mafics along with sphene, apatite and zircon occur as tiny enclaves or microxenoliths. Cancrinite and sodalite generally occur as accessory minerals; however, in some pegmatites they assume the status of essential minerals.

The feldspar is a single phase highly exsolved feldspar with a K-feldspar host. The composition of nepheline is restricted to the Morozewicz-Buenger convergent field in the system Ne-Ks-Qz. Such a composition is characteristic of subsolvous nepheline syenites. Cancrinite and sodalite show constant composition with relatively high SiO₂ and Al₂O₃. However, CaO is comparatively low. The sodium pyroxenes fall within the narrow field of aegirine-Jadeite. Hedenbergite is lacking. The aegirine composition ranges from Ae₈₀ Jd₂₀ to Ae₇₅ Jd₂₅. The fractionation trend of pyroxenes in this complex is rather unique and does not duplicate other complexes of the world.

Within the Biotite-Annite-Siderophyllite series in the Koga undersaturated rocks, four compositional groups may be recognized. 1. An₉₀Sd₁₀ to An₇₃Sd₂₇ with as much as 30 to 50% phlogopite, 2. An₉₅ Sd₅ with 15 to 30% phlogopite. 3. An₈₀Sd₂₀ to An₆₅ Sd₃₅ with 5 to 15% phlogopite. 4. An₇₀ Sd₃₀ to An₆₀ Sd₄₀ with 0 to 5% phlogopite.

B/67. Baloch, I.H., Ghazanfar, M., Dunham, A.C. & Chaudhry, M.N., 1997. First account of deep chemical weathering and its implications on the reserve and mining potential of Koga feldspathoidal syenite complex of north western Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

It is the first report and systematic study of deep chemical weathering affecting a plutonic igneous complex in Pakistan. Discovery that the patchy outcrop of Koga feldspathoidal syenite is not a result of separate intrusions but a result of the deep chemical weathering which has led to the isolation of the still intact patches which has been taken as separate intrusion in the past. Downwards below the zone of weathering the Koga feldspathoidal syenite must be fresh everywhere. This has a direct implication on reserve calculation. It throws light and invites further research on the nature and operation of deep-seated chemical weathering on feldspathoidal syenites. The new minerals found in the altered rock comprise kaolinite, illite, pyrophanite and siderite. It would be interesting to trace the exact sources of the ions required for these alterations. It is here suggested that aegirine, orthoclase and sphene have suffered partial breakdown. The CO₂ for the CO₃ had come from the rainwater and the soil.

It is interesting to note in the field that the weathered rock shows increase of volume and decrease of hardness which has resulted from the broad process of hydrolysis, carbonation and oxidation. The rock has become soft and swollen even though the broad textural fabric has been more or less maintained at many places. It is also significant that the total alkali content of even the highly weathered and altered rock does not fall below 10.84% from an average of 15%. This deficiency of alkali can be overcome by blending with high alkali foyaites which make it possible to utilize even the weathered material. This shows that the process of weathering though important from the mining, processing and academic point of view has not substantively affected the ore potential of the complex. Although

hydrothermal alteration of a small part of the Koga feldspathoidal syenite is known. However, implication of weathering for the mineability and reserve potential of this very important industrial rock deposit are profound. The deposit is composite in nature and composed of a number of plugs and dykes. But weathering gives a very wrong impression of the configuration of the internal structure of this complex. In the past composite outcrops, rising out of the weathered envelope were regarded as discrete intrusive bodies. Such an assumption fails to take into consideration the facts of weathering on the reserve and mineability.

The mineral chemistry of biotites has been investigated by the electron microprobe analysis performed on various rock units from the Koga feldspathoidal syenite complex. Four distinct groups- biotite-annite-siderophyllite series have been recognized; (1) $An_{70}Sd_{30}$ to $An_{60}Sd_{40}$ with 0 to 5% phlogopite (2) $An_{80}Sd_{20}$ to $An_{65}Sd_{35}$ with 5 to 15% phlogopite (3) $An_{95}Sd_5$ to $An_{73}Sd_{27}$ with 15 to 30% phlogopite (4) $An_{90}Sd_{10}$ to $An_{73}Sd_{27}$ with 30 to 50% phlogopite.

B/74. Baluch, A.Q., 1981-83. Geological mapping and site investigations of dam site and reservoir area of Basha Dam (Chilas Diemer). M.Sc. Thesis, Punjab University, Lahore. 99p.

The electric power demand of Pakistan is very high and the present generation capabilities of the country are insufficient to cope with the increasing load created by industry, agriculture and domestic consumers. In order to tide over the situation water and power development of Pakistan initially identify thirteen sites on the Indus River upstream of Tarbela upto Skardu, because the drop along Indus plains show attractive locations for hydro power development.

To study the potential/plan the development of 13 identified sites and feasibility of one best site, first Canadian Technical Assistant has been arranged. Basha damsite is the site selected by the Canadian Consultant for the feasibility purposes which is located on the Indus river near the village Basha about 45 km downstream of Chilas in Gilgit Agency.

Key words: Engineering geology, Basha, Chilas.

B/75. Baluch, S.Q., 1998. Geotechnical aspects of hydropower projects in Indus Kohistan, Northern Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 27-29.

A number of high head hydropower projects are being planned on the tributaries of the Indus River in Indus Kohistan. These projects, with locations as shown in Fig. 1, are at various levels of study and the first may come into operation around the year 2005. The estimated total installed capacity of 5,000 MW mostly in the form of peaking plants will significantly reduce the power deficit currently being faced by Pakistan. The main characteristics of these cascade schemes include storage dams at higher elevations with regulation facilities in the middle and lower catchment sections. As is the case with most high head hydropower projects, the planned schemes are in relatively remote areas and contain long waterways (tunnels) across areas of high overburden. High erosion rate in the Himalayan region will also result in deposition of sediments in the reservoirs requiring careful sedimentation management and provision of sediment handling facilities. Main geotechnical data available for the schemes is summarised and discussed in relevant detail. The Allai Khwar Hydropower Project is the most advanced and is a likely candidate for implementation ahead of others. The other cascade schemes on left bank of the Indus river in the adjacent catchments of Chor Nala and Spat Gah have been studied to conceptual and reconnaissance level, respectively. Based on geological and tectonic setting of the area, the process of site selection and establishment of design parameters are also presented.

The continued subduction and Arc-Continental collision (thrusting) induced several phases of faulting and metamorphism, resulting in a wide spectrum of low to high grade metamorphic rocks. The projects areas are in close vicinity of the Main Mantle Thrust (MMT); a major orogenic feature which marks collision boundary of the Indian plate to the Eurasian plate with intervening Karakoram micro-plate and Kohistan Arc. The alignment of MMT and other major tectonic features have been mapped within the projects area. Based on the regional geological conditions, the geotechnical zoning has been attempted to define expected geotechnical and geomechanical characteristics of rock mass along the long tunnel routes. Attempt has been made to predict tunnelling conditions and rock mass behaviour together with estimated rock support requirements.

Investigation techniques, including interpretation of satellite imagery, aerial photographs interpretation, engineering geological mapping, geophysical methods and core drilling is described together with their application from site selection to microlocation of the project structures. The paper describes the successful use of various geophysical investigation techniques and results obtained at the initial stage of site selection in these relatively remote and inaccessible areas. This allowed to replace expensive and time consuming drilling and other relevant rock mechanics testing. Systematic discontinuities surveys regionally and at selected sites were carried out to define characteristics of dominant discontinuities groups. Also presented is the use of this data in stability assessment of foundations, tunnels and slopes on various project sites. In the concluding section, recommendations are given for appropriate methodology and approach in obtaining geotechnical data and site selection for hydropower projects in northern areas of Pakistan.

Key words: Engineering geology, energy, Kohistan.

B/76. Baluch, S.Q. & Ali, I., 1998. Seismic risk assessment of hydropower projects with reference to the tectonic structure of northern Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 29-32.

Seismic phenomenon has been responsible for the severe damage to water-retaining structures in the ' world. Examples from USA include Sheffield dam, Hebgen Lake dam, Upper San Fernando dam, and Lower San Fernando dam. Similarly, Koyna dam; a concrete gravity structure in India sustained severe earthquake damage in 1967. However, a complete failure of a dam due to earthquake impact is virtually unknown. The safe design of dams to withstand destructive earthquakes is, therefore, extremely important because failure of such a structure may have disastrous consequences both on life and property. The paper briefly describes seismo-tectonic environment in the Himalayan region and its impact on existing dams in tilts area such as Bakhara-Nangal dam in India, Mangla and Tarbela dams in Pakistan. In addition, earthquakes that may pose a multitude of hazards to dams either by direct loading of the structure or by initiating a sequence of events that may lead to the dam failure are discussed with a special reference to tile tectonic structure of Northern Pakistan. The geological and tectonic setting of the Northern Pakistan is an example of Continental collision characterised by the occurrence of an ancient island arc. The continuing subduction and Arc-Continental collision (thrusting) induced several phases of faulting and metamorphism, resulting in a wide spectrum of low to high grade z-metamorphic rocks. The tectonic processes in the area have produced a mixed and very complex geological situation. The collision tectonics have resulted in formation of thrust and strike slip faults. Most of the high head hydropower projects planned in the Indus Kohistan area are located in close vicinity of the Main Mantle Thrust (MMT) and other major tectonic features. The rocks are foliated to cataclastic and mylonized with high degree of shearing and folding in vicinity of the MMT. The MMT, Indus Kohistan seismic Zone (IKZS), Thakot Shear Zone (TSZ) and the Main Boundary Thrust (MBT) in the form of a detachment fault underlying the project area are the main seismogenic features in the area. Relationship between distribution of seismic events and main seismo-tectonic features in Indus Kohistan is given in Fig. 1. The Northern areas of Pakistan are considered highly seismic and in spite of the fact that all the future main hydropower projects are being planned in this region, this area has never been covered by any seismic instruments in the past. Recently, M/S Allai Khwar Consultants (AKC) have managed a microseismic network study in Indus Kohistan area. The instruments installed at locations shown in Fig. 2 recorded several hundred seismic events during six months study period. The study indicated that the level of micro-seismicity in this region is fairly frequent and probably greater than in other parts of the Himalayan region. Another important aspect identified by the study is the shallow depth of seismic events. It is observed that even small magnitude events can produce high accelerations in Northern Pakistan. For example, an earthquake of April 17, 1970 with a body wave magnitude 4.9 produced 25% g and that of February 20, 1996 wave a magnitude 5.2 produced 27% g at the Tarbela site. Based updated geological information, historical earthquake data and preliminary results of the recent microseismic network study, design parameters such as Maximum Credible Earthquake (MCE), Operational Basis Earthquake (OBE) and acceleration (g) values are proposed. Relevance of various attenuation equations for this area are also discussed. Satellite imagery and aerial photographs to determine location and lengths of lineaments provided information on the probable extent of possible movement on major fault planes. Accurate geological and tectonic snapping allowed correlation of instrumental data with the known tectonic features. Based on the recommendations of the International Committee on Large Dams (IOCLD), the investigation methods used in site selection, classification of fault systems and identification of neo to recent tectonic activity are described. Relevant design features are proposed to minimise damage to dams avid appurtenant structures in case of extreme shaking during strong seismic events.

B/77. Baluch, W.A., Begum, I., Aslam, M. & Shah, A., 1982. Geology of Shergarh-Sar Complex, Allai Kohistan, Hazara. M.Sc. Thesis, Peshawar University, 55p.

This report covers the Geology of an area located in the Allai Kohistan, Hazara division between 34° 50' to 34° 60' N latitudes and 73° 0' to 73° 10' E longitudes. A detailed petrographic study together with a geological map is presented in this manuscript. Broadly, the rocks types of the thesis area are divisible into two major groups, i.e. amphibolites and ultramafics. In the studied area the amphibolites are divided into three groups: 1) Epidote-Amphibolites, 2) Garnet-Epidote-Amphibolites, and 3) Garnet-Amphibolites.

The amphibolites may be inferred to be metamorphosed product of oceanic crust. Ultramafics are peridotites, pyroxenites, dunites, and serpentinites. These ultramafics represent the obducted ophiolites. The area is located along MMT, which is a vital tectonic element of the Himalayan geology. Due to the involvement of MMT, the area has undergone complex tectonic episodes in response to the collision of Indian plate and Eurasian continent.

Economic mineral chromite is found in ultramafics whereas gem quality garnet is expected to be found in amphibolites. Vein deposits like Pb and Zn are also expected but no comprehensive work has been done.

B/78. Banaras, M. & Ghani, A., 1982. Petrography of the Tora Tigga Complex, Munda area, Dir District. M.Sc. Thesis, University of Peshawar, 157p.

This work presents a detailed geological map (1:12,500), petrography and a discussion regarding the petrogenesis of the ultramafic rocks of the Tora Tigga complex in Dir district (34°49' N, 71°44' E). The complex, covering about 7sq. km. area, is situated in the Southern Amphibolitic Belt along the Main Mantle Thrust. The amphibolites, hosting the ultramafic rocks, are divisible into metagabbros/ metanorites, banded- amphibolites and garnet-amphibolites. The metagabbros/metanorites consist of prograde hornblende and plagioclase (An₄₀₋₄₃) with or without quartz, white mica, apatite, rutile and ore. Clinopyroxene and orthopyroxene occur as relics, and chlorite and epidote as retrograde alteration products. The banded-amphibolites are composed of quartz, plagioclase (An₃₈) hornblende, biotite, sphene, and ore. The garnet-amphibolites are similar in composition to metagabbros except for the presence of garnet porphyroblasts and a slightly more calcic plagioclase (An₄₅). All these rocks have been metamorphosed under Barrovian-type amphibolite facies conditions. The ultramafic rocks are broadly classified into olivine-pyroxene-ultramafites and hornblendites. The olivine-ultramafites include peridotites, amphibole-peridotites, serpentinites and dunites. The pyroxene-ultramafites include hornblende - websterites - hornblende - orthopyroxenites, hornblende clinopyroxenites, hornblende-olivine-websterites and olivine-clinopyroxenites. There is a complete range from hornblende-pyroxenites to pure hornblendites, plagioclase (An₄₀₋₄₅) occurs in only a few hornblendites.

Felsic dykes, dykelets and veins, as well as epidote veins crosscut the hornblendites. The mineralogy of the felsic dykes and veins (hornblende- plagioclase (An₃₀₋₄₀) Quartz, epidote with or without garnet-biotite and rutile) is suggestive of metamorphism in the amphibolite-facies. However, retrogressive alteration accompanying shearing has led to the development of greenschist facies minerals (tremolite-actinolite-chlorite and secondary epidote).

The petrography of the ultramafites as well as the composition of the olivine (FO₈₉) and orthopyroxene (En₈₇) remain inconclusive regarding their petrogenetic affinity to one of the standard categories, i.e. alpine-, layered- or ring-complexes. They may represent an obducted slab of oceanic crust/upper mantle or a part of ultramafic rocks differentiated from a calc-alkaline or a basaltic magma. Most of the field and textural features suggest a metasomatic origin for the hornblendites generally at the expense of pyroxenites. They appear to have formed by the addition of H₂O, Al, Fe and (Ca) to the ultramafites. The metasomatism seems to have been synchronous with regional metamorphism and obduction of the ultramafites during the Early Tertiary.

Black shale, dolomitic limestone and chert are the predominant host rocks of the phosphorites occurring along Proterozoic Cambrian boundary in several parts of Asia. Detailed sampling along three stratigraphically measured sections in India, Iran and Mongolia and random samples from Hazara in Pakistan, provided the material for stable isotope analyses of carbon and oxygen in the carbonate, apatite and organic fractions of the phosphorite. A marked negative inflexion of data points at the base of Cambrian succession is coupled with an abrupt change to a positive excursion. Markedly light carbon isotopic shift can be related to the methanogenesis in the black-shale rich phosphorites. Carbonate hosted phosphorites are associated with bacterial degradation products and therefore are

heavier in their isotopic composition. This phenomenon is more or less consistent through all the sections in 4 different countries and show conformity with the results obtained from Greenland, Newfoundland and China.

B/81. Bangash, I.H., 1991. Petrology and geochemistry of the Southern Amphibolite Belt rocks from Mahak and surrounding area, Swat, Pakistan. M.Phil. Thesis, University of Peshawar.

The Mahak and surrounding area is located in the southern amphibolite belt of North, Pakistan. A detailed petrography and geochemistry of the Mahak area is presented. Rocks of the area are distinguished into amphibolite, Hornblendite, hornblende-pegmatite, diorites, metagabbros, metapyroxenites, and quartzo-felspathic veins and dykes. Amphibolites are the most abundant rocks of the area, and are distinguished into epidote-amphibolites, plagioclase-amphibolites, and epidote-plagioclase amphibolites. These are generally medium to coarse grained and consist of hornblende, plagioclase, epidote, clinopyroxene, orthopyroxene, sphene, quartz, ore, rutile, and chlorite. Hornblendites are usually monomineralic, but have a variable grain size. They are mainly composed of hornblende, cloudy plagioclase, epidote, chlorite, quartz, rutile and ore. Hornblende-pegmatites are coarse grained containing hornblende and plagioclase as dominant minerals, epidote, quartz, sphene, rutile and opaque minerals as accessories.

Key words: Petrology, geochemistry, amphibolites, Swat.

B/82. Banks, M.P., 1958. Rakaposhi climbed. Himalayan Journal, 21(6), 55p.

This is an account of the successful ascent of the Rakaposhi Range in the central Karakoram of Hunza. The expedition was conceived as a small but exacting experiment in international and inter-service co-operation. All the members were service officers and were drawn fairly equally from the Pakistan Army and the British Navy, Marines, Army and Air Force, making a total of nine climbers. Field-Marshal Sir Gerald W. R. Templer, G.C.B., G.C.M.G., K.B.E., D.S.O., Chief of the Imperial General Staff, and General Mohammad Ayub Khan, Commander-in-Chief of the Pakistan Army, lent their powerful support as joint Patrons; and the expedition committee was, appropriately, presided over by Major-General J. L. Moulton, C.B., D.S.O., O.B.E., Chief of Amphibious Warfare, and an officer of the Royal Marines.

The objective was the ascent of Rakaposhi, one of the unclimbed giants of the Karakoram Range. Rakaposhi has a long mountaineering history, closely associated with British climbers. In the dawn of Himalayan mountaineering, in 1892, Martin Conway (later Lord Conway of Allington) penetrated the Bagrot nulla to the south of the peak. The lower ramparts deterred him but he pronounced the upper mountain climbable. The peak lay unmolested until 1938 when two British climbers, Secord and Vyvyan, approached Rakaposhi from the West. They investigated the peak via the N.W. ridge but only attained a height of about 19,700 ft. The first determined attempt, which had some chance of success, was spearheaded by the celebrated 'Everester' H. W. Tilman in 1947. He was eventually turned back at about 19,000 ft. both on the N.W. ridge and on the S.W. spur. He regarded neither route as promising. In 1954, two expeditions had designs on Rakaposhi. An Austro-German expedition under Rebitch approached from the South but came to much the same conclusion as Conway had done sixty years earlier and they left the peak, dubbing it unclimbable from that direction as it most probably is. In the same season a Cambridge University expedition, under Tissi6res, and including Band who was on Everest in 1953 and was later to climb Kangchenjunga, again tried Tilman's routes. They discovered that the S.W. spur was the most hopeful line of approach and they reached about 20,800 ft. before their assault petered out through lack of impetus. The final 2,000 ft. of climbing had been up a great face of snow and ice called the Monk's Head. This was a most formidable obstacle, particularly for porters.

B/88. Bannert, D. & Raza, H.A., 1992. The segmentation of the Indo-Pakistan plate. Abstracts, First South Asia Geological Congress, Islamabad, p.7.

The Kirthar and Sulaiman ranges of western Pakistan and the Kohat and Potwar area adjacent to the northeast have been structurally analyzed using LANDSAT-MSS colour and black and white images at a scale of 1:250.000, literature studies, and a limited field survey. The pattern of tectonic deformation caused by the collision of the Indo-Pakistan Plate with the Eurasian plate have been analyzed. Tethyan oceanic crust covered by Triassic through Early Tertiary sediments, are preserved between the Eurasian Plate and the Indo-Pakistan Plate and called the Bela-Waziristan Ophiolite Zone. The oblique collision of the Indo-Pakistan Plate with the Eurasian Plate forced the Indo-Pakistan Plate to rotate in an anticlockwise mode. The collision further opened a number of basement faults that segmented the western part of the Indo-Pakistan Plate mostly on Pakistan territory -into several basement blocks, which were involved en-echelon in the collision. They are the Kirthar Basement Fault in the southwest, the Sulaiman Basement Fault, and the Jhelum Basement Fault in the northeast. The deformation of the sediments of the Indo-Pakistan Plate during the collision resulted in different tectonic patterns on the individual basement blocks.

B/89. Baqri, S.R.H., 1984. The Correlation of Khewra Sandstone (Salt Range) with a Cambrian Sandstone, exposed near Abbottabad, Hazara Division, North West Frontier Province, Pakistan. Kashmir Journal of Geology 2, 75-78.

The detailed lithological units of the Khewra Sandstone (Salt Range) and Tanakki-Sanghargali members have been compared for their probable correlation. The probable correlation of the Khewra Sandstone with the Tanakki-Sanghargali member indicates that the Khewra Sandstone extends as north as Riwat Rawalpindi in the subsurface. It is also inferred that the Khewra Sandstone is not localized in Salt Range only but extends regionally towards Abbottabad.

Key words: Stratigraphy, sandstone, Cambrian, Khewra, Hazara.

B/90. Baqri, S.R.H. & Dawood, H., 1995. The stratigraphic importance of Pasu Slates and Gujhal dolomite and their stratigraphic relations with the Baltit Group. Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, 22-23.

The south western flank of the Sost anticline displays the exposures of the Pasu Slates and Gujhal Dolomite in the Upper Hunza Valley which form the most prominent and distinct lithological features, representing rugged topography and high cliffs. The Pasu Slates and Gujhal Dolomite represent the same lithological units as Misgar Slates and Kilk formation, respectively, exposed on the north eastern flank of the Sost anticline. The basal and upper contacts of the Pasu Slates and Gujhal Dolomite were studied at several places such as Pasu, Dih, Sost etc. as it is very difficult to observe these contacts at one place due to severe tectonic activity in the area.

The Pasu Slates unconformably lie over the Pak China Friendship Formation (mainly quartzites with lenticular pebbles and gravels) and are conformably overlain by the Gujhal Dolomite. The Pasu Slates are dark grey to grey, flaggy, thin to medium bedded, thinly laminated, sandy, silty, more arenaceous towards base and more calcareous/marly with lenticular limestone beds towards its top. The slates display the random distribution of the perfect diagenetic crystals of pyrite, the size of which increases towards the base. The slates are about 2000m thick and have been assigned a Permian age due to the discovery of the products fossils in the Gircha Formation. The Gujhal Dolomite overlies conformably on the Pasu Slates and is unconformably overlain by the Shanoz Conglomerate. The Gujhal Dolomite is dirty yellowish grey to grey, lenticular bedded, massive bedded, occasionally argillaceous and display two beds of lenticular intraformational conglomerates, near the base and the middle of the formation. The dolomite is about 750 m thick at Pasu and has been assigned a Permian age.

The Pasu Slates and Gujhal Dolomite are severely folded, faulted, intruded mostly by acid igneous rocks and display generally faulted contacts. They occupy stratigraphically same position as the Baltit Group exposed in the lower Hunza Valley. These studies revealed that the Pasu Slates and the Gujhal Dolomites were comparatively highly metamorphosed into schists, gneisses and marbles (Baltit Group) around the older original intrusive backed contacts with the Karakoram batholith (Cretaceous) in the southern areas at lower Hunza Valley as compared to the younger thrust contacts of the Karakoram batholith with these formations in the northern side in the upper Hunza Valley (north west of Husaini Village).

B/91. Baqri, S.R.H., Javed, M., Ahmed, Z. & Haq, A., 1995. The X-ray diffraction and geochemical studies of the Hunza ruby and associated rocks. Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, 21-22.

The sample of the dark pinkish red ruby and its associated carbonate rocks (marbles) were collected from the ruby mine of Hunza, located on Karakoram Highway, near Aliabad. The X-ray diffraction and geochemical studies on the Hunza ruby and associated rocks were conducted to understand the influence of the mother solutions during the mineralization of Hunza rubies and the nature of the lattice parameters. The Hunza ruby displays perfect X-ray diffraction pattern giving all the important reflections and may be called a well crystallized precious gem variety. The mother solutions originated during the intrusion of the Karakoram batholith into the country rocks.

B/93. Baranowski, J., Armbruster, J., Seeber, L. & Molnar, P., 1984. Focal depths and fault plane solutions of earthquakes and active tectonics of the Himalaya. Journal of Geophysical Research 89, 6918-6928.

We have compared synthetic seismograms with long-period body waves for nine earthquakes with epicenters in the Himalayan arc to determine depths of foci and to improve fault plane solutions. Focal depths are shallow (10–20 km). Inferred slip vectors are locally perpendicular to the mountain range; they plunge very gently ($\square 10^\circ$ in the eastern sections of the range and more steeply ($\square 25^\circ$) in western sections. Assuming India to be a rigid plate, the radially oriented slip vectors imply that southern Tibet extends at about half the rate of underthrusting in the Himalaya and therefore probably at about 5–10 mm/yr. The shallow depths and gentle dips of the fault planes, at least for the events in the eastern half of the range, are consistent with coherent underthrusting of the Indian plate beneath, at least, the Lesser Himalaya. The steeper dips of fault planes in the western part of the arc might reflect deformation of the overriding thrust plate or simply a steepening of the main underthrusting zone beneath the Greater Himalaya.

B/94. Barbieri, M., Caggianelli, A., Di Florio, M.R. & Lorenzoni, S., 1994. Plagiogranites and gabbroic rocks from the Mingora ophiolitic melange, Swat valley, NW Frontier Province, Pakistan. *Mineralogical Magazine*, 58, 553-566.

Major, trace element composition and Sr isotopic data were collected for gabbroic rocks, plagiogranites and albitites in the ophiolite assemblage from Swat Valley (NW Frontier Province, Pakistan). Petrographic study revealed that these rocks were subjected to important structural and mineralogical modifications due to greenschist-epidote-amphibolite facies sub-sea-floor metamorphism and to brecciation. On the other hand, the examination of whole rock chemical composition and of chemical trends showed that these rocks were affected by some chemical modifications, concerning especially Na₂O, K₂O and Rb. The very low contents of HFS (high field strength) and RE elements found in gabbroic rocks and plagiogranites were considered to be a primary magmatic feature pointing in part to their cumulitic nature and in part to an origin from a refractory parental magma. The Sr isotopic data indicate that gabbroic rocks and plagiogranites were subjected to exchange-with sea water. The particular chemical features shared by gabbroic rocks and plagiogranites suggested that fractional crystallization was a possible evolution process. In contrast, albitites are characterized by anomalously high contents in HFSE and LREE and by values of the ⁸⁷Sr/⁸⁶Sr ratio very close to sea water. These features suggest a more complex origin with respect to gabbroic rocks and plagiogranites.

B/95. Bard, J.P., 1978. Initiation of intra–continental subduction in the Himalayas. *Journal of Geophysical Research*, 83(310), 4975–4987.

Independent arguments based on topographic stress and crustal strength give upper limits of 200 bars and 300 bars, respectively, for the average shear stress on the intracontinental thrust fault that formed the Himalaya. According to either a one-dimensional or a two-dimensional fault model, such stresses could not have produced the Himalayan granites by friction, unless overthrusting velocity exceeded 30 cm/yr. More probably, Himalayan metamorphism was caused by exposure of continental crust to hot asthenosphere prior to the formation of the intracontinental thrust. Crust was exposed by peeling away of Indian subcrustal lithosphere in response to the force and moment exerted by the Tethyan slab. This detachment of buoyant crust from dense lithosphere better explains the metamorphic pattern and also explains why the distributed crustal shortening at the beginning of the collision orogeny was replaced by localized thrusting or intracontinental subduction.

Key words: Intracontinental, subduction, Himalaya.

B/96. Bard, J.P., 1983a. Metamorphic evolution of an obducted island arc: example of the Kohistan sequence (Pakistan) in the Himalayan collided Range. *Geological Bulletin, University of Peshawar* 16, 105-184.

In the northern Pakistan, the extraordinary 40km thick Kohistan sequence of mafic, ultramafic and calc-alkaline layered plutonic and volcanic (mainly andesitic and rhyodacitic) rocks has been interpreted as the only complete vertical section of an intraoceanic island arc presently exposed anywhere in the world. Plate-scale models have been suggested to explain the origin and the tectonic evolution of this arc in the Himalayan collided range. Despite some

noticeable differences in the models, there is a general agreement that the Kohistan sequence represents the crust of an arc obducted onto the Indian plate before the Oligocene collision of India against Asia.

The purpose of the present paper is to give new data on the tectono-metamorphic evolution of the Kohistan sequence and to try to estimate its changing metamorphic conditions on petrological, mineralogical and crystal chemistry grounds. The structural, textural and mineralogical data suggest two main tectono-metamorphic events that have affected the Kohistan arc before late lower grade overprints. From various geothermometry estimates as well as from field zonations, it is concluded that the major (D1) phase developed with a thermal structure strongly controlled by thermal anomalies in the metamorphic pile. These anomalies seem centered around isolated bodies of two-pyroxenes and cpx-garnet granulites. Because the petrographical evidences indicate the latter are derived from large pre-tectonic layered calc-alkaline intrusion(s), the former anomalies are interpreted as remnant magmatic heat source(s) within the arc. This interpretation fits nicely with theoretical thermal models. Assuming D1 is contemporaneous with obduction of the arc and together with the geochronological data, it is suggested that the tectonic emplacement of the Kohistan arc was 20 ± 5 m.y. after the intrusion of enormous calc-alkaline pluton(s) within the arc crust. Such a relatively short elapsed time between a strong magmatic activity and a tectono-metamorphic event may explain why the T-P paths during D1 produced sinuous geotherms in the petrogenetic grid, i.e., the dT/dp are varying from $350^\circ\text{C} \pm 50^\circ\text{C}/\text{km}$ upto $1000^\circ\text{C}/\text{km}$ in the 40 km thick pile.

The second (D2) phase is contemporaneous with syn-kinematic low- to mid-grade retrogression upto the epidote-amphibolite facies conditions. The T – P curve during this phase is a classical one and the D2 geotherm approached $250^\circ\text{C} \pm 50^\circ\text{C}/\text{km}$ within a re-equilibrated thermal structure. Scarce geochronological data suggest the D2 was contemporaneous with the Oligocene collision of India against Asia and possibly synchronous with the Oligocene Barrovian metamorphism which has affected the Indian plate south of Kohistan. The origin of the rocks of the Kohistan granulites as well as the significance of a blueschist belt under the Kohistan metamorphic pile are briefly discussed.

Key words: Metamorphism, petrology, Kohistan.

B/97. Bard, J.P., 1983b. Metamorphism of an obducted island arc: example of the Kohistan sequence (Pakistan) in the Himalayan collided range. *Earth and Planetary Science Letters* 65, 133-144.

In northern Pakistan, the extraordinary 40-km-thick Kohistan sequence of metamorphosed mafic, ultramafic and calc-alkaline layered plutonic and volcanic (mainly andesitic to rhyodacitic) rocks has been recently reinterpreted as the only complete vertical section of an intra-oceanic island arc presently exposed anywhere in the world. Plate scale-models have been suggested to explain the origin and the tectonic evolution of this arc in the Himalayan collision range. Despite some noticeable differences in the models, there is general agreement that the Kohistan sequence represents the crust of an arc obducted onto the northern edge of the Indian plate before the Oligocene collision of India against Asia. New data on the tectonometamorphic evolution of the Kohistan sequence have led to the conclusion that a first major D1 event developed with increasing metamorphic grades oriented downward the Kohistan pile but also toward “ensandwiched” basic-ultrabasic granulitic rocks. Rare geochronological data and petrological evidence indicate that the latter granulites (pyroxenites and various plagiopyroxenites, pyroxenites, metatroctolites, metawebsterites, metadunites, etc.) were parts of enormous Lower to Middle Cretaceous layered calc-alkaline plutons emplaced during the arc-building stages. As the D1 metamorphic event is correlated with the Upper Cretaceous obduction process of the Kohistan onto India, it is proposed that the D1 thermal structure was strongly controlled by remnant magmatic heat source(s) within the obducted arc. This interpretation fits nicely with recent theoretical thermal models since the obduction of the arc was probably shortly after (10–20 Ma) the emplacement of the former plutonic arc rocks. A blueschist “tectonic mélange” underlying the obducted arc was possibly synchronous to the obduction and not clearly linked to the older subductive process. The Oligocene collision of India against Asia was associated with a Barrovian overprinting metamorphism in the Kohistan arc. During this second event the dynamo-thermal structure was much more classical and not controlled by the occurrence of the Cretaceous metaplutonic rocks. A tentative model of the thermal structures during the major events which affected the Kohistan arc is proposed.

This account describes the Indus suture mélange stretching from Kaghan to Shangla. It contains blueschists locally, such as those near Shangla. The high-pressure metamorphism is related to the suturing of the Indian plate and Kohistan island arc during the Late Cretaceous.

Key words: High-P metamorphism, blueschist, Indus suture, Himalaya.

B/99. Bard, J.P., Maluski, H., Matte, P. & Proust, F., 1980. The Kohistan sequence: crust and mantle of an obducted island arc. Geological Bulletin, University of Peshawar 13, 87-94.

The Kohistan sequence outcrops in the western part of the western Himalayan syntaxis. It is a thick pile (30-40km) of metamorphosed magmatic, volcanic and sedimentary rocks. It is composed of six main units i.e. from bottom to top: the southern amphibolite belt with basal ultramafics, the "pyroxene granulite" belt (10-15 km thick), the northern amphibolite belt, intruded by various dioritic bodies, a metasedimentary oceanic series (Kalam series), a volcanic calc-alkaline series (Utror Volcanics), up to 6-8 km thick, an upper detrital series (Yasin group, Lower Cretaceous). This sequence is interpreted as a complete cross-section of a mature island arc formed by subduction during Mesozoic in the southern part of the Neotethys and obducted onto the Indian plate in Upper Cretaceous time.

The magnetic polarity zonation of the terrestrial strata exposed in the Dhok Pathan area of Pakistan has been established utilizing data from 204 paleomagnetic sites. Individual magnetic transitions are traced laterally over 15 km and provide convenient time lines for correlating the fluvial facies of the middle Siwalik Group. A pervasive, normal polarity zone dominates throughout the region and has been interpreted as Magnetic Polarity Epoch 9. Based on this interpretation and using the absolute ages from the published magnetic time scales the average sedimentation rate in the area is calculated at 0.8 m/1000 years, and the average elapsed time between fluvial cycles is 56,000 years. Major sandstone units are minimally time transgressive in an east-west direction. The Nagri Formation in the Dhok Pathan area spans the time from 10.0 to 8.6 m.y. B.P. Ramapithecus and other hominoid primates are found in Epoch 9 at about 9 m.y.

B/105. Barry, J.C., 1980. Occurrence of a Hyaenodontine Creodont (Mammalia) in the Late Miocene of Pakistan. *Journal of Paleontology* 54, 1128-1131.

A recently discovered hyaenodontine mandible from the Nagri Formation of northeast-ern Pakistan extends the stratigraphic range of the Creodonta into a considerably younger geological period than previously known. An estimated age of eight to nine million years (N. M. Johnson, pers. comm.) makes this specimen two or three million years younger than the proviverrine *Dissopsalis carnifex* Pilgrim, previously the youngest known hyaenodontid (Pilbeam et al., 1977). By comparison hyaenodontids apparently became extinct in North America during the early Arikareean Land Mammal Age at approximately 27 million years (Macdonald, 1970; Mellet, 1977); in Europe during the middle Miocene (Helbing, 1925); and in Central Asia in the middle or late Oligocene (Mellet, 1968, 1977). In East Africa creodonts were still present in the middle Miocene, approximately 14 million years ago (Savage, 1965, 1978), while in North Africa a specimen was found in beds that may be as young as 12 million years (Savage, 1978; Cooke, 1978). By contrast in Pakistan there were at least four genera of hyaenodontids as recently as 12 million years ago. The recently discovered mandible was found in situ by Grant Meyer (then of the Yale A recently discovered hyaenodontine mandible from the Nagri Formation of northeast- ern Pakistan extends the stratigraphic range of the Creodonta into a considerably younger geological period than previously known. An estimated age of eight to nine million years (N. M. Johnson, pers. comm.) makes this specimen two or three million years younger than the proviverrine *Dissopsalis carnifex* Pilgrim, previously the youngest known hyaenodontid (Pilbeam et al., 1977). By comparison hyaenodontids apparently became extinct in North America during the early Arikareean Land Mammal Age at approximately 27 million years (Macdonald, 1970; Mellet, 1977); in Europe during the middle Miocene (Helbing, 1925); and in Central Asia in the middle or late Oligocene (Mellet, 1968, 1977). In East Africa creodonts were still present in the middle Miocene, approximately 14 million years ago (Savage, 1965, 1978), while in North Africa a specimen was found in beds that may be as young as 12 million years (Savage, 1978; Cooke, 1978). By contrast in Pakistan there were at least four genera of hyaenodontids as recently as 12 million years ago. The recently discovered mandible was found in situ by Grant Meyer (then of the Yale Peabody Museum) at Yale-Geological Survey of Pakistan locality Y311. Judging from the preservation of a delicate predepositional fracture on the ascending ramus there is little possibility the mandible has been reworked. Locality Y311 is one of the richest localities yet found by the Yale-GSP group and is undoubtedly the same locality from which many fossils of Pilgrim's "Nagri Stage" fauna came (Pilgrim, 1939). This locality has also been worked by Dehm and von Koenigswald (Pilbeam et al., 1977). Locality Y311 is located in the type section of the Nagri Formation near the village Sethi Nagri. The locality has been dated by paleomagnetic methods at between 9.7 and 8.3 million years (N. M. Johnson, pers. comm.). The fauna is highly varied and includes among the mammals *Sivapithecus indicus*, *Gigantopithecus* cf. *G. bilaspurensis*, *Percrocuta carnifex*, the small bovid *Elachistoceras khauristanensis* (Thomas, 1977), and *Hipparion* (s.l.), as well as a probable para- doxurine carnivore. Other mammal

groups still being studied include several suids and bovids, giraffes, anthracotheres, tragulids, rodents, rhinoceroses, and a deinother. At least one bird has also been recovered. The ecological affinities of this fauna are not clear.

B/112. Barry, J.C., Jacobs, L.L. & Kelley, J., 1986. An early middle Miocene catarrhine from Pakistan with comments on the dispersal of catarrhines into Eurasia. *Journal of Human Evolution*, 15 (6) 501-508.

An isolated catarrhine primate molar from the Kamlial Formation of northern Pakistan is shown by magnetic polarity stratigraphy to be 16.1 My old, making it the oldest securely dated catarrhine in Eurasia. It is most similar to small catarrhines from East Africa and China, particularly *Micropithecus* Fleagle and Simons, 1978, and *Dionysopithecus* Li, 1978. It is distinctly different from European pliopithecids, suggesting that the dispersal of catarrhines into Europe and Asia, while broadly contemporaneous, took place in the context of at least partly independent immigration events. In terms of morphology, the specimen sheds no more light on the ancestry of gibbons than do other small early Miocene catarrhines with a phenetic resemblance to gibbons. However, as part of the Siwalik Miocene provincial fauna which has clear affinities with the modern fauna of Southeast Asia, it is perhaps a more likely candidate for gibbon ancestry than other purported gibbon ancestors.

B/113. Barry, J.C., Johnson, N.M., Raza, S.M. & Jacobs, L.L., 1985. Neogene mammalian faunal change in southern Asia: correlations with climatic, tectonic and eustatic events. *Geology*, 13, 637-640.

The fluvial Neogene Siwalik formations of northern Pakistan span long time intervals with only minor hiatuses and, being highly fossiliferous, are uniquely suited for studies of change in mammalian faunas. Magnetostratigraphic correlations of a critical stratigraphic section give dates for 45 middle and late Miocene biostratigraphic events. These mark either first appearances or extinctions in the mammal fauna and show that in the Siwaliks there were major fauna turnovers at between 20 and 16 Ma and at 9.5 and 7.4 Ma. Two minor faunal events are dated at 13.2 and about 12 Ma. Many species making their first appearance were immigrants from Europe or Africa and indicate when connections to those regions existed. Immigration and extinction were the dominant modes of faunal change; in situ evolution was much less important. The Siwalik biostratigraphic record correlates closely to climatic, oceanographic, and tectonic events, which probably controlled immigration into southern Asia. Abiotic events were therefore important factors affecting evolution of the mammal communities.

B/114. Barry, J.C., Lindsay, E.H. & Jacobs, L.L., 1982. A Biostratigraphic zonation of the Middle and Upper Siwaliks of the Potwar Plateau of northern Pakistan. *Palaeogeography, Palaeoclimatology, Palaeoecology* 37, 95-130.

Two biostratigraphic reference sections are designated for the middle and upper Siwalik formations of northern Pakistan. The stratigraphic ranges of 41 mammalian taxa are established in the reference sections and the two sections are correlated to each other and to the standard Magnetic Polarity Time Scale by the magnetic-polarity stratigraphy. The resulting stratigraphic and magnetostratigraphic framework is used to define four contiguous biostratigraphic interval-zones. The proposed interval-zones are bounded by five important faunal events which are identified in the reference sections. The four proposed interval-zones and the approximate ages in the reference sections of their lower and upper boundaries are: (1) the "Hipparion s.l." Interval-Zone 7.4–9.5 m.y. B.P.; (2) the *Selenoportax lydekkeri* Interval-Zone 5.3–7.4 m.y. B.P.; (3) the *Hexaprotodon sivalensis* Interval-Zone 5.3-2.9 m.y. B.P.; and (4) the *Elephas planifrons* Interval-Zone 2.9-1.5 m.y. B.P. The paleomagnetic and biostratigraphic evidence indicates that the Tatrot Beds, from which Pilgrim developed his "Tatrot Faunal Zone", are between 2.5 and 3.4 m.y. B.P., with a preferred maximum age of 2.9 m.y. B.P. The biostratigraphic evidence indicates the Sethi Nagri locality (Y311)—the primary source of Pilgrim's "Nagri Faunal Zone"—is in the "Hipparion s.l." Interval-Zone. The paleomagnetic evidence suggests an approximate age of 9 m.y. B.P. A major faunal event at 9.5 m.y. B.P. introduced equids, suids, and large giraffes from Eurasia into the Indian subcontinent. A second, more diffuse faunal event between 5.3 and 2.9 m.y. B.P. introduced several African taxa as well as Eques and cervids from Eurasia.

B/115. Barry, J.C., Morgan, M.E., Flynn, L.J., Pilbeam, D., Jacobs, L.L., Lindsay, E.H., Raza, S.M. & Solouniass, N., 1995. Patterns of faunal turnover and diversity in the Neogene Siwaliks of northern Pakistan. *Palaeogeography, Palaeoclimatology, Palaeoecology* 115, 209-226.

The fluvial Neogene Siwalik formations of northern Pakistan contain a long and richly fossiliferous sequence of terrestrial vertebrate faunas in which patterns of faunal turnover and changes in diversity can be documented and analyzed for intervals having durations of 0.5 m.y. The complete sequence extends from circa 18.5 to 1 Ma, but the part between 18.5 and 5.5 Ma is best sampled, and most intervals within it are well represented.

Thirteen orders of Siwalik mammals have been identified, with well-sampled intervals having 50 or more species. Most Siwalik mammals, however, are either rodents or artiodactyls. Bovids are the most common and most speciose of the larger mammals, while murid and "cricetid" rodents dominate the small mammal assemblages.

Between 18.5 and 5.5 Ma species diversity varied considerably. Among artiodactyls and rodents the number of species first increased between 15 and 13 Ma and then fell. Data on stratigraphic ranges of rodents and artiodactyls show that faunal change in the Siwaliks was episodic, occurring during short intervals with high turnover followed by longer periods with considerably less change. Maxima of first appearances occurred at approximately 13.5 and 8.5 Ma, while maxima of last occurrences were at 12.5 and 8.0 Ma.

Some of the observed faunal events can be correlated to climatic and environmental changes. The Middle Miocene diversification occurred during a period of global cooling, while the latest Miocene decline in diversity and increased turnover accompanied oxygen and carbon isotopic changes that correlate to globally increasing seasonality and aridity. Other correlations are ambiguous. The marked decrease in diversity and the major turnover events between 13 and 8 Ma do not correspond to known local or global events.

The Neogene Siwaliks and Paleogene Bighorn-Crazy Mountains sequence in Wyoming and Montana share many similarities. They have equivalent levels of temporal resolution and similar levels of completeness of their fossil records. Siwalik ordinal abundance and diversity patterns differ markedly from those of the Paleogene, but generic, and probably species, diversity was approximately the same, although the Siwalik faunas may have been slightly less diverse. Over time, changes in diversity were of comparable magnitude, with monotonic trends persisting for more than 5 million years. The magnitude of faunal turnover was also similar, ranging from less than half to 3.5 times that expected. In both sequences faunal change appears to have been episodic, with strong pulses between intervals of low turnover. The Siwaliks, in contrast to the Paleogene sequence, may have had more distinct pulses and longer intervals between pulses. Neither sequence has peaks of first occurrences coinciding with peaks of last occurrences.

B/116. Barry, J.C., Morgan, M.E., Winkler, A.J., Flynn, L.J., Lindsay, E.H., Jacobs, L.L. & Pilbeam, D., 1991. Faunal interchange and Miocene terrestrial vertebrates of southern Asia. *Paleobiology*, 17, 231-245.

Problems of stratigraphic completeness and poor temporal resolution make analysis of faunal change in terrestrial sequences difficult. The fluvial Neogene Siwalik formations of India and Pakistan are an exception. They contain a long vertebrate record and have good chronostratigraphic control, making it possible to assess the influence of biotic interchange on Siwalik fossil communities. In Pakistan, the interval between 18 and 7 Ma has been most intensively studied and changes in diversity and relative abundance of ruminant artiodactyls and muroid rodents are documented with temporal resolution of 200,000 years. Within this interval, diversity varies considerably, including an abrupt rise in species number between 15 and 13 Ma, followed by a decline in ruminant diversity after 12 Ma and a decline in muroid diversity in two steps at 13 and 10 Ma. Significant changes in relative abundance of taxa include an increase in bovids between 16.5 and 15 Ma, a decrease in tragulids after 9 Ma, and a very abrupt increase in murids at 12 Ma. Megacricetodontine rodents also decrease significantly at 12 Ma, and smaller declines are recorded among myocricetodontine and copemyine rodents after 16 Ma. An increase of dendromurine rodents at 15.5 Ma is also observed. There is also a trend of progressive size increase among giraffoids and bovids throughout the sequence. We have also investigated relationships between biotic interchange and diversity, body size, and relative abundance, concluding that (1) the rapid increase in ruminant and muroid diversity was largely due to immigration, whereas in situ speciation had only a secondary role; (2) during intervals of increasing diversity, resident lineages did not have higher than average rates of in situ speciation; (3) during intervals with rising diversity, greater extinction did not accompany increased immigration; (4) during intervals with falling diversity, there may have been greater extinction in recently invading lineages; and (5) change in diversity was independent of changes in relative abundance and body size.

B/118. Bashir, M., 1992-93. Structure, stratigraphy, micropalaeontology and petrography of Jabri-Bodla areas Districts Haripur & Abbottabad, Hazara (NWFP), Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 78p.

The Jabri-Bodla area lies in the Attock-Hazara fold-and-thrust belt of the northwestern Himalaya of Pakistan. Precambrian to Cenozoic sedimentary rocks are folded and imbricated during the Tertiary-Himalayan collision. The oldest exposed stratigraphic unit is the Precambrian Hazara Formation. The formation is composed of slates, shales and phyllites. The presence of ripple marks and graded bedding shows that the Formation is deposited in shallow water turbidity environments. The Middle Jurassic Samana Suk Formation, Late Jurassic to Early Cretaceous Chichali Formation and Early Cretaceous Lumshiwal Formation were deposited in shallow marine conditions. The late Cretaceous Kawagarh Formation was deposited in deep to shallow water shelf environment. The late Cretaceous to Early Paleocene uplift in the area caused the regression of the Tethyan Sea. The Tethyan regression initiated the deposition of ferruginous sandstone of the Hangu Formation. The lower Tertiary sequence of Early to Late Paleocene Lockhart limestone, Late Paleocene Patala Formation, Early Eocene Margalla Hill Limestone and Early to Middle Eocene Chorgali formation mark the complete cycle of transgression and regression of the Tethyan Ocean. The presence of early Paleocene to Late Eocene foraminiferal assemblage like globorotalia, globogorina, lockharia, assilina and nummulites in the limestones and shales of the Lower Tertiary sequence show the tropical sub-tropical open sea upper slope to outer shelf environments. The Paleocene-Eocene boundary cannot be marked on the basis of microfossils in the area because the Patala Formation lacks microfossils. However, the tentative Paleocene-Eocene boundary between the Patala Formation and the Margalla Hill Limestone can be marked at the base of Margalla Hill Limestone on the basis of first appearance of Early Eocene microfossils.

The structural analysis of the investigated area shows that the Precambrian to Eocene rocks record at least two major events of deformations i.e D1 and D1 deformation phases. The D1 deformation is divided into D1a and D1b deformation phases. The D1a is associated with the southeast-directed thrusts and southeast vergent F1 folds. The second phase of D1b deformation is related with the backsteeping of the major thrusts and northwest overturning of the major F1 folds. The northwest plunging F2 cross-folds are recognized as D2 deformation phase in the project area. These F2 cross-folds are related with the development of the Hazara-Kashmir syntaxis.

B/120. Basit, M.A., Hasan, S.K., Fazil, M. & Ahmed, Z., 1990. Total chlorine in Pakistan coal. *Proceedings, First SEGMITE Conference on Industrial Minerals*, Peshawar, 88-91.

The contents of chlorine, moisture, ash, volatile matter, fixed carbon, total sulphur and calorific values (BTU/Lb) are determined in coals in various parts of Pakistan, and the chlorine content is compared with averages of the coals from USA (Illinois Basin, eastern USA and western USA) and worldwide average. Total chlorine content as chloride in Makerwal is 155 ppm and in Kotli 1936.6 ppm, which are much much higher than those of the USA and the world.

B/121. Basra, M.A., 1994-96. Geotechnical studies for land slide problems along Karakoram Highway from Danyor to Aliabad. M.Sc. Thesis, Punjab University, Lahore, 124p.

This thesis mainly composed of the study of about land sliding along Karakoram Highway from Danyor to Aliabad. A brief description of other Geotechnical features is also included in the thesis. The Geological map shows the different types of socks present in the project area.

Detailed study has been made in the project area to collect the data about discontinuities as joints, which play the dominant role in case of sliding in hard rocks. This data has been plotted on equal-area stereonet to check the stability of the slopes. In case of sliding in soft material like alluvial fan, samples were collected and tested for detailed analysis. Finally, on the basis of this analysis, the road is classified into stable, potentially unstable and unstable regions.

Key Words: Engineering geology, landslides, Hunza, KKH.

This is not a Pakistan specific paper. It deals with the evolution of the Carboniferous to Cretaceous rocks of the Tethyan domains along the periphery of the Indian shield.

Key words: Tectonics, Tethys, Carboniferous, Cretaceous, Indian shield.

B/123. Bates, R.H., 1986. The Ulugh Muztagh. American Alpine Journal 28, 27-38.

For me the long quest began in 1966 on the slopes of Mount Russell in the Alaska Range, where I shared a two-man tent with Eric Shipton. Adams Carter had invited me to join him on an expedition and now we were sheltering from a week-long storm that drove in from the coast. Finally, we looked at each other and yawned.

"Eric," I said, "if you were doing everything all over again, what would you change?"

"Well, I certainly wouldn't spend six years trying to climb Mount Everest. That's too long for any mountain."

"What would you have done instead?"

"Somehow I would have got to the Ulugh Muztagh."

"The Ulugh Muztagh? What's that?"

"It's a big mountain in Central Asia—nobody knows how high—reached in the 1890s by an Englishman who surveyed it as being well over 25,000 feet. It's probably the hardest place in the world to get to, harder than the Antarctic, because the land around it is so high and nobody lives near it. Bill Tilman and I had hoped to get there but it is too far in."

That was all I knew about the mountain for years, but in 1973 I found that Nick Clinch had also talked to Eric. In no time, Nick and I decided to become partners in a quest: to get to the mountain, find its height and climb it—and together we began to push ahead. First Betsy Clinch, Nick's wife, found an article by an Englishman, St. George Littledale, in an 1896 issue of the Geographical Journal of the Royal Geographical Society. Littledale, his wife, his terrier and his nephew ("of Oxford University boating renown") in 1895 had passed the Ulugh Muztagh and surveyed it while attempting to reach Lhasa from the north. The article had a map showing his route from the Southern Silk Road into Tibet, and told how after three weeks on horseback they had reached the "Great Ice Mountain" (Ulugh Muztagh in Turki). Our next success was securing publicly available satellite photos of the mountain, showing great glaciers flowing out from it, but what we could not secure was permission from the Chinese to let us go there. In the days before ping-pong diplomacy we even tried to get permission for a joint China-Pakistan-U.S.A. expedition, under Pakistan leadership, but the Chinese turned that down too.

In February, 1979 in Beijing, I again applied, this time in person to Mr. Shi Zhan Zhun of the Chinese Mountaineering Association, but learned that "the area is not yet open to foreigners"; and annually thereafter we continued to apply until late January, 1985 when we learned that our mountain had suddenly been made available to somebody else. At this, Nick Clinch rose from a sick bed, flew to Beijing and discussed our previous negotiations. To our delight the Chinese agreed that the permission should be ours, but the agreement was not finally signed until May 30, and that only after Nick had made two more visits to China.

During the three months that followed, Nick Clinch, an old pro at organizing expeditions, showed his usual skill. By September 11, when the eight members of the expedition left by air from San Francisco, we were what we called a

“geriatric expedition.” I had told Nick I was by now too old to be any use, but he insisted on my going. The real climbers, in addition to Nick, starting with the oldest, were Pete Schoening (in charge of equipment), Tom Hornbein (also our doctor), Jeff Foott and Dennis Hennek. Peter Molnar and Clark Burchfiel, distinguished geologists from M.I.T, both with wide experience in China and Tibet, completed the party. The Chinese were supposed to have twelve climbers, but by the time we had flown to Beijing and on to Urumchi (Woolamoochi) the number had grown to 16, with 27 support personnel, including 12 drivers, a cook, 4 geologists, a doctor, a radioman, photographers, reporters, and so forth. This joint mountaineering expedition was to be the first the Chinese shared with Americans. (They had had only one previous joint expedition, one with the Japanese a few months before.) Also, as our Chinese hosts kept telling us, we were the first foreigners to be allowed into the southern part of the Xinjiang since Chinese Turkestan became part of the People’s Republic 30 years ago. Celebration of that event explained the size of our Chinese team, for ascent of the Ulugh Muztagh was to be a major part of the celebration activities. Chinese climbers are all paid professionals, and naturally success on the mountain was to be of the greatest professional importance to our partners.

Burchfiel and Molnar were already in China when the other six of us took off from San Francisco on September 11. We had 87 bags or boxes with us, including identical personal equipment items for eight Americans and twelve Chinese. In Beijing we were warmly greeted by old friends of the Chinese Mountaineering Association, who gave us a splendid banquet. It was here that we met Governor Tehmer of the Xinjiang; Lu Ming, head of the All China Sports Federation of the Xinjiang and our expedition’s overall leader (though she would not go to the mountain); and Wang Zheng Hua, in charge of transportation to and from the mountain, and of all Chinese on the mountain. He had led the recent attempt on Namcha Barwa.

In Urumchi, which we reached by air, we were generously welcomed again. It was here that we agreed on the purposes of the expedition: to climb the mountain, find its height, and whether or not it is a volcano. If it were, it would be the world’s highest. At Urumchi too, we checked the condition of our survey instruments. These consisted of a satellite surveyor (a computer that uses the Doppler effect to establish latitude, longitude and altitude), a Uniranger electronic distance measuring device (borrowed from Bradford Washburn of the Boston Museum of Science), a 7-crystal cluster to use with it (loaned by Cubic Precision), and a Kern T-2 theodolite and tripod loaned by the Thompson School, University of New Hampshire. All were in good shape, but when we opened the box whose bill of lading declared it held the antenna for the satellite surveyor, we found only spare parts. Someone had goofed. We were to leave at dawn two days later on our 1,100-mile safari to the mountain. We were shocked. It looked as if it would now be impossible to find the height of our mountain, a major responsibility of the expedition.

I won’t go into detail about what happened, but some brilliant work on the part of someone in the company, and by the Chinese Mountaineering Association in Beijing and Urumchi, ended with a jeep chasing us, three men taking turns driving night and day, and catching us near the point where they could no longer follow.

The 1100-mile drive to the mountain in seven huge army trucks, three land-rovers and two jeeps was in many ways the most interesting part of the expedition, but hard travelling. It took ten days, including two days off to work on the vehicles. At Korla, where we expected to find a small town, we instead found a city of 120,000, with ten hospitals, a tire factory, a washing machine factory, and so on. Beyond it a yellow brick road led us to Rojeng, formerly Charklik, where Marco Polo had stopped many centuries ago and Sven Hedin had wintered at the turn of the last century. From here we continued along the north side of the Altyn Tagh Range, finally crossing it on a beautifully engineered road. We also crossed the great Altyn Tagh fault before reaching a big asbestos mine, our jumping-off point. Now we headed out across the roadless desert, finding hard going for the trucks. After a night in a game warden’s house, the last habitation, we pushed on to Acchikul Lake, 40 miles long, where we saw brown-headed seagulls, Orongo antelope, wild asses, a number of yaks, bears, a wolf and a fox. On the second of October, long after the first view of our handsome peak, we crossed an arid valley, forced our way up a canyon and set up our Base Camp tents on the east side of the mountain at what we later learned was over 17,400 feet. Burchfiel and Molnar learned that the Ulugh Muztagh strictly speaking is not a volcano, though it is a result of volcanic processes*.

Our plan at Urumchi had been to hold a sort of short training camp at Base, testing one another’s skills, learning to work together despite language difficulties and becoming acclimatized, but Wang Zheng Hua was anxious to get to work on the mountain. After a flag raising ceremony involving the entire group, with Pete Schoening carrying the American flag, three Chinese went off to reconnoiter. The Chinese had been on the mountain for the first time a year before, when they had made a brief attempt to climb it. Accordingly we followed their choice of route, though a more thorough reconnaissance would have improved it. Soon all climbers began packing to Camp I, with every man responsible for carrying his sleeping bag, personal gear and a good load of expedition equipment, for there were no porters. At age 74, I was no longer good at load carrying and I determined to focus entirely on the survey and try to be useful at Base Camp thereafter.

By October 9 Camp I was well established at the snout of a glacier, reached by a climb over a rounded foothill and a descent of several hundred feet; and shortly afterward loads began to be cached five or six miles up the glacier at what was to be Camp II. Peter Molnar and Clark Burchfiel now showed the advantage of their acclimatization, built up during the past summer's geological expedition. They began to help the other load carriers. Hennek, Foott and Tom Hornbein were carrying big loads but Pete Schoening was getting over some sort of flu (which Nick caught later) and Nick is slow to acclimatize. Tom, as our climbing leader, was also working out routes and the logistics of where food and equipment would be needed, and how much.

Meanwhile our survey was moving along. All equipment had survived the rough bouncing around, and the Doppler Satellite Surveyor had by now been moved to a site on the great outwash plain below our canyon and left running. From there, despite a furious wind, Molnar, Burchfiel, Schoening and I completed our theodolite work. Peter Molnar's final computations from observations at three points on our seven-mile baseline, allowing for curvature of the earth and the difference between geoid height and sea level height, gave us at a much later date a final figure of 6,987 meters $\pm$ 10 meters for the higher peak—roughly a disappointing 23,000 feet.

On the 12th, Pete Schoening felt better and left Base Camp for Camp I. From then on he and Tom Hornbein spearheaded the route above Camp II, which by now had been occupied. Next day Nick Clinch returned to Base Camp with a bad cold that had settled in his chest and seemed more like pneumonia. He was utterly exhausted when he arrived and looked very ill. On the 13th Tom, Pete Schoening and Clark Burchfiel began putting in ice screws to fix the route to Camp III, but the wind was very bad. Weather continued bad with some snow on the 14th and wind and cloud on the 15th, but Pete and Tom moved higher and established a cache at 6,200 meters. At Camp II the next morning there was nearly a meter depth of blown snow and no possibility of climbing. On the 17th several Chinese and Jeff and Dennis returned to Base to conserve food packed to Camp II. They told of big drifts at II and development of potential windslab danger. We woke to light snow on the 18th, but the weather cleared and Foott, Hennek and several Chinese took loads to Camp II.

All of us by now were worrying about whether the mountain would be climbed in the time left to us. On the morning of the 19th I went with Zhou Zheng and the Chinese geologists to see where two continents had met long, long ago. We saw a mass of serpentine rock that had been sea bottom at the time Gondwanaland had pushed into southern Asia millions of years ago and formed India. The sea bottom had been thrust northward over the region of the Himalayas and even over the Kun Lun to reach its present position. On our return, to our great surprise, Foott and Hennek appeared at Base Camp. They were to have been our summit team, but a major misunderstanding had developed about the number of Chinese climbers they could safely lead to Camp III and higher. Original plans had been changed. At this point Foott and Hennek came down to Base. Nick, now feeling stronger, pushed back up to Camp II the same day, and Tom Hornbein and Pete Schoening came down to II to try to sort out the confusion. This put them out of position for an immediate summit climb. Tom had been pushing himself very hard and was not feeling well, and so after a discussion at II he continued on down to Base Camp to recuperate. Next day, October 20, the weather was perfect and so the Chinese at Camp III moved up to Camp IV within easy striking distance of the summit. Since bad weather was still likely any day and we had such a short time left, we urged Wang Zeng Hua to tell his man at IV not to wait for Pete Schoening, who was returning to III with Burchfiel and Molnar, intending to go for the summit on the 22nd. The night of the 20th-21 st two Chinese photographers lost the route near Camp IV, and were not found and brought in—too cold to speak—until three A.M. The members of the assault party were searchers, and the effort took a good deal out of them. They did not leave Camp IV until after lunch and did not reach the summit until 7:28. When they radioed the good news to Base Camp there was pandemonium, but we were all concerned about their getting down. They were Hu Fengling, Zhang Baohua, Ardaxi, Mamuti and Wu Qiangxing.

Pete Schoening and his companions at Camp III did not get the news that evening. They went to bed early, planning an early start so as to climb the peak and return the same day. When they waked at dawn on a clear, cold morning, however, they saw that there had been an accident. A figure was lying unmoving on a snowfield far below, while another, who seemed hurt too, was trying to pull him. That changed everything. You can't go for a summit when injured men you can help may be dying. They went down.

They reached the injured men at about the same time Nick Clinch did, for three members of the five who climbed the mountain had arrived in Camp II late the night before, but two were missing, and he had gone out to look for them. All had come down by a different route from the one they had used to go up—and after sunset! Both injured climbers had had a 500-meter fall. One of them, Hu, looked so badly hurt that Clinch and Schoening thought he might not live until they reached Camp II, but later it was determined that despite multiple bruises his worst injury was having badly frozen feet. His companion was badly bruised too, but somewhat better. Hu's friend Guo, our interpreter, had reached Hu before anyone else, and soon four Chinese and four Americans combined efforts and were able to get the injured ones across the ice and up to Camp II.

There was now no chance for a second climb of the mountain and the following morning (the 23rd) everyone on the mountain began moving to Base. Hu had to be carried, a process painful for him and for his carriers, while his companion and a third Chinese who had also had a fall were able to limp down on their own. It took a long time to get everyone down. Some arrived after midnight and Hu and his carriers did not get in until nearly seven on the morning of the 24th. Dennis Hennek and Tom Hornbein did marvelous work caring for them as they came in. Our interpreter at this point was so moved by the care the Americans were taking of the Chinese that he remarked, "Americans must be the kindest people in the world."

On the 24th there was a great sorting and breaking camp, and next day after the Base Camp area was in large measure policed the long journey back began. It was far colder than when we had arrived, we were low on food and everyone was eager to get back. We drove straight to Acchikul Lake, stopping only to pick up a fuel cache, but stayed only long enough to gulp some quick-cooking noodles. It was dark now, but we all wanted to go on. Tom Hornbein and I, who rode in truck number six, will never forget that bumpy drive across the endless, snow-covered, deserted land, shining in the moonlight. Siberia can not be more desolate. At dawn we stopped for an hour or more at the warden's cabin, then continued our hard driving to Mangyai Chen, which we reached 27 hours after leaving Base Camp. We were here a day, then drove on to Ro-jeng, where eight pretty dancing girls cavorted ahead of us as we marched two or three hundred yards through streets lined with people. Banners crossed the street exhorting people to "follow the example of the joint (sic) expedition." If they followed our example at the huge banquet that followed, the price of melons, pear-apples and all sorts of their delicacies must have soared, for we were very hungry. That day we continued on to Army Camp 34, where we were welcomed by another delicious banquet, which ended at one o'clock in the morning. Then on again towards Korla. Some 20 or 30 kilometers before we reached the city we found Lu Ming, the marvelous Chinese woman who was the joint leader, waiting for us. She hugged us all, with tears running down her cheeks, saying again and again, "Oh, I was so worried about you." She told us of a celebration in Korla and she was right. Welcoming banners flew across the street and several thousand people lined the sides. Flashbulbs popped, firecrackers went rat-a-tat, big drums boomed, school children squealed, hollered or tootled horns, and pretty girls came up to pin rosettes on us and give us big bunches of artificial flowers. Heady stuff.

Then there was a further welcome at Urumchi, with Governor Tehmer, and the Party Secretary and others standing in the snow to greet us. Two days later came the big celebration. We put on the black suits and knitted red ties especially made for a magnificent victory banquet in the newly built Great Hall of the People. A whole roast sheep was wheeled in as a special expression of friendship, and Chinese and Americans ate, drank and danced together with a warmth and enthusiasm none of us will ever forget.

A few days later, after warm send-offs in Urumchi and Beijing, and still wearing our hats from Korla, we were on the way home. Long before our arrival, however, there had been a moment when Nick and I looked at each other, raised a glass and murmured, "To ERIC SHIPTON."

Measurement of the Altitude of Ulugh Muztagh

The altitude and position of the Ulugh Muztagh were much easier to determine in 1985 than they were in 1895 because of the extraordinary array of new surveying equipment that has been developed in recent years. The Magnavox Company leased the party its latest position-finding Geociever, the University of New Hampshire loaned one of its light but precise Kern T-2 theodolites, and Boston's Museum of Science loaned its Keuffel & Esser Uniranger electronic distance-measuring instrument.

Bob Bates, who was in charge of these observations, working closely with Bradford Washburn, made detailed surveying plans long in advance of the actual expedition, knowing with certainty that the peak was surrounded with a treeless desert which would make intervisibility of many survey stations extremely simple. Also the high desert atmosphere seemed to assure virtually perfect visibility (given good weather, which was rarely the case!).

Because the peak was too far from Base Camp to make a single direct electronic distance-measurement from there to its summit, it was planned to have three valley-survey-stations, arranged so as to have a precise baseline almost twice as long as the Uniranger's 5-mile limit. The summit of the peak was also definite enough so that it could be clearly identified from all three stations without the need for installing a target on top-extremely lucky in view of the problems later encountered by the climbers who actually got there.

Using the theodolite and the Uniranger, a basic triangle was established with all three points intervisible and with both of the summits of the Ulugh Muztagh also visible from all three. The composite baseline was 10,460 meters (6.5 miles) long, giving excellent strength to this little survey network. The distances to the summit from these stations were 22, 18 and 14 km. (13.6, 11.2 and 8.7 miles).

The Magnavox Geociever was used to determine the geographical location of this base network, observing Doppler signals resulting from scores of passes by five navigation satellites. Unremitting cold, wind and cloudiness, as well as the 18,000-foot altitude, made this otherwise relatively simple work both miserable and difficult.

The results of the Doppler observations were computed for the expedition by the Defense Mapping Agency in Washington and the triangulation network computed and balanced by Prof. Peter Molnar.

This field work determined the altitude of the highest peak of Ulugh Muztagh to be 6987 meters (22,923 feet) with an estimated possible error of ± 6 to 10 meters. This is compared with the Chinese determination of the peak's altitude to be 6970 meters (22,867 feet)—and Littledale's 1895 estimate of 7723 meters (25,338 feet). The geographical coordinates of the Base Camp are now considered to be North Latitude: $36^{\circ} 25' 09.2357$ East Longitude $87^{\circ} 29' 47.264$ ".

Although the long-fabled Ulugh Muztagh did not turn out to be nearly as high as everyone had hoped it would be, it is still indeed a fascinating mountain massif in the midst of some of the world's most exciting geology.

A detailed account of these observations may be found in the full report of the expedition which is on file at the Library of the American Alpine Club in New York City.

B/124. Baticci, G. & Poretti, G., 1988. Gravity models of the deep structures of the Karakorum Range. Abstracts, 4th Himalayan- Karakoram-Tibet Workshop, Lausanne, Switzerland, p. 8.

A gravimetric modeling of the Karakoram Range has been carried out taking into account all the geophysical data available. The regional behavior of the Bouger anomaly has been computed interpolating with 2nd order polynomial surface gravity data available in the area along the Hindu Kush and Karakoram mountain ranges.

Four two-dimensional orders have been considered along profiles crossing the Kohistan-Kashmir areas. The first along the 1978 DSS profile, runs from Nanga Parbat to Karakul in the USSR and takes into account the results of the seismic processing, establishing the possible average values of thickness and density for the upper crust underneath. The second model fits the residuals on the same profile and the remaining two on the profiles crossing the Kohistan island arc region. The modeling of the residual has been planned considering the geophysical and geological data available from surface observations and the surface measured and tabulated densities existing in recent literature.

These models fit reasonably well the field results for a discontinuity at 10-15 km depth. In order to get an acceptable regional model along the DSS profile, according to the data of seismic survey, it appears that the density of the upper crust must be higher than the standard 2.67 g/cm^3 value. The trend of the seismic layers fits the regional gravity anomalies with a density contrast of 2.25 gcm^3 between the upper and lower crust and 0.7 g/cm^3 between the lower and the upper mantle.

B/127. Baud, A., Atudorei, V. & Sharp, Z.D., 1996. Late Permian and Early Triassic evolution of the northern Indian margin carbon isotope and sequence stratigraphy. *Geodinamica Acta*, 9, 57-77.

The Northern part of Great-India underwent an early rifting phase in the late Paleozoic, just at the end of the large scale Gondwanian glaciation. The beginning of the rifting processes is marked by large hiatus and discontinuities (paraconformities) between the early or middle Paleozoic sedimentary succession and the discontinuous middle-late

Permian Traps and transgressive sediments. The Northern Indian passive margin consists of the present High and Lower Himalaya and a small part of the Indian craton and their sedimentary cover. The Permian rift shoulder is located in the Higher Himalaya, with part being in the underthrust Lower Himalaya. The rim basin landward of the shoulder) is well developed in the Pottawar -Salt Range area. From the rifting to the beginning of the drifting stages (early late Permian to late early Triassic time), the sedimentary evolution is characterized by three transgressive-regressive (T-R) second order cycles, two in the late Permian and one in the early Triassic. The break-up of the rift occurred during the second cycle (late Dzhulfian).

In the Salt Range area, these three T-R cycles have been subdivided in eight third order sequences, five sequences for the upper Permian and three for the lower Triassic.

At the end of Permian, hiatuses, gaps and local erosion of part of the margin are direct consequences of a first order relative sea-level fall; this is also the time of the largest extinction event of the Phanerozoic that deeply affected the carbonate productivity and the stratal patterns. With the following worldwide sea-level rise, a rapid and large scale transgression occurred in the early Triassic, well dated and recorded on the whole margin. High rate thermal subsidence gave way to generalized pelagic deposits about 2 My after the transgression.

Profiles of whole rock inorganic carbon and oxygen isotopes from Guryul Ravine and Palgham sections in Kashmir, Nammal Gorge and Landu sections in Trans Indus Ranges (Pakistan), Thini Chu section in Kali Gandaki Valley, Central Nepal are presented in connection with the sequence stratigraphic analysis. The upper Permian record of high positive $\delta^{13}\text{C}$ values are closely correlated with the second order T -R cycles and the third order sequences. The results presented in this study confirm the drastic drop of $\delta^{13}\text{C}$ from the high positive values that characterized the upper Permian to lower values in the lower Triassic time. Stratigraphic correlation problems in the lower Triassic using carbon isotope geochemistry are briefly discussed. A positive $\delta^{13}\text{C}$ excursion of 4-5‰ near the Smithian-Spathian substages boundary is observed for the first time.

The $\delta^{18}\text{O}$ values of samples from all the sections display major variations suggesting that the oxygen isotope record has been significantly affected by meteoric diagenesis, deep burial diagenesis or land monsoon signature.

B/128. Beck, R.A., 1995. Late Cretaceous ophiolite obduction and Paleocene India-Asia collision in the westernmost Himalaya. Ph.D. Thesis, University of Southern California, Los Angeles.

Some information from the thesis is extracted in the following two descriptions

Key words: Cretaceous, ophiolite obduction, collision, Himalaya.

B/129. Beck, R.A., Burbank, D.W. & Sercombe, W.J., 1995. Evidence for a very Late Cretaceous to Paleocene Collision between India and Asia: Paleogeographic, isotopic and climatic implications. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

The collision of India and Asia strongly influenced Cenozoic earth history. Decades ago it was argued that the Indian-Eurasian collision instigated not only the formation of the Himalaya, Karakoram and Tibet, but the wider deformation of Asia (Argand, 1924; Molnar and Tapponnier, 1975). Others have boldly suggested that the collision drove global plate reorganization (Patriat and Achache, 1984). Regardless of disagreements on the details, many would argue that the Indian-Eurasian collision was the most important tectonic event of the Cenozoic or even the latest Cretaceous (see Burchfiel and Royden (1991) for summary).

More recent research has suggested additional fundamental links between the Indian-Eurasian collision and the Earth's oceanic circulation patterns (Stille, 1992), global biogeochemical cycles and the isotopic record (Raymo and Ruddiman, 1992; Edmond, 1992); Paleogene global warming (Kerrick and Caldeira, 1993; Beck, et al., 1994), Neogene global cooling, (Selverstone and Gutzler, 1993; Raymo and Ruddimari, 1992) and evolution (Jaeger et al., 1989). However, knowledge of the kinematics and timing of collision at several points along the Indian-Eurasian suture zone is necessary before hypothetical links between the collision and global change may be evaluated. A growing body of evidence from terrestrial paleomagnetism and sea-floor magnetic anomaly studies (Besse et al., 1984; Chen et al., 1993; Besse and Courtillot, 1988; Klootwijk et al., 1992), paleontology (Jaeger et al., 1989), stratigraphy (Cassaigneau, 1979; Tapponnier et al., 1981; Burg and Chen, 1984; Beck et al., 1995; Einsele et al., in press), radioisotope chronologies of metamorphism (Chamberlain et al., 1995; Searle et al., 1988; Spencer, 1993;

Tonarini et al., 1993), marine oxygen isotopes (Kerrick and Caldeira, 1993) and marine carbon isotopes (Beck et al., 1994) indicates that the Neo-Tethys was at least locally closed (our definition of collision) before the end of the Paleocene.

Evidence from several areas along the Indian-Eurasian suture zone suggests that the collision may have been relatively synchronous (i.e. latest Cretaceous to Paleocene) from NW Pakistan to Tibet (Bossart and Ottiger, 1989; Searle et al., 1987; Searle et al., 1988; Gaetani and Garzanti, 1991; Gaetani et al., 1983; Garzanti and Critelli, 1993). Some diachrony is likely, but its magnitude is unknown along the Indus-Tsangpo suture north of the Higher Himalaya. Diagnostic evidence regarding the timing of collision is difficult to find (Beck et al., 1995). Therefore further research regarding the kinematics and timing of collision is needed along the entire length of the suture.

We summarize the broad paleogeographic, kinematic, isotopic, and climatic implications of a Paleocene collision for Paleogene earth history in the context of recent research in the Waziristan and Kurram tribal areas of Pakistan's Northwest Frontier Province (Figure 1) (Beck et al., 1995). A graphic summary of our provisional, composite, tectono-stratigraphy for the NW Indian-Eurasian suture zone is shown in Figure 2. It is remarkably similar to that of the Indus-Tsangpo suture zone north of the Higher Himalaya (Gansser, 1964; Thakur, 1981; Sinha and Upadhyay, 1990; Searle et al., 1988; Gaetani and Garzanti, 1991; Gaetani et al., 1983).

The most important paleogeographic implication of an early collision is that pre-collisional India extended farther to the north and/or pre-collisional Asia extended farther to the south (Powell and Conaghan, 1973; Besse, et al., 1984; Besse and Courtillot, 1988; Achache, et al., 1983; Chen et al., 1993; Klootwijk and Bingham, 1980; Treloar and Coward, 1991) (Figure 3). Because our data are from the westernmost Himalaya, we cannot preclude the existence of early Eocene back-arc basins or small remnant oceans similar to the modern Mediterranean in areas to the east or south of our study area. Regardless, closure of the Neo-Tethys at any point would stop deep, through going, Neo-Tethyan ocean circulation between India and Asia. Loss of this component of circulation influenced the eastern Atlantic Ocean as recorded by an increase in marine $^{143}\text{Nd}/^{143}\text{Nd}$ values (Stille, 1992).

While the deep Neo-Tethys was at least locally closed by collision during the latest Cretaceous and Paleocene, a flexural marine foreland basin (Wells, 1984) formed via tectonic loading in front of the arc fragment/prism/trench complex as it was thrust onto the NW Indian craton (Yeats and Hussain, 1987; Gaetani and Garzanti, 1991; Bossart and Ottiger, 1989; Beck et al., 1998). At least one during the Late Paleocene, erosion regionally beveled the allochthonous Asian rocks before upper Paleocene shallow marine limestones were deposited above them (Davies, 1926, 1940b, 1950). The marine foreland basin gradually filled during the latter early Eocene with lacustrine, evaporitic and fluvial sediments (Wells, 1984, Pivnik and Sercombe, 1993) before a late middle Eocene transgression drowned the foreland and resulted in the deposition of regionally extensive shallow marine limestones (Davies, 1926b, 1937b; Wells, 1984; Meissner et al., 1974, 1975).

We reanalyzed the stratigraphic and paleontological work of Davies (1926, 1940) in the light of plate tectonic theory and new biostratigraphic, lithologic and structural data from the Waziristan and Kurram tribal areas to provide a more rigorous chronology for the collision. Upper Paleocene and upper lower Eocene shallow marine limestones separate and date two discrete and significant phases of thrusting which transported parts of Eurasia onto India during the Paleogene (Beck et al., 1995). Our scenario is summarized in Figure 4. The unconformable upper Paleocene shallow marine limestones overlap deformed and eroded remnants of the prism/trench complex and Indian outer shelf/slope. Similar upper lower Eocene limestones higher in the sequence unequivocally tie the Asian rocks to the Indian craton before 49 Ma (Davies, 1926; Beck et al., 1995).

This refined timing for two major phases of collision (66-55.5 and 55.5-49 Ma), along the westernmost Indian-Eurasian suture, has larger implications regarding the Paleogene marine isotopic record and global climate change (Beck et al., 1994). The revised timing for collision is consistent with hypothetical mechanisms for well substantiated early Eocene global warming. One of the most provocative hypotheses is that of Kerrick and Caldeira (1992, 1993), which invokes the volatilization of carbonates during early Eocene Himalayan metamorphism. This hypothesis, in its purest form, might satisfy the marine oxygen isotopic record ($\delta^{18}\text{O}_{\text{carb}}$) (Douglas and Woodruff, 1981; Zachos, et al., 1992) via an increase in pCO_2 and sea surface temperature but would tend to shift marine carbon isotope values ($\delta^{13}\text{C}_{\text{carb}}$) in the wrong direction relative to what is observed (Beck et al., 1994) (Figure 5). Although the Kerrick and Caldeira hypothesis is not precluded by this observation it must be part of a larger system in which very large fluxes of ^{12}C -rich carbon entered the biosphere during the early Eocene (≈ 58 -54 Ma) (Shackleton, 1987).

In view of the constraints imposed by the marine stable carbon isotopic record (Shackleton, 1987) and what little is presently known about the timing of collision, we have formulated an alternative hypothesis which links the Indian-Eurasian collision, the $\delta^{13}\text{C}_{\text{carb}}$ and $\delta^{18}\text{O}_{\text{carb}}$ records, pCO_2 , and early Eocene global warming (Beck et al., 1994) (Figure 6). We suggest that ^{12}C -rich organic carbon exhumed from the active and passive margins during the collision was oxidized to CO_2 , which entered the biosphere. New data regarding the organic carbon content of the largely

eroded continental margins (Table 1) has allowed us to construct organic carbon budgets, reduced by the amount reburied in Paleogene Himalayan flysch (Table 2), which satisfy published mass balances based on $\delta^{13}\text{C}_{\text{carb}}$ values for the interval (Shackleton, 1987). These imbalances in the late Paleocene/early Eocene carbon cycle exceed some published thresholds considered necessary for climate change by up to three orders of magnitude (Selverstone and Gutzler, 1993). Thus, our collisional organic carbon exhumation hypothesis might explain the rapid Paleocene-Eocene decline in $\delta^{13}\text{C}_{\text{carb}}$ values, contemporaneous global warming (Wolfe, 1990) and decreasing $\delta^{18}\text{O}_{\text{carb}}$ values.

If one considers the carbon and oxygen isotopic record of benthic foraminifera ($\delta^{18}\text{O}_{\text{benthic}}$ and $\delta^{13}\text{C}_{\text{benthic}}$) (Zachos et al., 1993) rather than bulk carbonates values ($\delta^{18}\text{O}_{\text{carb}}$ and $\delta^{13}\text{C}_{\text{carb}}$) (Shackleton, 1987), it might be argued that $\delta^{18}\text{O}_{\text{benthic}}$ values began to decline up to a million years before $\delta^{13}\text{C}_{\text{benthic}}$ values. This relationship implies that organic carbon exhumation was not the only mechanism involved Paleogene global warming. Given the complex network of feedbacks within the Earth's biogeochemical system, this is not surprising. The net climate signal is the sum of many processes (Raymo and Ruddiman, 1992). Some of these processes may have had little or nothing to do with the Indian-Eurasian collision.

Nevertheless, in view of the new evidence, which indicates at least part of the collision occurred between 66 and 55.5 Ma, it is tempting to consider other tectonic-climatic mechanisms. The first, which comes to mind is a decline of (rather than an end to) Trans-Himalayan volcanism and the production of sulfate aerosols. Sulfate aerosols are powerful cooling agents (Rampino and Self, 1991): one volcanic eruption can cool the Earth's atmosphere by 3-5°C for several years by reflecting a portion of incoming solar radiation (the "Pinatubo effect").

This hypothetical late Paleocene increase in global temperature due to a decrease in the "Pinatubo effect" is supported by existing geochronologic data. For example, volcanism in the Baluchistan-Afghan sector of the Trans-Himalayan arc declined markedly at 66 Ma with a few areas experiencing volcanism until 55 Ma (Debon et al., 1987; Wolfart and Wittekindt, 1980). Isotopic cooling ages indicate that magmatism in the Trans-Himalayan Batholith and Arc of what is now northern India and Tibet slowed between 60-50 Ma (Searle et al., 1988).

Deposition of the wide spread upper lower and lower middle Eocene "nummulitic" Tethyan limestones may have damped contemporaneous global temperatures through the storage of CO_2 as carbonate (Kerrick and Caldeira, 1993). Large quantities of organic carbon were contemporaneously sequestered in the Laramide basins of western North America and elsewhere, drawing down pCO_2 , and driving $\delta^{13}\text{C}_{\text{carb}}$ values upward. This phase of Rocky Mountain deformation may have been due in part to a global plate reorganization triggered by the Indian-Eurasian collision (Patriat and Achache, 1984). Further cooling of the Cenozoic Earth during the late Paleogene and Neogene could have proceeded due to deep subduction of carbon in the Alpine-Himalayan orogen (Selverstone and Gutzler, 1993) and/or the weathering of calcium silicates in the metamorphic core of the Himalaya and fertilization of the oceans during the Neogene according to the "Raymo hypothesis" (Raymo et al., 1988).

We hypothesize that the Indian-Eurasian collision may have been the dominant driver of the Earth's long-term (>1 My) climate throughout the entire Cenozoic by the following means: 1) Between 66 and 58 Ma the collision may have passively warmed the earth by extinguishing at least some explosive arc volcanism thus decreasing the "Pinatubo effect"; 2) From 58 to 54 Ma $\delta^{18}\text{O}_{\text{benthic}}$ and $\delta^{13}\text{C}_{\text{benthic}}$ values decreased and imply that the rate of net organic carbon burial decreased (Shackleton, 1987; Zachos et al., 1993) which suggests that the collision may have actively warmed the earth further by exhuming organic carbon from the colliding continental margins and increased the greenhouse effect (Beck et al., 1994); 3) From 54 to 52 Ma $\delta^{18}\text{O}_{\text{benthic}}$ and $\delta^{13}\text{C}_{\text{benthic}}$ values increased and imply that the rate of net organic carbon burial increased (Shackleton, 1987; Zachos et al., 1993) possibly due to deposition in the Himalayan foreland (Wells, 1984; Bossart and Ottiger, 1989; Burbank, et al., 1995) or other basins created by the collision; 4) From 52 to 48 Ma $\delta^{18}\text{O}_{\text{benthic}}$ and $\delta^{13}\text{C}_{\text{benthic}}$ values were relatively stable and suggest that carbon storage in upper lower and middle Eocene Tethyan "nummulitic" carbonates and shales (Kerrick and Caldeira, 1993) and to a lesser degree subducted eclogitic rocks (Selverstone and Gutzler, 1993) may have set the stage for Neogene global cooling; 5) From 48 Ma to 38 Ma $\delta^{18}\text{O}_{\text{benthic}}$ values steadily increased while $\delta^{13}\text{C}_{\text{benthic}}$ values remained relatively constant and suggest that cooling was driven by modest rates of calcsilicate weathering rather than organic carbon burial (e.g. Raymo, 1994); 6) From 38 Ma to <20 Ma $\delta^{18}\text{O}_{\text{benthic}}$ values generally exceeded $\delta^{13}\text{C}_{\text{benthic}}$ values and suggest that carbon was sequestered as carbonate because of high rates of calcsilicate weathering in the core of the Himalaya ("Raymo hypothesis") (see Edmond, 1992; Raymo, 1994), and to a lesser degree, as organic carbon (the "Monterey hypothesis" of Vincent and Berger, 1985; see Raymo, 1994).

Obviously some of these mechanisms overlapped in time and some acted in opposite directions with respect to the Earth's isotopic record and climate. However, it is the relative size of the associated chemical fluxes, which is important with respect to the Earth's long-term biogeochemistry (Berner, 1991; Edmond, in press; Edmond, 1992;

Raymo and Ruddiman, 1992; Raymo, 1994). Although the Indian-Eurasian collision was not the only event of the Cenozoic, its timing, magnitude and numerous interactions with the rest of the present lithosphere and biosphere, indicate that the hypotheses recounted above must be explored further in order to understand the long-term global context of the Himalaya, Karakoram, and Tibet.

B/130. Beck, R.A., Burbank, D.W., Sercombe, W.J., Khan, A.M. & Lawrence, R.D., 1996. Late Cretaceous ophiolitic obduction and Paleocene India–Asia Collision in the westernmost Himalaya. *Geodynamica Acta*, 9, 114–144.

Collision of the Kohistan island arc with Asia at similar to 100 Ma resulted in N-S compression within the NeoTethys at a spreading center north of the Indo-Pakistani craton. Subsequent India-Asia convergence converted the Neo-Tethyan spreading center into a short-lived subduction zone. The hanging wall of the subduction zone became the Waziristan, Khost and Jalalabad igneous complexes. During the Santonian-Campanian (late Cretaceous), thrusting of the NW Indo-Pakistani craton beneath Albian oceanic crust and Cenomanian volcano-sedimentary complex, generated an ophiolite-radiolarite belt. Ophiolite obduction resulted in tectonic loading and flexural subsidence of the NW Indian margin and sub-CCD deposition of shelf-derived olistostromes and turbidites in the foredeep. Campanian-Maastrichtian calciclastic and siliciclastic sediment gravity flows derived from both margins filled the foredeep as a huge allochthon of Triassic-Jurassic rise and slope strata was thrust ahead of the ophiolites onto the Indo-Pakistani craton. Shallow to intermediate marine strata covered the foredeep during the late Maastrichtian. As ophiolite obduction neared completion during the Maastrichtian, the majority of India-Asia convergence was accommodated along the southern margin of Asia. During the Paleocene, India was thrust beneath a second allochthon that included open marine middle Maastrichtian colored melange which represents the Asian Makran-Indus-Tsangpo accretionary prism. Laterites that formed on the eroded ophiolites and structurally higher colored melange during the Paleocene were unconformably overlapped by upper Paleocene and Middle Eocene shallow marine limestone and shale that delineate distinct episodes of Paleocene collisional and Early Eocene post-collisional deformation.

Stratigraphic evidence for an early collision between northwest India and Asia. *Nature* 373, 55-58.

The collision of India with Asia had a profound influence on late Cretaceous and Cenozoic oceanography, climate, fauna extinctions and the motion of at least some of the Earth's lithospheric plates. As the collision ended a period of rapid Indo-Asian convergence, a precise knowledge of its timing (when the crust of the neo-Tethys ocean was completely subducted, at some point along the plate boundary) is important for understanding its wider consequences. But current estimates of the collision age range from 65 to 38 Myr before present⁶, 8–11. Here we report the results of extensive biostratigraphic analyses from Waziristan and Kurram in northwest Pakistan, which show that accretionary-prism and trench strata were first thrust onto the northwest Indian passive margin after 66 Myr but before 55.5 Myr. After this time, volcanic-arc fragments, the accretionary prism, trench material and imbricates of the north Indian slope were raised to shallow water depths and overlapped by upper Palaeocene shallow-water carbonates and shales^{12–14}, indicative of post-collision thrusting in this region. Finally, both the suture and the Indian craton were overlapped by continuous unconformable upper Lower Eocene shallow-marine strata, demonstrating that suturing was complete by 49 Myr.

B/138. Beg, M.I. & Awan, A.Q., 1971. Statistical properties and petrography of the Misri Banda quartzite, Nowshera Tehsil, NWFP Geological Bulletin University of Peshawar 6, 82-89.

This paper presents the statistical properties and petrography of the Devonian and Carboniferous Misri Banda Quartzite. It occurs interbedded and overlying the Nowshera Formation of Siluro-Devonian reef complex. The statistical analyses show that most of the quartzite samples fall in the well-sorted range and are unimodal in their distribution. The size frequency curves show maximum sorting towards the coarse grades and skewness towards finer grades. Kurtosis values of size distribution range between 0.27 and 0.24.

Microscopic examination of several slides reveals that quartz grains, embedded in a carbonate matrix, are elongated with their longer axis being parallel to each other and to the longer dimensions of calcite/dolomite grains. Well-rounded grains of zircon, tourmaline, and other heavy minerals are present in lesser amounts. The high degree of textural and mineralogical maturity of the Misri Banda Quartzite and its association with the reef carbonates indicate a long history of transportation, reworking, and winnowing in shallow waters dominated by stable shelf environments. Statistical data, heavy mineral distribution, and field observations indicate that the Misri Banda Quartzite conformably overlying the Nowshera Formation and beds and stringers of quartzite, occurring interbedded with the reef carbonates are one and the same derived from a common source.

B/142. Behrensmeyer, A.K. & Tauxe, L., 1982. Isochronous fluvial systems in Miocene deposits of northern Pakistan. *Sedimentology* 29, 331-352

A Palaeomagnetic isochron dated at about 8.1 Myr BP and detailed lithostratigraph of a 40 m interval exposed along strike for 40 km establish the depositional patterns of two contemporaneous, interfingering fluvial systems in the upper part of the Middle Siwalik sequence.

The two systems, referred to as the buff and blue-grey, differ in unit shape, lithofacies, bedding sequence, palaeocurrent direction and sand composition. Interfingering occurs along the south-west-north-east strike of the outcrops, with the palaeodrainage directions of the two systems generally perpendicular to this line. The axis of the blue-grey system, which deposited widespread sheet sands and silts, lay toward the south west end of the study area. The more complex axis of the buff system, which deposited shoe-string sand bodies and large volumes of silt and clay, lay toward the north-east. The source area for both systems was the rising Himalayan belt to the north and north-east of the study area. At maximum extent the blue-grey system occupied a channel belt at least 25 km wide. Channel belt widths and depths for the buff system are 1–3 km and 3–7 m, respectively. Current directions average 94° for blue-grey sands and 136° for buff sands. Blue-grey sands contain 20% more rock fragments and are otherwise less mature than buff sands.

The buff system shows a vertical pattern of avulsion, palaeosol formation and floodplain aggradation which we attribute to autocyclic processes of parallel rivers. The blue-grey system shows phases of erosion accompanied laterally by palaeosol formation, followed by valley fill and overflowing of interfluvial surfaces. This pattern may be caused by allocyclic processes affecting the source area. We interpret the blue-grey system as a major drainage from the interior Himalayas (perhaps the ancestral Indus) and the buff system as a complex of smaller drainages along the mountain front which were probably tributaries to the bluegrey system.

Vertebrate fossils including hominoid primates from the area are almost exclusively associated with lithofacies of the buff system, and this probably reflects both taphonomic and palaeoecological differences between the two systems.

B/143. Behrensmeyer, A.K., Willis, B.J. & Quade, J., 1995. Flood plains and paleosols of Pakistan Neogene and Wyoming Paleogene deposits - A comparative study. *Palaeogeography, Palaeoclimatology, Paleoecology* 115, 37-60.

Comparative study of fossil-bearing fluvial deposits in the Eocene Willwood Formation of northern Wyoming and the Miocene Chinji Formation of northern Pakistan indicate how tectonic and climatic processes operating at

different scales controlled physical and chemical features of floodplain environments and affected preservation of the paleontological record.

The architecture of Willwood Fm. floodplain deposits represents a combination of avulsion-belt sediment packages and overbank sediments that formed alluvial ridges. The architecture of the Chinji Fm. floodplain deposits was controlled by widely distributed crevasse-splay deposition and floodplain topography. Similarities in individual paleosol-bounded overbank sequences from the two formations indicates that the internal structure of such deposits can be independent of channel belt proximity to areas of aggradation. Chinji Fm. paleosols have little vertical zonation and show no consistent pattern of lateral change in relation to major channels, while overbank paleosols in the Willwood Fm, exhibit considerable soil horizon development and a pattern of increasing maturity from alluvial ridge to distal floodplain. The “pedofacies model” of Bown and Kraus (1987) based on such lateral trends in the Willwood paleosols is not applicable to the Chinji Fm.

Plant and animal fossils are abundant in the Willwood overbank deposits, with vertebrate remains concentrated in paleosol A horizons. Plant remains are rare in the Chinji Fm. and vertebrate fossils occur primarily in channel fills rather than in paleosols. These differences relate to contrasting patterns of floodplain deposition and to levels of oxidation that controlled penecontemporaneous recycling of organic material, particularly in paleosols. Different large-scale climatic and tectonic controls on temperature and rainfall, water table fluctuations, and soil biota are proposed to account for the differences in organic preservation. Large and small-scale environmental processes also affected spatial and temporal resolution of the organic record, resulting in important differences in the paleoecological and evolutionary information that can be reconstructed from the two sequences.

Geodetic Surveys in the Pakistan Baltistan and new measurement of the height of Mount K-2. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, p.11.

In July-August 1996 GPS measurements along the profile from Skardu to Askole and to the K-2 Base Camp were performed. Along the route gravity and deflections of the vertical were measured. In the K-2 Base Camp Area, across the Godwin Austen glacier a topographic network was established with points on bedrock and on the moving glacier surface. A tripod with a sight target and two reflecting primes was installed at the top of K-2 in order to measure angles and distances from the points of the base network to the summit. Meteorologic observations were performed to determine the atmospheric refraction coefficient. Taking into account the movements of the glacier it was possible to link the summit of Mount K-2 to the trigonometric network of Pakistan improving the accuracy of the height of the mountain compared with the past measurements.

Structure of the lithosphere along the deep seismic sounding profile: Tien Shan-Pamirs-Karakoram-Himalayas. *Tectonophysics* 70, 193-221.

During 1973–1977, as part of the International Geodynamic Project, some seismic investigations of the Earth's crust have been carried out by geotraverses of the Tien Shan-Pamirs-Karakorum-Himalayas. The seismic data obtained together with other geophysical information, allow the construction and interpretation of the lithospheric section through the Pamirs-Himalayas structure. This section includes thick crust with complex layering, supra-asthenospheric and asthenospheric layers of the upper mantle. The thickness of the Earth's crust increases from 50–55 km in the north, in the Ferghana depression (Tien Shan), to 70–75 km in the south, near the Karakul Lake (Northern Pamir). It varies within 60–65 km for the Central and Southern Pamir, Karakorum and the Inner Himalayas. Its thickness is least (35–37 km) in the south, under the outer margin of the Himalayan foredeep. Extreme gravity minima and depressions on the geoid surface correspond to the regions with maximum thickness of the Earth's crust. The centers of the disturbing masses on the geoid surface are located in the vicinity of the asthenosphere's upper layer; this determines the effect of the whole lithospheric layer, including its asthenospheric layer, at intense changes of gravity anomalies. The asthenospheric upper layer is recorded at a depth of about 120 km, its base at a depth of 200 km, in the northern and southern regions, and 300 km in its central part (Southern Pamir, Karakorum). In the middle asthenospheric layer, wave velocities decrease to 7.5 km/sec, under the base they increase to 8.4 km/sec and reach 9.4 km/sec at a depth of about 400 km. In the supra-asthenospheric layer of the upper mantle, longitudinal and shear wave-velocities slightly increase (by less than 0.1 km/sec) towards its base.

This region comprises very high mountains, adjacent to which are depressions where crustal blocks have sunk to great depth. The region is characterized by very high heat flow negative gravity anomaly, and high seismic activity. The gravity field of the traverse reflects the zoning of the geological structure of the upper crust. The principal role in the development of deep gravity anomalies is played by the Moho interface, and only to a small degree by the upper mantle inhomogeneity. The seismicity of the lithosphere in the region is controlled by geodynamic processes

that are manifested in its upper part by crustal block movements, and in the lower lithosphere by displacement of steeply dipping mantle blocks. The region has high seismicity originating in the intermediate part of the Earth's crust.

All these facts show that geodynamic processes that occur at depth under the Pamir-Himalaya are complicated. The upper mantle has a low density. In the Pamirs, considerable upwelling of the anomalously heated material from the Earth's deep parts is quite possible. This heated material might move NW-ward to the Pamirs and Tien Shan along the "weak zones" asthenospheric channels. It is along this direction that tensile stresses in the earthquake source show a horizontal alignment. Fields of intensive stresses of mechanical and thermal origin may concentrate above such regions and particularly along their periphery, and their release may result in intensification of seismic activity.

Key words: Geophysics, structure, lithosphere, Tien Shan, Pamirs, Karakoram, Himalaya.

B/152. Belyaevsky, N.A., 1965a. Main feature of the geology of Karakorum (translated from Russian). *International Geological Review* 8, 127-143.

There have been several publications in Russian literature on the transect from Tien Shan and Pamir to Himalaya, through the Karakoram – Hindukush ranges. This paper gives a summary of the geological contributions on the geology of the Karakorum range.

Key words: Geology, Karakoram.

B/153. Belyaevsky, N.A., 1965b. Major Geological features of Karakorum. *Soviet Geology* 1, 54–75 (in Russian).

This document is not very different from Russian version of Belyaevsky 1965a.

B/155. Bender, F.K. & Kazmi, A.H., 1995. Non-metallic raw materials. In: Bender, F.K., & Raza, H.A. (Eds.), *Geology of Pakistan*. Gebrüder Borntraeger, Berlin, 258-281.

The book, *Geology of Pakistan*, comprises papers on various aspects of geology of Pakistan. This particular paper deals with non-metallic minerals of the country. As can be seen, Pakistan is endowed with a fair number of non-metallic mineral occurrences.

Key words: Mineral deposits, raw material, non-metallic.

B/156. Bender, F.K. & Raza, H.A. (Eds.), 1995. *The geology of Pakistan*. Beihefte zur regionalen geologie der Erdd. Band 25, Berlin, Stuttgart: Gebrüder Borntraeger, 414p.

This wonderfully done book is the first of its kind on the geology of Pakistan. It contains chapters by ten different authors. Following General introduction (Chapter 1: Raza and Bender); it covers Geological framework (Chapter 2: Bender, D. Bannert, Raza & F.A. Shams); Sedimentary sequence (Chapter 3: A.H. Kazmi); Igneous and metamorphic rocks (Chapter 4: Shams); Tectonics and structure (Chapter 5: Bender, Shams and Bannert); Palaeogeographic and geodynamics evolution (Chapter 6: Bender and Bannert); Energy resources (Chapter 7: Raza, Bender, H. Porth, Kazmi, Shams, F. Barthel and H. Fohse); Metallic raw materials (Chapter 8: Shams); Non-metallic raw materials (Chapter 9: Bender and Kazmi); Water (Chapter 10: Bender); Soils (Chapter 11: F.H. Gurneberg). There is an extensive bibliography spread over 53 pages, and includes papers published up to 1992. The volume is accompanied by three sheets of a wonderfully drafted geological map on a scale of 1:500,000 covering the western fold belt. The book is nicely illustrated with 140 figures, 38 tables and ten foldouts (some colored).

Key words: Bibliography, tectonics, paleogeography, mineral resources, water, hydrocarbons.

B/157. Benn, D.I. & Owen, L.A., 1998. The role of the Indian summer monsoon and the mid-latitude westerlies in Himalayan glaciation: review and speculative discussion. *Journal of the Geological Society, London* 155, 353-363.

New dates for late Quaternary glaciations in the Himalayas show that, during the last glacial cycle, glaciations were not synchronous throughout the region. Rather, in some areas glaciers reached their maxima at the global glacial maximum of c. 18–20 ka bp, whereas in others glaciers were most extensive at c. 60–30 ka bp. Comparison of these data with palaeoclimatic records from adjacent regions suggest that, on millennial timescales, Himalayan glacier fluctuations are controlled by variations in both the South Asian monsoon and the mid-latitude westerlies.

Tangir covers 351-km² area located between Kohistan in the South and Yasin in the North. According to plate tectonic concept it lies in between Indo-Pakistan and Eurasian plates comprising a part of Kohistan Island Arc. The particular project area is mapped on a scale of 1:62500. In the thesis, an attempt is made to introduce the detailed Geology of the above area. Bulk geological sequence of the area is consisted of Norite, Diorite, Amphibolite, Granodiorite and Granite which is obducted on to the Paleozoic rocks of Indo-Pakistan plate in the south and subducted under the Eurasian plate towards the North. The Northern part of the area is in contact with Yasin Group, which is volcanic. So Tangir area constitutes the lower sequence of Kohistan Complex.

B/172. Bhatti, N.A., 1983a. Chronostratigraphic position of Panjal Formation in Azad Kashmir: A stratigraphic discrepancy. *Kashmir Journal of Geology* 1, 117-118.

Reported occurrence of Permo-Carboniferous fauna from the Panjal Formation and an interbedded nature of the Panjal Formation within Sirban Formation of Cambrian age in Azad Kashmir is in discrepancy. This is only explainable in the event of two isolated phases of volcanic activity. However, re-examination of the contact relationship between the two units-the Panjal Formation and Sirban Formation may finally clarify this discrepancy.

Key words: Stratigraphy, Panjal Formation, Azad Kashmir.

B/173. Bhatti, N.A., 1983b. Cathodoluminescence study of the dolomitized phosphate of Hazara. *Kashmir Journal of Geology* 1, 122.

Petrological examination of some of the Mg bearing phosphate rock of Hazara exhibits an illustrative relationship of the Phosphate deposition and the dolomitization process. MgO is an undesirable impurity in the phosphate ore and its higher values than the permissible limitations render the ore uneconomical.

Cathodoluminescence refers to the emission of light during electron bombardment. Energy levels of the light thus emitted are characteristics of the individual material and correspond with the chemical compositional and textural changes. These changes within a material itself, which are not otherwise discernable, become distinguishable under cathodoluminescence and are seen as variation in the intensities of the luminescence.

Different concentrations of Mg produce different colors and intensities in the phosphate rock. These colors and intensities are helpful in tracing the flow direction of the Mg bearing ions which in turn can be utilized in delineating the phosphate ore bodies of the low Mg content.

Cathodoluminescence can be an useful tool in locating the phosphate ore bodies of the desirable composition.

Key words: Phosphate, cathodoluminescence, Hazara.

B/174. Bhatti, N.A., 1983c. Deposition of phosphate in the Hazara Himalayas and the Precambrian glaciation. *Geological Bulletin, University of Punjab* 18, 18-21.

Tanakki Conglomerate in Hazara is located at the base of formation, which lies below the phosphate-bearing unit of Cambrian age. Though some diagnostic characteristics of mudflow as well as of aquatic preluvial sediments are evident in some parts of the outcrop but dominant compositional and textural features indicate this unit to be of glacial origin.

Regional stratigraphic location of Tanakki Conglomerate fits well into the global picture when viewed in the context of Late Precambrian glaciation. A broad correlation of Tanakki Conglomerate with Late Precambrian Tillites based on the comparison of dates from other continents and particularly from Tien Shan, China is proposed.

Considering various views on water cooling effects on the phosphate deposits, it is likely that Late Precambrian glaciation in this region could have contributed, though indirectly, towards deposition of phosphate in Hazara by raising the phosphorous concentration in the sea.

Key words: Phosphate, Hazara, Precambrian glaciation, Himalaya,

B/175. Bhatti, N.A., 1984. Deposition of phosphate in Hazara and its implication on the collision boundary. Abstract Volume, First Pakistan Geological Congress, Lahore, p.76.

The descriptive similarities of Hazara phosphate deposits with those of Tien Shan geosyncline of neighbouring Russia and China are remarkable. The Hazara phosphate as well as lien Shan geosynclinal phosphate deposition both are associated with Late Precambrian glacial tillites, manganiferous and volcanic sediments, and occupy an identical distribution with the same rock types in their regional stratigraphic column. They were effected by the same tectonic event-the Baikalian orogeny. All these similarities in the environment and the tectonics and their present-day proximity point out that Hazara phosphate as well as lien Shan geosynclinal phosphate were deposited in one and the same geosynclinal basin. It is most logical that these deposits have continuously occupied their position unchanged. As unchanged position of Hazara deposits with respect to contemporaneous phosphate deposits of lien Shan imply that Hazara is part of Eurasia continent rather than of the Indian subcontinent.

Key words: Phosphate, Hazara, tectonics, Himalayan collision,

B/176. Bhatti, N.A. & Alam, A., 1989. Heavy mineral analysis of stream sand samples from Gilgit Agency. Geological Survey of Pakistan. Information Release, 336, 11p.

Stream sand sampling was carried out in the report area of Gilgit Agency under the Mineral Exploration program of the Geological Survey of Pakistan. 34 samples were collected by panning the detrital sands from the tributaries of the Gilgit River covering a drainage area of about 2,500 sq .miles. Heavy mineral concentrates from these samples were examined for the identification of their mineral constituents and their percentage composition. This report provides the locations of these samples and their percentage of mineral constituents. Some anomalous values of certain minerals have been noted and as such, their pertinent areas of occurrence are recommended to be of consideration for further exploration work in the area .

B/179. Bhatti, N.A. & Khan, A.M., 1992. Status of gemstone in North-West Frontier Province, Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, 7-8.

The gem resources of North West Frontier Province of Pakistan comprises of variety of gemstones that are being processed and sold worldwide as Pakistani gems. These include exquisite deep green to bluish green emeralds from district Swat, rare variety of topaz in natural pink color from district Mardan and sky blue color of aquamarine from district Chitral. All form highly prized rough and cut gemstones as well as mineral specimen.

Detailed exploration in the remote areas of the province has also revealed occurrences of emerald or green beryl, garnet, jade and epidote from Mohmand and Bajaur agencies, rosy quartz, bicolor tourmaline, garnet and beryl from

Chitral and Corundum, and aquamarine and garnet from Dir area. These gem deposits could not be mined or developed either due to their poor quality and grade or due to their hostile location in the tribal agencies.

All the above mentioned gemstones are the result of the processes that were generated due to complex tectonic activities and are associated with pegmatites, hydrothermal veins and ophiolitic mélange.

Key words: Gemstone, NWFP.

B/185. Bignold, S.M. & Treloar, P.J., 1998. The Kohistan island arc, N. Pakistan: A geochemical perspective on arc stratigraphy. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 38-39.

The Kohistan terrane represents a Cretaceous arc initiated offshore of Asia as an intraoceanic arc. At ca 100Ma it was accreted to the southern margin of Asia, and subsequently behaved as a continental margin volcanic arc until being underplated by continental India at the initiation of the India-Asia collision.

Three main volcanic sequences have now been recognized in the arc: from the south, these are the Kamila Amphibolites, the Jaglot Group and the Chalt Volcanic Group. On geochemical criteria, Treloar et al., (1996) argued that the Kamila Amphibolites can be divided into two suites: one which predated the arc and has a chemistry typical of ocean plateaux, and one which relates to the erection of a supra-subduction fore-arc on the ocean plateau sequence. They argued that subduction was to the north, and that the bimodal Chalt Volcanic Group, which contains

deformed, pillowed lavas, some of which have basaltic komatiite-high Mg basalt to high-Mg andesite and boninite chemistry, was extruded into a back-arc basin. In contrast, (Khan et al., 1997) proposed that the direction of subduction was southwards, and that the Chalt Volcanic Group represents a fore-arc sequence, the Kamila Amphibolites forming a back-arc basin. In an attempt to resolve this difference, we present new geochemical data from both the Chalt Volcanic Group and Kamila Amphibolite sequences, as well as the first full data set for the Jaglot Group. Preliminary interpretation of these data shows a clear geochemical transition from the rocks of the Kamila Amphibolites to those of the Jaglot Group. This is consistent with the field evidence that the Jaglot Group rocks overlie the Kamila Amphibolites with a consistent northward dip.

Although all rock units have clear subduction-related chemical signatures, those of the Chalt Volcanic Group are distinctly different from the others. The boninitic geochemistry of some of these rocks, and in particular the rare earth element pattern, bears a close similarity to the boninites from the Eocene Zambales Ophiolite in the Philippines (Yumul, 1996) and the Group III lavas from the Limassol Forest Complex, Cyprus (Rogers, et al., 1989), which are characteristic of a supra-subduction zone setting in a primitive intraoceanic arc or incipient back-arc or marginal basin. Ongoing geochemical, isotope and modeling programmes should enable the erection of a model for the initiation of subduction, the evolution of magma source regions and the role of crustal contamination in magma evolution.

Key words: Geochemistry, stratigraphy, Kohistan arc.

B/186. Bignold, S.M., Treloar, P.J. & Petford, N., 1999. The Kohistan island arc, N. Pakistan: Identification of changing magma sources during intra-oceanic evolution. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop Kloster Ettal, Germany, 15.

The Kohistan arc terrane was initiated offshore of Asia during the mid-Cretaceous as an intraoceanic island during the mid-Cretaceous as an intraoceanic island arc above the subducting Tethyan oceanic slab. At ca. 100 Ma it was accreted to the south margin of Asia, and subsequently behaved as a continental margin volcanic arc until being underplated by continental India in the early Tertiary.

Three main volcanic and volcano-sedimentary sequences are recognised from the intraoceanic stage of arc evolution. Modelling of geochemical differences from basaltic rocks from these sequences illustrates significant changes in magma source regions during arc evolution. The oldest sequence, the Kamila Amphibolites, are tholeiitic to calc-alkali basalts, erupted on to thickened, plateau-like oceanic crust. Trace element and REE chemistry have clear arc signatures. Modelling shows the basalts were derived by up to 16% melting of spinel lherzolite at between 30 and 80 km. Field and geochemical data demonstrate an apparent upward transition from this sequence into the Jaglot Group. Jaglot Group basalts are also tholeiitic to calc-alkali, but are interbedded with turbiditic volcanoclastic sediments, the proportion of sediment to volcanic rocks increasing eastward. Basalts in the west are chemically similar to those in the Kamila sequence. Those from the eastern part of the sequence are more enriched in the REE than in the west although both have similar patterns. Modelling shows these basalts were derived by high (>80-km) pressure melting of garnet lherzolite, differences in REE chemistries being consistent with lower percent melting in the west (8%) than in the east (12%). Basalts from the Chalt Volcanic Group in the north of the arc, which include tholeiitic, pillowed, high-Mg basalts and high-Mg andesites and boninites, have significantly different geochemical signatures from basalts of the other sequences. In contrast to those, the Chalt basalts are H, REE-enriched relative to the LREE. Modelling suggests derivation through 10% melting of a cpx-depleted spinel-rich mantle at shallow depths, probably during back-arc rifting, above a north-dipping subduction zone.

On the basis of geochemistry and modelling there is no evidence for significant metasomatism of the mantle wedge in the source region. It is hence likely that differences in basalt chemistry reflect differences in depth of melting and of melt percentage, both of which can be related to either magmatic thickening of the arc or to extensional thinning.

Key words: Mid-Cretaceous, Kohistan arc.

B/187. Bignold, S.M., Treloar, P.J. & Petterson, M.G., 2001. The Chalt Volcanic Group, Kohistan, N. Pakistan: Formation of a small back-arc basin. *Journal of Asian Earth Sciences* 19, p.4.

The Chalt volcanic have passed through low-grade metamorphism and commonly display pillow structure. They are a prominent feature of the northern part of the Kohistan magmatic arc. They have been variously interpreted in term

of tectonic locale. This paper gives geochemical details in support of a small back-arc basin in which the Chalt volcanic originated.

Key words: Mineral deposits, exploration.

B/190. Bilgrami, S.A. & Farah, A., 1986. Plate tectonics and mineral potential of Pakistan. Die Naturwissenschaften in Pakistan, Deutsch-Pakistanisches Forum, 239-257.

It has now been agreed that plate tectonics have a bearing on the mineral deposits. In this document, with two figures and two tables, the authors describe in detail plate tectonics and mineral potential of Pakistan.

Key words: Tectonics, mineral deposits.

B/191. Bilham, R., Panth, G.B. & Jacoby, G.C., 1984. A preliminary study of ancient trees in the Hunza valley, and their dendroclimatic potential. In: Miller, K.J., The International Karakoram Project, Volume 2. Cambridge University Press.

Trees of great age are found on the high mountain slopes bordering the Hunza Valley and tributary valleys in the Karakoram Mountains. The survival of ancient trees is partly attributable to the enlightened local practice of culling branches for fuel rather than felling entire trees. We have subjected two specimens of juniper found at elevations of 3,800 m and 4,150m to ring analysis and determined maximum ring counts of 1200 and 479, respectively. The detection of incomplete rings in different radial sections from both specimens suggests that some rings may be missing and that the age of the trees may be more than their ring counts indicate. The lower and older of the two specimens consisted of a dead stump of unknown absolute age and an attempt to crossdate the specimen with the higher, living specimen was unsuccessful.

The two specimens are unlikely to be the oldest or most climatically sensitive trees in the region. We conclude that there is a strong possibility for deriving climatic information for the last several centuries from the ancient trees of the region. A knowledge of past climate has Important consequences in the study of glacial movements, erosion, and agriculture in the Hunza Valley.

Key words: Paleobotany, climate, Hunza valley.

B/192. Bilham, R. & Simpson, D., 1984. Indo-Asian convergence and the 1913 survey line connecting the Indian and Russian triangular surveys. In: Miller, K.J., The International Karakoram Project, Volume 1. Cambridge University Press.

In 1913 a 480-km long north-south triangulation survey was conducted across the Karakoram and Pamirs near the 73rd meridian. It spans more than one third of the zone of convergence characterizing the collision of the Eurasian and Indo-Australian plates and its remeasurement after more than 65 years is expected to reveal considerable crustal deformation.

This article discusses the errors associated with the 1913 survey and attempts to predict the magnitude and style of deformation that may have occurred since then. It is known that the original survey accuracy is associated with errors greater than $\pm 10^{-6}$ strain and that, unless a convergence rate of more than 6 cm/year has occurred, uniform compression of the survey line will be undetectable. At 73° E the Indo-Asia convergence is expected to be 4 cm/year. However, it is clear from historical and continuing seismicity that the convergence is not uniform and that locally large deformations may have occurred. Two areas appear particularly promising. These are the area just north of Gilgit and the area north of Lake Karakul in the Soviet Pamirs.

B/193. Billington, S., Isacks, B. & Barazangi, M., 1977. Spatial distribution and focal mechanisms of mantle earthquakes in the Hindu Kush-Pamir region: a contorted Benioff Zone. *Geology* 5, 699-704.

Seismological evidence based on the spatial distribution and focal mechanism solutions of mantle earthquakes in the Hindu Kush-Pamir region supports a model in which suboceanic lithosphere that existed between the converging Eurasian and Indian continents is subducted into the upper mantle. Two lines of evidence support this model. First, a careful selection of well-defined hypocenters in the region from 1950 through 1973 defines a thin (about 25 km thick) contorted Benioff zone within the upper mantle. The zone dips steeply (about 70°) toward the north in the western part of the region and has a shallower dip (about 50°) toward the southeast in the eastern part of the region. Second, focal mechanism solutions of intermediate-depth earthquakes have extensional (T) axes oriented parallel to the dip of the Benioff zone. The thin slab-like distribution of hypocenters and the downdip extensional stress are similar to features found in many other more typical regions of active lithospheric subduction. In addition, comparison of the focal mechanism solutions and the spatial distribution of earthquakes demonstrates the presence of a fault plane at about 200 km depth within the western part of the subducted lithosphere. Similar fault planes have also been observed in other areas of subduction. Comparison of the seismicity of the Hindu Kush-Pamir region with the apparent lack of mantle earthquakes along the main Himalayan arc suggests that the region is the site of the final stage of subduction of suboceanic lithosphere along the collision boundary between the Indian and Eurasian plates.

Key words: Earthquakes, seismology, Hindukush, Pamir.

B/195. Bilqees, R., Tanoli, S.K. & Hussain, V., 1995. Petrological studies of some phosphorite deposits of Hazara, Pakistan and their Economic importance. Abstracts, International Symposium and Field Workshop on Phosphorites and other Industrial Minerals, Abbottabad, 35-36.

Phosphorites occurring in Hazara are the only commercially workable deposits in Pakistan. These phosphorites are of sedimentary origin belonging to Cambrian age occurring in a number of localities in the area. The rock phosphate in Kakul area occurs in a folded and faulted sequence of Cambrian to Jurassic sediments. The geology of the area has been complicated by thrusts which have divided the phosphate bearing strata into a number of discrete thrust sheets. There are two phosphatic horizons in this area. The main occurrence is in the Abbottabad Formation where it is associated with chert and dolomite while, in Hazira it is associated with siltstone. Present studies are based on the phosphorite deposits of Kakul and Lambidogi belonging to Abbottabad Formation. Field and laboratory studies reveal that these phosphorites were formed by the upwelling currents in the shelf environments. Later, when high energy conditions prevailed, this authigenically formed phosphate mud was reworked and pellets were formed. The associated dolomite is of secondary origin which probably was formed by the alteration of limestone, whereas chert was formed by the incorporation of silica. Hazara phosphorites are of good quality and the estimated reserves are about 20 million tones which are sufficient to fulfil the requirements of our phosphatic fertilizers in Pakistan. Despite known large resources of phosphorite in Hazara, its annual production is about 40,000 tones. The selective mining of rock phosphate is being done at Kakul thus leaving huge quantities of low grade ore as dump. There is a

need to undertake beneficiation and direct application studies for utilizing rock phosphate resources of the country more judiciously. Further, these deposits should be exploited at a faster pace and efforts should also be made to explore the new ones in this district. Encouraging results in these directions can be obtained when the provincial and federal governments provide or facilitate the necessary technical and financial Inputs to this phosphorite project, as has been done in case of Saindak metallic project in Balochistan.

B/196. Bird, P., 1978. Initiation of intracontinental subduction in the Himalaya. *Journal of Geophysical Research* 83, 4975-4987.

Independent arguments based on topographic stress and crustal strength give upper limits of 200 bars and 300 bars, respectively, for the average shear stress on the intracontinental thrust fault that formed the Himalaya. According to either a one-dimensional or a two-dimensional fault model, such stresses could not have produced the Himalayan granites by friction, unless overthrusting velocity exceeded 30 cm/yr. More probably, Himalayan metamorphism was caused by exposure of continental crust to hot asthenosphere prior to the formation of the intracontinental thrust. Crust was exposed by peeling away of Indian subcrustal lithosphere in response to the force and moment exerted by the Tethyan slab. This detachment of buoyant crust from dense lithosphere better explains the metamorphic pattern and also explains why the distributed crustal shortening at the beginning of the collision orogeny was replaced by localized thrusting or intracontinental subduction.

B/197. Bishop, M.P. & Shroder, J.F.Jr., 2000. Remote sensing and geomorphometric assessment of topographic complexity and erosion dynamics in the Nanga Parbat massif. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 181-200.

The dynamic mountains of the western Himalaya are the result of complex interactions involving tectonic, structural, lithological, climatic and surface processes. The multi-scale dynamics of surface processes in this region are largely unknown. This paper assesses the spatial complexities of the topography at Nanga Parbat, as we seek to understand erosion dynamics, differential denudation and the geodynamics of uplift and denudation. Spatial analysis of a high resolution digital elevation model and three-dimensional terrain simulation using satellite imagery indicate that the topographic complexity of Nanga Parbat is highly scale-dependent and exhibits a hierarchical order that is reflective of erosion dynamics. Observations and analyses reinforce prior understandings of rapid rates of uplift and high rates of surficial denudation. Results indicate that climate controls the topographic complexity of the massif although a tectonic influence is present and is largely masked by the overprinting of surface processes with time. Consequently, Nanga Parbat is seen to owe its origin to erosionally induced tectonic uplift and rapid surficial denudation. Rapid uplift altered erosion dynamics and further accelerated erosion resulting in extreme relief. Nonetheless, the differential denudation resulting from erosion dynamics does not appear to be in spatial balance with the regional scale tectonic mass flux. Systematic integration of dynamic models that account for the scale-dependencies of subsurface and surface processes are required to study the nature of this complex system and explain topographic evolution.

B/198. Bishop, M.P., Shroder, J.F.Jr., Hickman, B.L. & Copland, L., 1998a. Scale-dependent analysis of satellite imagery for characterization of glacier surfaces in Karakoram Himalaya. *Geomorphology*, 21, 217-232.

Information regarding process-structure relationships and change in the Karakoram Himalaya is of great importance in studying glacier hydrology, mass balance, and dynamic environmental change. Such information is not readily available. Detailed spatio-temporal assessment requires field investigation coupled with quantitative remote sensing studies. We conducted an investigation of the large Batura Glacier in Pakistan to determine if spectral variability can be quantified and used to characterize glacier surfaces. Specifically, SPOT Panchromatic satellite data were evaluated for differentiating features of glacier structure resulting from ice movement, ablation, and supraglacial

fluvial action. Image semivariogram analysis was conducted for assessing spectral variability patterns and fractal analysis was used to examine scale-dependent variation in the data. Results indicate that spectral variability from fields of ice seracs can exhibit fractal characteristics, although most surface features on the glacier exhibit a change in the fractal dimension over different ranges in scale. The fractal dimension was found to be useful for differentiating between glacier surfaces such as white ice and debris-covered ice. Characteristics of the debris-load and the scale-dependent nature of calculating the fractal dimension ultimately determined the potential of class separability.

B/199. Bishop, M.P., Shroder, J.F.Jr., Sloan, V.F., Copland, L. & Colby, J.D., 1998b. Remote sensing and GIS technology for studying lithospheric processes in a mountain environment. *Geocarto International* 13, 75-87.

Analysis of relationships between uplift and denudation in complex mountain environments requires integrated approaches using remote sensing and geographic information systems (GIS) analyses in combination with field investigations. We present multidisciplinary research focusing on the Nanga Parbat Himalaya of northern Pakistan. Remote sensing of the subsurface includes radio-echo sounding to investigate glaciers, magnetotelluric sounding, and seismic tomography to investigate shallow to deep aspects of the lithosphere. Remote sensing of the landscape includes satellite image acquisition, multispectral analysis, geomorphometric analysis of a satellite-derived digital elevation model (DEM), and the application of GIS and pattern recognition procedures to analyze topographic complexity and the geomorphology of the mountain massif. Detailed mapping requires topographic normalization of satellite imagery using the non-Lambertian model. Radar measurement of thicknesses of glacier ice, coupled with assessment of satellite imagery and field data, have enabled calculation of ice and sediment discharge. Collectively, scientific observations reinforce prior understandings of rapid rates of uplift and high rates of surficial denudation. The integration of data has thus enabled a systematic approach to study localized coupling between tectonic and surface processes. In future studies of this kind, it will become ever more important for geoscientists to integrate quantitative remote sensing and GIS into a standard analytical framework in order to solve complex problems.

B/200. Bishop, M.P., Shroder, J.F.Jr. & Ward, J.L., 1995. SPOT multispectral analysis for producing supraglacial debris-load estimates for Batura Glacier. *Geocarto International*, 10, 81-90.

SPOT multispectral and panchromatic data were evaluated to determine their utility to detect debris-load characteristics of the Batura Glacier located in the Karakoram Himalaya. Debris-depth measurements, surface samples, and ground photography were obtained and used with satellite-derived information to produce supraglacial debris-load and discharge estimates. Visual analysis of panchromatic data indicated that structural characteristics of the glacier exhibited unique textures associated with surface structure characteristics. Multispectral analysis revealed that stratified unsupervised classification of principal components can be used to produce classifications depicting supraglacial lithology and shallow debris-load variability. Debris-load discharge estimates ranged from 48-97 x 10³ m³ yr⁻¹. These results indicate that SPOT multispectral data may be used to produce reasonable quantitative estimates of debris-load characteristics for glacier mass balance and regional denudation studies.

B/204. Blisniuk, P.M., 1996. Tectonic evolution of the NW-Himalayan thrust front: Implications from sediment characteristics in the Trans-Indus Ranges, Northern Pakistan. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy 13-14.

This paper presents the results of sedimentological, magnetostratigraphic and structural work constraining the latest Miocene to recent tectonic evolution in the area of the present-day NW-Himalayan thrust front. In the Trans-Indus Ranges of northern Pakistan, forming the western part of the NW-Himalayan thrust front, unconformities, changes in paleocurrent directions and locally derived conglomerates contained in syn-orogenic foreland basin deposits provide evidence for local deformation between ≥ 3.5 and ≥ 3 Ma. The tectonic history of the Trans-Indus Ranges has previously been described in terms of a well-documented single episode of major thrusting starting at ~ 1 Ma [e.g., Khan et al., 1998], thus the work presented here implies, instead, that there were two distinct phases of local deformation, at ~ 6 to 5 Ma and ≤ 2.5 Ma to present [e.g., Burbank and Beck, 1989], this study demonstrates that the presence of two phases of deformation during latest Miocene to recent time is a regional-scale phenomenon, and these two phases are probably correlative along the present-day NW-Himalayan thrust front.

In the Salt Range, the earlier deformation can variously be interpreted as either initial thrusting along the Salt Range Thrust [e.g., Burbank and Beck, 1989], or normal faulting in the foreland basin [e.g., Lillie et al., 1987]. However, in the Trans-Indus Ranges, the reconstruction of possible source areas for the locally derived conglomerates shows that the earlier deformation is much more likely related to normal faulting than to thrusting. In combination with other workers' flexural and gravity modeling [Duroy et al., 1989], the results present here suggest that the tectonic evolution in the area of the present-day thrust front is characterized by: 1) latest Miocene to early Pliocene north-dipping normal faulting in the footwall of the frontal thrust system related to flexure of the Indian plate in response to topographic loads emplaced to the north on older NW-Himalayan thrust, and 2) subsequent south-directed thrusting along the present-day thrust front, related to outward growth of the NW-Himalayan thrust wedge since the latest Pliocene. The geometry of the present-day thrust front appears to be largely controlled by normal faults and monoclines formed during the earlier deformation and acting as thrust ramps during the still active younger deformation.

This mechanism may not only be responsible for the basement offsets observed in the subsurface of the thrust front, but also for others that appears to have controlled the location of several other major structures underneath the NW-Himalayan foreland fold-and-thrust belt, e.g. the Northern Potwar Deformed Zone [Leathers, 1987], and structures on the Kohat Plateau [Pivnik and Sercombe, 1994]. Basement normal faults acting as structural ramps have also been observed in other areas along the Himalayan thrust front [Talkadar and Sudhakar, 1972] as well as in other orogens such as the Western Alps [Butler, 1989] and Ouachita Mountains in Arkansas and Oklahoma [e.g., Briggs and Roeder, 1975]. Therefore, the interplay between thrust stacking above basal detachment of fold-and-thrust belts and syn-orogenic flexural deformation beneath the detachment may be a more significant component of collision-related deformation than previously recognized.

B/205. Blisniuk, P.M. & Saheed, G., 1993. The Tectonic evolution of fault systems with strong lateral variations in tectonic style: The Trans-Indus Ranges (Northern Pakistan). Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 62-63.

The main focus of this ongoing study is the structural evolution of fault systems with lateral variations in tectonic style between compression and transpression. Such fault systems have been recognized in many mountain belts. However, due to the complex pattern of deformation their formation is still poorly understood, and the tectonic interpretation of regions affected by this kind of deformation is difficult. The Trans-Indus Ranges are part of the

young and still active frontal thrust system of the NW-Himalayan foreland fold-and-thrust belt which is characterized by the occurrence of several pronounced structural re-entrants and promontories. Studies of such structurally complex fault systems in actively deforming regions are important because they can provide information that is usually not available in older mountain belts but necessary to understand the mechanics of their formation. A particularly attractive aspect of the ongoing project is the young age of deformation in the study area (< 1 Ma ?), which allows a very precise quantitative assessment of the rates of deformation. Furthermore, thermal and tectonic overprinting which has occurred in many older mountain belts is absent, and exposure is excellent in most of the region.

Preliminary results of a first field season in the Trans-Indus region (11/91 to 1/92) indicate that the emergence of the Trans-Indus Ranges was controlled by a system of frontal ramps that form the centers of re-entrants and promontories, and lateral or oblique ramps that form their edges. The Construction of balanced cross-sections shows that the total shortening along the frontal ramp segment represented by the western Khisor Range is on the order of at least 10 km. This suggests that the deformation along the lateral and oblique ramps is characterized by a strike-slip Component of similar magnitude. Pronounced bends of structures in the Khisor Range near the transition zones to adjacent regions of transpressive deformation suggest that vertical axis rotations occur in these areas. Structures show an apparent clockwise rotation near the western end of the Khisor Range, which is truncated by a right-lateral strike-slip fault, and an apparent counterclockwise rotation near its eastern end, which seems to be truncated by a left-lateral strike-slip fault. The sense of the apparent rotations is therefore compatible with the assumed relative motions along the lateral terminations of the Khisor Range. Alternatively, the observed bends could simply reflect a complex ramping geometry, in which case vertical axis rotations would not have occurred at all. Present fieldwork (12/92 to 3/93) therefore includes sampling for a paleomagnetic investigation to test these hypotheses.

With the exception of the results of our previous investigations in the Trans-Indus Ranges, quantitative data on the deformation in that region are not yet available. The main goal of our study therefore is a qualitative analysis of the structural style of deformation, and a quantitative assessment of the total deformation.

The area presently represented by the Trans-Indus Ranges was part of the Himalayan foreland basin and received synorogenic deposits during Late Neogene folding and thrusting further north, and was subsequently deformed as part of the hanging wall of the younger frontal thrust system in the south. The onset of deformation in the Trans-Indus region should be reflected by decreasing sedimentation rates of the more distal facies with a source area further north, and subsequent nondeposition and erosion, or deposition of proximal deposits that have the Trans-Indus Ranges as source area. Ongoing research therefore integrates sedimentological and chronostratigraphic studies of the synorogenic deposits with structural investigations in this area.

The structural portion of this work includes detailed field mapping to provide constraints on the style of deformation. This mapping also is the basis for the construction of balanced cross-sections that are needed to quantify the total amount of shortening along the Trans-Indus Ranges. The chronostratigraphic studies will include paleomagnetic age determinations of young synorogenic molasse deposits, and fission track dating of volcanic ashes within that sequence. These studies will provide information on the age ranges and deposition rates of syntectonic sediments. Together with sedimentological mapping of syndeformational unconformities, facies changes and paleocurrent analyses these results will constrain the temporal and spatial character of deformation in the NW-Himalayan foreland.

The major element and Sr isotope geochemistry of surface waters, bedrock, and river sands was investigated in the Raikhot watershed within the Himalayan Crystalline Series (HHCS) in northern Pakistan. Mass-balance calculations of mineral-weathering contributions to the dissolved flux of ions from the watershed indicate that 82% of the HCO₃⁻ flux is derived from the weathering of carbonate minerals and only 18% is derived from silicate weathering, even though the bedrock is predominantly quartzofeldspathic gneiss and granite with only 1% carbonate in the watershed. This study demonstrates the importance of rare amounts of bedrock carbonate in controlling the water chemistry of glacial watersheds. We suggest that the flux of Sr with a high ⁸⁷Sr/⁸⁶Sr ratio in the major Himalayan river may be derived in large part from weathering of trace amounts of clacite within the largely silicate HHCS. Models that use the flux of radiogenic Sr from the Himalayas as a proxy for silicate weathering rates may, therefore, overestimate the amount of CO₂ consumption due to silicate weathering in the Himalaya.

During his journey in the Karakoram Himalayas, Mr. W. M. Conway collected more than 300 specimens of rocks and minerals, which, however, were generally rather small. These were sent to us for examination at University College, London. Thin slices have been prepared of the specimens which promised to be the more interesting. Of the rest, the mineral composition was verified in cases of doubt by examining pulverised fragments under the microscope. Since the detailed results of our examination, which practically form an annotated catalogue of the specimens, will be printed as an appendix to Mr. Conway's forthcoming volume, we restrict ourselves in this paper to a summary of our work, and to a notice of a few specimens which appear to be of more than local interest.

B/218. Boota, M., 1978-80. Geology, Petrology and Geochemistry of Chalt-Hini Area, Gilgit Agency. M.Sc. Thesis, Punjab University, Lahore, 179p.

The project area (Chalt-Hini) lies in the Hunza Valley District Gilgit at (E) $74^{\circ} 35'$ to $74^{\circ} 18'$ latitude (N) $36^{\circ} 19'$ to $36^{\circ} 13'$ and has been mapped on tectonically. The area is located in the center of the Karakoram Mountain and represent a part of a cross section through this mighty range. Area is intensely disturbed tectonically being involved in Himalayan Orogeny, which is evident from the strained, crushed and deformed lamellae of the minerals in the rock.

Structures found in the area are orthotectonic; the most important are Sikandarabad anticline, Chalt Fault, Boudalus Fault and Hini Fault. The project area is composed mainly of metamorphic and igneous rocks.

The metamorphic rocks are sedimentary in origin. Rocks were originally deposited in eugeosynclinal conditions as argillaceous sediments and afterward these were regionally metamorphosed and uplifted due to stress during Himalayan Orogeny. These are of Permo-Carboniferous or Cretaceous to Eocene in age, and grade from chlorite to garnet. Lithologically metasediments units include Khizarabad Slate, Calcareous Quartzite, Chlorite Mica Schist, Biotite Schist and Garnet Mica Schists. Igneous rocks in the area are, Karakoram Axial Granodiorite which is acidic plutonic rock of Tertiary age Greenstone which is a basic volcanic rock of Pre-Carboniferous age. Mineralogical description and petrographic analysis of these rock units are reported in detail. An attempt is made to interpret the petrogenesis of rock type. Detailed geochemical study of rocks has been described. Study also covers the ore microscopic deposits, which show the presence of ore minerals such as magnetite, hematite, pyrite etc. Orogenesis is discussed in detail. Economic mineral found in area is also described.

B/219. Bordet, P., 1978. The Western border of the Indian Plate; Implication for Himalayan geology. *Tectonophysics* 51, 171-176.

The study of regions situated beyond the western margin of the present-day Indian plate (Afghanistan principally) point to the following facts:

(1) During the Late Precambrian—Early Paleozoic, stratigraphical continuity existed between western and central Iran, Central Afghanistan, Salt Range and western Pakistan. (2) During the Paleozoic a similar epicontinental cover existed in central Afghanistan, Kashmir and Tibet, with Gondwana tillites and associated cold fauna, such as in India (Umaria); however, a so-called Hercynian zone exists also in northern Iran—Hindu Kush and northern Pamir: it exhibits a Middle Paleozoic unconformity (Upper Devonian Carboniferous) on metamorphic Early Paleozoic. (3) The end of the Paleozoic, is marked by: a fracturation of the basement of the Hercynian zone, with powerful volcanic eruptions at the northern part of Hindu Kush, Kashmir (Panjal trap) and also Nepal (Nar valley) the formation of a geosynclinal zone at the southern part of Hercynian zone (Turkman, Penjaw). (4) During the Jurassic: the geosynclinal evolution of the Turkman—Penjaw furrow accelerated, with the accumulation of flysch, radiolarites, ophiolites, olistolites and incipient HP metamorphism. A general subduction took place followed by a Neocimmerian orogenic phase with overthrusting of the central Afghanistan ranges on the scar of the geosynclinal furrows. (5) During the Cretaceous: the geosynclinal evolution ended: Lower Cretaceous lies unconformably on the folded Jurassic flysch. In eastern Afghanistan and northern Pakistan, during the Middle (?) or Upper Cretaceous, a new geosynclinal zone was created. (6) During the Cenozoic, central Afghanistan was emerged; northwards, sedimentary basins were created along the Herat fault, with volcanic and magmatic activity. A southeastern geosynclinal furrow evolved with accumulation of flysch, ophiolites and finally molasse deposits (Katawas—Soleimans). Its western border began overthrusting, but this movement changed into a left lateral fault i.e., the presentday Chaman Arghandeh fault.

Conclusion: Two major phases of dislocation took place during the geological history of Gondwana: the first one began during the Permian and ended in the Jurassic; the second one began during the Cretaceous and is still active. The important Eocimmerian orogenic phenomena, existing in the Central Afghanistan and northern Pakistan, took place at the edge of a Gondwana continental fragment, which was larger than the presentday Indian plate. Coeval phenomena may exist in the Himalayan region and perhaps in one of the ophiolitic sutures of Tibet.

B/222. Bossart, P., Chaudhry, M.N., Dietrich, D., Ghazanfar, M., Greco, A., Meier, A., Ottiger, R., Papriz, K., Ramsay, J.G., Rey, R., Spencer, D.A. & Wahrenberger, Ch., 1992. A review of the geology of the northern Indian plate, Kaghan valley, NE Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 6-7.

A review is presented of the regional significance of the tectonic and metamorphic structure of the northern part of the Indian plate lying beneath the Main Mantle Thrust (MMT) of the Himalayas. The region in and around the Kaghan Valley is especially relevant in that it displays what is probably the best exposed and most easily accessible cross section of the overthrust nappes of the Himalayas in Pakistan.

From south to north the section passes from the northern Foreland of the Indian plate, with its sedimentary cover of Cambrian, Paleocene and Eocene (Murree) formations, which is overthrust along the Main Boundary Thrust (MBT)

by Precambrian rocks of the Lesser Himalayas and which are themselves overthrust along the Main Central Thrust (MCT) by the metamorphic rocks of the Higher Himalayan units. All these structural thrust slices lie beneath the Kohistan Island arc volcanics and their basement of granulite facies basic rocks and separated by the Main Mantle Thrust (MMT) from these overlying units.

Much of the displacement along the main thrust planes which demarcate the main structural units was accomplished after the main Himalayan high temperature (and high pressure) metamorphism. There is always a metamorphic jump across the major thrust surfaces such that higher grade (pressure P and temperature T) rocks always lie structurally above units with lower P-T conditions. However, within each overthrust slice there is a general systematic increase in P and T from south to north. Beneath the MBT the rocks show little or no metamorphism. In the units between the MBT and MCT metamorphic grades range from greenschist to low amphibolite facies and in the Higher Himalayan structural unit between the MCT and MMT the dominant metamorphism is of middle to high amphibolite facies. However, in the Higher Himalayas the Himalayan metamorphism is complicated in that there appears to have been an early high pressure-medium temperature phase, with local production of eclogites, followed by an overprint of amphibolite grade and later greenschist facies minerals. We have found no evidence to suggest the existence of abrupt metamorphic discontinuities of Himalayan age within the main structural units. However, within the formations making up the Higher Himalayan unit, there are preserved certain lithological and metamorphic characteristics which appear to predate the Himalayan overprint and which suggest that pre-Himalayan metamorphic and structural features are preserved: features which can be used to separate rock groups into 1) a pre-Himalayan metamorphic "crystalline" basement (Precambrian ?) and two overlying sequences of cover rocks predominantly of sedimentary aspect, a lower 2) Naran Formation of pelitic and greywacke-like sediments of late Precambrian or early Paleozoic age (?) and an upper 3) Burawai Formation of calc-pelites and interbedded basic lavas (Panjal Traps?) of Tethyan aspect possibly of late Paleozoic and Mesozoic age (?). Although all these rocks have suffered a strong Himalayan metamorphic overprint, there are locally preserved sedimentation structures (graded bedding in the Naran Formation and syn-sedimentary extensional faults and stromatolitic fossils in the Burawai Formation).

The structural styles seen in the various thrust slices are complex and are interpreted as being the result of superposed deformations with differing regional shortening directions. In the Foreland region and Lesser Himalayan Unit markers are available to determine local

and regional variations in the finite strain states and to give some indication of the progressive strain history. In the Higher Himalayas such markers are rarely identifiable but, where present, indicate that the strain states are often lower than that seen at the unit contacts. Strain markers along the locations of the MBT, MCT and MMT indicate extremely high deformations with the formation of shear zones and ductile mylonites. In the Lesser and Higher Himalayan Units the earliest deformations of Himalayan age appear to be broadly syn-metamorphic and appear to have developed large scale fold nappes, with isoclinal anticlinal folds cored with pre-Himalayan basement gneisses and granitoids. These structures were later refolded and now the geometry appears to be the result of complex fold interference patterns. In the Lesser Himalayas an early low amphibolite or greenschist fades (syn-nappe formation) shows late developed retrogression associated with the late fold superposition. In the Higher Himalayas an early eclogite facies (early subduction effect?) is locally very well preserved but, in general, the high pressure mineralogy is overprinted by amphibolite or greenschist metamorphic minerals and fabrics. In many regions this overprint is more or less complete and only traces of symplectite textures and abundance of rutile fingerprint, albeit imperfectly, the earlier high-pressure metamorphism.

The Kaghan cross-section appears to record the earliest subduction of the Indian plate beneath the Asian plate and the development of high pressure-medium temperature metamorphism (Eclogite facies). The stacking of large fold (and thrust?) nappes was followed by a thermal rise, development of further shortening and superposed folding and thrusting of individual regional units, uplift and erosion. The sediment debris was eroded from the uplifted collision zone and transported southwards to be deposited in an embryonic, low topographic, shallow marine foreland basin (the Murree Formation of the Foreland) in Paleocene to early Eocene time, and these foreland sediments were themselves involved in the late stage compressions, and overthrust by the more internal tectonic units along the Main Boundary Thrust.

B/223. Bossart, P., Dietrich, D., Greco, A., Ottiger, R. & Ramsay, J.G., 1984. A New structural interpretation of the Hazara Kashmir Syntaxis southern Himalayas, Pakistan. *Kashmir Journal of Geology* 2, 19-36.

The stratigraphic and structural features of the Hazara Syntaxis are described. The principal lithological features of the geological formations are reviewed and special type of rhythmic sedimentation which characterises the structurally lowest Murree formation is described in detail. The region is one of overthrust and shear zone tectonics associated with the development of at least two superimposed sets of major folds and associated minor structures (Microfolds, cleavage, vein systems and various types of lineations related to rock strain or intersection of planar structures). It is concluded that the syntaxis results from an early set of nappe units developed by southwestward overthrusting of a previously metamorphosed (Himalayan) rocks followed by the formation of a large shear zone structure and finally by the transport of overthrust units from northwest to southeast.

Key words: Structural geology, Hazara-Kashmir Syntaxis, Himalaya.

B/224. Bossart, P., Dietrich, D., Greco, A., Ottiger, R. & Ramsay, J.G., 1985. A new structural interpretation of the Hazara Syntaxis, NE Pakistan. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

The stratigraphic and structural features of the Hazara Syntaxis have been remapped by a research team from the ETH. The region has been shown to contain overthrust and shear zone tectonics associated with the development of two sets of major folds and their attendant small scale structures (microfolds, cleavages, vein systems and various types of lineations related to total rock strain or to the intersection of differently oriented planar structures). Evidence will be presented that the syntaxis has been developed first by southwestward overthrusting of a series of metamorphic nappes over the Murree (Tertiary age) Formation. This thrusting event was followed by the formation of a large, steeply inclined shear zone structure and finally by the transport of overthrust nappes from the northwest to the southeast.

Key words: Structural geology, Hazara-Kashmir Syntaxis, Himalaya.

B/225. Bossart, P., Dietrich, D., Greco, A., Ottiger, R. & Ramsay, J.G., 1988. The tectonic structure of the Hazara-Kashmir syntaxis, southern Himalayas, Pakistan. *Tectonics* 7, 273-297.

The stratigraphic and structural features of the Hazara syntaxis are described. A special aim of this work was to integrate modern approaches to rock deformation with the regional tectonics. The region is one of overthrust and shear zone tectonics associated with the development of at least two superimposed sets of major folds and associated minor structures (microfolds, cleavage, vein systems and various types of lineations related to rock strain or intersections of planar structures). It is concluded that the syntaxis results from an early set of nappe units developed by southwestward overthrusting of previously metamorphosed (Himalayan) rocks followed by the formation of a large shear zone structure and finally by the transport of overthrust units from northwest to southeast.

B/226. Bossart, P. & Ottiger, R., 1989. Rocks of the Murree Formation in northern Pakistan: indicators of a descending foreland basin of Late Paleocene to Middle Eocene age. *Eclogae Geologicae Helveticae* 82, 133-165.

The red clastic sand and shale deposits of the Murree formation have been regarded as continental deposits of Miocene age. A new and more detailed sedimentological and micropaleontological survey on a profile of about eight kilometers in length, in the apex region of the Hazara-Kashmir Syntaxis in Northern Pakistan, has shown that these rocks were deposited in a very shallow marine, tidally influenced environment. This hypothesis is based on the recognition and interpretation of the cyclic sedimentation seen in these rocks. One can interpret a single cycle as the product of meandering tidal channels in a continuously subsiding foreland basin. Each cycle starts with typical channel fill deposits (microconglomerates, crossbedded sandstones) and passes upwards into tidal flat deposits (laminated and strongly bioturbated sand and siltstones). The uppermost part of a cycle is composed of red clayey silt with local horizons containing calcareous concretions which are interpreted as a type of fossil Caliche. Chrome-spinels out of coarse grained sandstones from the base of the Murree formation, near Balakot, indicate the Kohistan complex as a possible source area. It therefore seems likely that the Murrees are derived from the North and not from the South as previously presumed. Age determination based on syndepositional nummulites and assilines indicate an age of late Iberan (latest Paleocene) at the base of the Murree formation and late middle Lutetian at a

position some into thirds from the base of the profile. In the North, the Murree formation is therefore much older than it is in the South (Kohat, Potwar) where data suggests an early Miocene age. This age discrepancy is explained by a southwestward migration of the Himalayan thrust front that led to a southwestward migration of the Himalayan foreland basin and the Murree facies belt. As a consequence the Murree deposits prograded on to progressively younger shallow marine deposits. The introduction of a new formation for the marine part of the Murree formation is recommended to the Stratigraphical Committee of Pakistan.

B/228. Bossart, P., Ottiger, R. & Heller, F., 1990. Rock magnetic properties and structural development in the core of the Hazara-Kashmir syntaxis, NE Pakistan. *Tectonics* 9, 103-121.

Paleomagnetic and structural analyses have been conducted on three well-exposed sections through a 6–8 km thick pile of molassic red beds (Murree formation) in the lowermost tectonic unit of the Hazara-Kashmir Syntaxis. Micropaleontological age determinations of the lowermost Murree sediments indicate Late Paleocene deposition (55 m.y.). From south to north, the sections are situated in the Jhelum, Neelum (both in Azad Kashmir), and Kaghan (northeastern Pakistan) valleys. Thermal demagnetization experiments suggest that haematite with high unblocking temperatures carries stable characteristic remanence directions. The relationship between finite strain and magnetic fabric was established by mapping deformed reduction spot strain markers and by measuring the anisotropy of magnetic susceptibility (AMS). For the Jhelum valley the weakly tectonized Murree beds are characterized by flattened AMS ellipsoids resulting from diagenetic compaction. Inclination values suggest that the Murree foreland basin started to develop at about 8°N during the early suturing of India and the development of island arcs to the north. India has moved northward by at least 2600 km since collision with Eurasia in the Paleocene. Declination values suggest 45° of clockwise rotation of the block supporting the Murree formation relative to the Indian craton. For the Neelum and Kaghan valleys, quantitative strain mapping shows a progressive increase of deformation northward. NRM directions rotate passively toward the cleavage plane which parallels the foliation of the AMS ellipsoids. NRM directions and AMS ellipsoids are deformed because of superposition of tectonic strain on a primary compactional strain. The AMS pattern is interpreted in light of this superposition, and a regional deformation path from south to north is suggested. A tectonic rotation model is proposed which is consistent with the transport directions around the Hazara-Kashmir Syntaxis and the rotation of thrust sheets indicated by the NRM data. This model relates the convergent transport directions with the mean indentation direction of India into Asia.

B/229. Boulin, J., 1981. Afghanistan structure, greater India concept and eastern Tethys evolution. *Tectonophysics* 72, 261-287.

The large and complex area between Central Asia and the Arabia-India block includes, from north to south, the Tien Shan and Hindu Kush-Kun Lun Hercynian belts, the Turkman-Farah Rud and Tanghla Shan Neokimmerian belt, the Zagros-Makran-Baluch-Himalayan Alpine belt and relics of corresponding oceanic spaces. The Angarian or Gondwanian affinities of the different blocks separated by these successive peri-Indian belts are discussed. An interpretation is proposed for the paleogeographic and structural evolution of this area, from Early Paleozoic to Present. This interpretation is based on geologic and paleomagnetic data and on global tectonic considerations. The Hindu Kush-Kun Lun pre-Hercynian ocean probably separated Laurasia from Gondwanaland. It was an Early Paleozoic Tethys (Tethys 1). The Tien Shan ocean may have been a marginal basin for the Hindu Kush-Kun Lun ocean. The Turkman-Farah Rud-Tanghla Shan pre-Neokimmerian ocean resulted from the break-up of the Gondwanaland margin. Its opening seems to have been related to the pre-Hercynian ocean closure resulting in the formation of a new Tethys (Tethys 2). Its subsequent closure may also have been related to the opening of the

Zagros-Baluch-Indus-Tsang Po pre-Alpine ocean (Tethys 3). According to this interpretation, Eurasia appears to have increased from Early Paleozoic to Cenozoic by successive accretion of cratonic blocks which came from the south through the Tethys. This evolution can be compared to the similar Mediterranean evolution. This interpretation is in agreement with the Greater India concept. However, the northern border of Greater India differs according to the stage of the Gondwanaland evolution which is considered. Actually, Greatest India extended north to the Caledonian belt and consequently has recorded the whole history of the Eastern Tethys.

B/230. Boulin, J., 1988. Hercynian and Eocimmerian events in Afghanistan and adjoining regions. *Tectonophysics* 148, 253-278.

The area centered around Afghanistan is a collage of continental blocks derived from Gondwanaland. This collage comprises, among others:

(1) a Hercynian orogenic belt widely represented in Afghanistan and also by some sparse outcrops in the northern Iran; it is a subduction-type orogen constructed at the margin between the Paleotethys and the Turan-Turkestan-Tarim block;

(2) a northern Eocimmerian orogenic belt, widely represented in Afghanistan and the north of Iran; it is a collision-type orogen constructed in the same place as the Hercynian orogenic belt and resulted from the closure of the Paleotethys and the collision of the central Iran and central Afghanistan blocks with the Turan-Turkestan-Tarim block;

(3) a southern Eocimmerian orogenic belt of which outcrops are now confined to southern Iran but which may project beneath the Neogene and Quaternary formations of southern Afghanistan; it is a subduction-type orogen constructed at the margin between the Neotethys and the central Iran-central Afghanistan block, which itself was at that time subjected to regional extension; this belt is now incorporated in the Alpine-Himalayan orogen. The geology of these belts suggests that the opening of the Neotethys became effective only from the Permian or Triassic, and was in a Red Sea-type phase during the Upper Devonian. Its initial rifting possibly occurred during the Lower Paleozoic, much like the Paleotethys, in which initial rifting also occurred in Lower Paleozoic time and whose opening became effective from the Ordovician. Thus, each of the oceanic realms in this region appears to have possibly resulted from the same extension of Gondwanaland during the Lower Paleozoic after which they followed more or less different paths of evolution. Moreover, the proposed geodynamic interpretation implies that during the Permian and Triassic there was in this region a certain coexistence of the vanishing Paleotethys with the relatively young Neotethys, which was beginning to subduct.

B/234. Bridge, J.S., 1996. Architecture of Miocene overbank deposits in northern Pakistan-Discussion. *Journal of Sedimentary Research*, Section B, 65, 401-403.

Willis and Behrensmeyer (1994) have presented a remarkably detailed description and analysis of the architecture of ancient overbank deposits from the Miocene Chinji Formation of northern Pakistan (see also Behrensmeyer 1987, Willis 1993a). They described meters-thick paleosols bounded sequences that are defined by an alternation of relatively mature paleosols and stratified deposits with a lesser degree of pedogenesis. They asserted that the mature paleosols represent relatively long periods of very low deposition rate, whereas the stratified deposits represent relatively short periods of high deposition rate. They proposed and evaluated five end-member hypotheses for the origin of the paleosol-bounded sequences. They concluded that the stratified deposits were formed by local rapid filling of low areas on the floodplain, independently of the position of major channels: such filling may have been a more or less continuous process, or may have been a short-lived event associated with river-channel avulsion. They specifically dismissed the possibility that the nature of the stratified deposits was related to the proximity of major channels and the growth of alluvial ridges. They also dismissed the possibility that paleosol-bounded sequences could have been related to regional variations in sediment supply and deposition rate, or to valley incision and filling. In my view, these far-reaching conclusions are flawed, for three main reasons: (1) whether or not the overbank sediment bodies appear to fill topographic lows in the paleo-floodplain depends critically on the way the stratigraphic cross sections were constructed, which was not justified adequately; (2) the hypotheses for the origin of the stratified deposits are misleading; and (3) the sections studied do not extend sufficiently in a direction normal to paleoflow direction to test adequately the hypotheses presented. I will expand upon these points in turn.

B/235. Bridge, J.S., Behrensmeyer, A.K., Khan, I.A., Willis, B.J. & Zaleha, M.J., 1997. Evolution of Miocene fluvial environments in northern Pakistan. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, 20-23.

Fluvial deposits of the Miocene Siwalik Group (Chinji, Nagri, and Dhok Pathan Formations; age from 15 to 7 Ma), Potwar Plateau, Northern Pakistan were studied in order to: (1) reconstruct the nature and evolution of paleoenvironments across part of the ancient Himalayan foredeep; (2) assess depositional controls such as river diversions, tectonism, climate and base-level change, and; (3) examine the relationship between changing paleoenvironments and faunal evolution. Kilometers-long sedimentologic-paleomagnetic logs were constructed in three separate areas of the Potwar Plateau (near the towns of Chinji, Khaur, and Dma). Detailed sedimentological cross sections (up to 100 m thick and 4 km across), spanning different stratigraphic intervals in each area, were constructed using photomosaics and closely spaced vertical logs. Litho- and chrono-stratigraphic correlation of the strata between the three study areas was attempted.

The strata comprise relatively thick (100 to 101 m) sandstone bodies and mudstones that contain thinner sandstone bodies (101 to 100m) and paleosols. Thick sandstone bodies are km to tens of km wide normal to paleoflow, and are composed of large-scale stratsets (storeys) stacked laterally and vertically adjacent to each other. These sandstone bodies are single or superimposed channel belts of major braided (mainly) and meandering rivers, and large-scale strata sets represent channel bars and fills. Channel belts were km wide, had bankfull river discharges on the order of 103 - 104 cumecs and braiding parameter upto to about 3. Individual channel segments had bankfull widths, maximum depths and slopes on the order of 102 in, 101 m and 104, respectively, and sinuositities around 1.1. Rivers of the Nagri Formation are 2 to 3 times wider and deeper than those of the Chinji and Dhok Pathan Formation. The rivers generally flowed to the southeast. Flow was perennial with seasonal flooding. These rivers are comparable to many of those flowing over the megafans of the modern Indo-Gangetic basin, and a similar depositional setting is likely.

Thin sandstone bodies within mudstone sequences extend laterally for on the order of 102 m and have lobe, wedge, sheet and channel-form geometries; they represent crevasse splays, levees, single sheet-flood deposits and floodplain channels. Mudstones are laminated and variably bioturbated/disrupted and represent mainly floodbasin and lacustrine deposits. Floodplain lakes were both ephemeral and perennial, were up to a few tens of km across and probably less than 10 m deep. Extremely disrupted strata with m-thick horizons with pedogenic features are 'mature'

paleosols that extend laterally for tens of km. Many paleosols have a nodular calcite horizon overlain by a noncalcareous horizon, and were generally formed under relatively well-drained conditions. Other paleosols have matrix calcite and lack such distinct horizons, and formed in relatively poorly drained topographic lows. All mature paleosols indicate extended periods of slow deposition. A variety of features indicate episodic wetting and drying as water tables fluctuated seasonally. Paleosols are similar to modern alluvial soils of the Indo-Gangetic basin, which is consistent with interpretation of a monsoonal paleoclimate. Paleosol-bounded sequences are m to 1Gm thick, km to 10 km wide lenses of stratified, moderately disrupted overbank deposits bounded by mature paleosols. They are interpreted to represent periods of relatively rapid deposition, associated with progradation of crevasse sills-levees into low area of the floodplain, alternating with long periods (103 - 104 years) of very low deposition rate.

Trace fossils and body fossils within all rock types indicate the former existence of terrestrial and aquatic vertebrates, molluscs (bivalves and gastropods), arthropods (including insects), worms, trees, bushes, grasses, and aquatic flora. Vertebrate remains are particularly common, invertebrate (mollusc) remains are uncommon, and plant fossils (including pollen and spores) are rare. Plant macrofossils occur as impressions in crevasse-splay mudstones, and tree-trunk casts in channel fills and upper portions of major channel fills, less common in other floodplain deposits, and relatively uncommon in major channel sandstones. Vertebrate fossils are, thus, more abundant in the Chinji and Dhok Pathan Formations than in the Nagri Formation, with the exception of Nagri locality Y311, that represents an unusual, fine-grained fill of a large-scale abandoned channel.

The proportion of sandstone bodies varies vertically on three scales in all study areas. Relatively small-scale variations are tens-of-in-thick alterations of thick sandstone bodies (major channel deposits) and mudstone-sandstone strata (overbank deposits), or paleosol-bounded sequences, that represent on the order of 103 - 104 years. These can be explained by repeated river avulsions that may be autocycle and/or triggered by tectonic activity. However, some paleosol-bounded sequences may result from local shifts in deposition of crevasse splay-levees without major-channel avulsion.

At an intermediate-scale are 100 m-scale variations in the proportion and thickness of thick sandstone bodies (representing on the order of 104 - 105 years).

Such variations are due to either changes in the thickness of channel-bar deposits or in the degree of superposition of channel belts. They can only be traced laterally for up to tens of km. Theoretical modeling indicates that increases in the proportion and thickness of major channel sandstone bodies can be explained by increasing channel-belt sizes (mainly), average deposition rate and avulsion frequency on a megafan comparable in size to modern examples. 100 in-scale variations could thus result from regional shifts in the position of major channels on a megafan, or temporal changes in sediment input and/or basin subsidence resulting in progradation and retrogradation of individual megafans.

The largest scale variations define Formations (i.e. 102 to 103 m thick, representing on the order of 105 -106 years). The Nagri Formation has more abundant and thicker and coarser grained sandstone bodies than the Chinji and Dhok Pathan Formations. This increase in thickness and abundance of sandstone bodies is due mainly to increase in thickness of channel-bar deposits (i.e. channel size), but also to increasing superposition of channel belts. As proportion of sandstone bodies increases, deposition rates increase and paleosols are less well developed. Formations can be correlated across the Potwar Plateau for at least 100 km, although they may be diachronous by on the order of a million years. Formation boundaries in the Potwar Plateau decrease in age towards the west.

Formations and 100 in-scale stratal variations may be associated with regional changes in tectonic uplift, climate sediment supply and basin subsidence. The Nagri Formation possibly resulted from diversion of a relatively large river and its associated megafan to the Potwar Plateau area. River diversion or piracy was possibly associated with spatially variable increases in uplift and subsidence rates, and probably took place in the mountain belt. Alternatively, changing river sizes and sediment supply rates may be related to climate changes affecting the hinterland (but possibly also linked to tectonic uplift). The deposits generally yield no direct evidence for climate change in the sedimentary basin: however, independent evidence indicates global cooling throughout the Miocene, and the possibility of glacial periods (e.g. around 10.8 Ma, corresponding to base of Nagri Formation), fluctuations in the degree of glaciation of the higher Himalayas may have resulted in varying sediment supply to megafans on time scales of 104 to 106 years. Eustatic sea-level changes are associated with global climatic change: however, they are not directly related to Siwalik stratigraphic changes because the Potwar Plateau was 1000 km from the Miocene shoreline. There is a period of vertebrate faunal extinctions between 13 and 12 Ma that may be correlated with global cooling, and a faunal turnover near the base of the Nagri Formation may be related to faunal immigration during a sea-level low stand.

Stable carbon and oxygen isotopes in pedogenic carbonate nodules indicate a marked shift in vegetation and climate from 8 to 6 Ma. The shift from C3 and C4-dominated vegetation recorded in the carbon isotope shift, and the increase in soil evaporation inferred from the oxygen isotope shift, indicate intensification of the regional monsoon

and increased seasonality (warmer dry periods and more pronounced wet seasons). This climate change is not reflected in the alluvial architecture of the Dhok Pathan Formation, although there are some changes in paleosols that may be linked to the climate shift. However, the vertebrate fauna shows a prolonged period of turnover associated with this change, with declining species diversity and extinction of some notable taxa such as *Sivapithecus*. This is consistent with the replacement of woodlands and forest with drier, more open habitats. Thus, it appears that the history of the Siwalik biota was tied to climatic changes in the depositional basin and faunal migrations from other regions, and not to changes in the Siwalik fluvial systems that were more strongly linked to the tectonics and climate of the Himalayan source areas. Identification of specific controls on depositional environments, alluvial architecture and faunal change will require more sedimentologic-paleomagnetic studies from other parts of the basin.

The occurrence of ophiolite nappes has been considered evidence for the siting of ancient subduction zones. A study of the detailed stratigraphy and plate motions associated with Upper Mesozoic to Pliocene ophiolite nappes of the Pacific, Indian and Mediterranean shows that transcurrent faulting during changes in relative plate motions is the major cause of initial ophiolite nappe emplacement. Giant ophiolite nappes are not related to subduction zones or island arcs.

In terms of simple metamorphic facies scheme and sketch map, the paper summarizes the metamorphic events and history of the hitherto little known areas of northwestern India and Pakistan (north of the main Himalayan ranges). The evidences suggest following four main phases of metamorphism:

(1) Mid-Cretaceous metamorphism was associated with the development of an island arc along the Indus suture zone. The volcanic arc core is represented by transitional low-intermediate pressure regional metamorphism, while in the south the fore-arc region represented by sedimentary and ophiolitic *mélange* contains fragmentary glaucophane schists.

(2) Late Eocene to Oligocene metamorphism was associated with the development of an Andean-type magmatic arc on the northern edge of the Indian plate (the Ladakh batholith complex). This consists of medium-pressure Barrovian regional metamorphism towards the east. At higher level, lower pressure metamorphism towards the west is observed.

(3) Miocene metamorphism was associated with the development of the Andean-type Karakorum magmatic arc on the southern edge of the 'Tibetan' plate. This has a relatively high pressure metamorphic belt in the south (the Shyok *mélange*) with a Barrovian medium-pressure belt in the north (Karakorum batholiths).

(4) Post-Miocene low-pressure regional metamorphism was associated with the late stage anatectic granites of the Karakorum mountains.

B/244. Brookfield, M.E., 1993a. Paleodrainage patterns and basin evolution of the NW Himalaya. Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 7.

During the late Tertiary the NW Himalaya rose rapidly due to crustal shortening, thickening and differential erosion. At the same time adjacent basins subsided accumulating thick prisms of sediments, which were continually compressed, uplifted and eroded as thrust sheets migrated over them. The interplay of tectonism with erosion by changing river systems is particularly apparent in the Pamir arc, which indented Asia only within the last 20 ma, involving almost 1000 km northward thrusting of already assembled collision belts over the Tadjik marginal basin.

The age and nature of the foredeep sediments of the Tarim and Tadjik basins have been used to infer pulses of contemporary tectonism in the mountains. Net rates of erosion derived from radiometric and fission track dating, sediment budgets and river drainages can be compared with GROSS rates of uplift derived from fossil faunas and floras. These studies show that each range has an independent history of uplift and erosion within the framework of generally increasing late Tertiary uplift. And so has each basin. Deposition in basins is determined by the courses of the major rivers, which have not remained constant. The thickness of sediment accumulating in marginal basins and the isostatic uplift of ranges depends on when rivers changed their courses, on when and how much temporary storage occurred within intermontane basins, and the time at which the intermontane barriers were breached and their sediments eroded.

Establishing the Cenozoic courses of the major rivers of Central and Southeast Asia shows that coarse clastic sediment pulses cannot be used to infer increased tectonism in adjacent ranges, they may simply reflect river capture. Though this places constraints on the tectonic history of collision, it also provides an opportunity to reconstruct the landscape as well as orogenic evolution of the mountain belt.

Key words: Paleodrainage, basin evolution, Himalayan orogeny.

B/245. Brookfield, M.E., 1993b. The interrelations of post-collision tectonism and sedimentation in Central Asia. International Association of Sedimentologists, Special Publication 20, 13-35.

During the Late Tertiary the northwest Himalaya and adjacent ranges underwent progressively increasing uplift associated with crustal thickening and differential erosion. At the same time the adjacent Tarim and Tadjik basins

and the Himalayan foredeeps subsided accumulating thick piles of clastic sediments. The ages of these accumulations have been used to infer contemporary tectonism in the mountains. Radiometric and fission track dating together with faunal and floral studies and sediment budget and river drainage studies allow gross rates of uplift and subsidence to be compared with net rates for different areas. These studies show that the bulk of the derived clastics were eroded from the fronts of the Karakorum, Himalayan and Pamir allochthons during progressively increasing rates of uplift and thrusting from Early Miocene times onwards. Nevertheless, cooling Cenozoic climates, partly driven by uplift, have also contributed to increasing physical erosion and coarsening of the deposited sediments through time. Furthermore, each range shows an independent history of uplift and erosion within the framework of generally increasing uplift and erosion in Late Tertiary times. Contemporary deposition in adjacent basins is partly dependent on the timing of adjacent uplifts. But uplift and deposition also depend on erosion and deposition along the courses of major rivers which have not remained constant. The thickness of sediment accumulating in marginal basins and the isostatic uplift of ranges depend on when the river changed its course, on when and how much temporary storage occurred within intermontane basins, and the time at which the intermontane barriers were breached and their sediments eroded. In some cases, e.g. the Indus, Tsangpo, Salween and Mekong, the rivers have even switched into different major oceans or basins. Coarse clastic sediment pulses cannot be used to infer increased tectonism in adjacent ranges.

B/246. Brookfield, M.E., 1993c. The Himalayan passive margin from Precambrian to Cretaceous times. *Sedimentary Geology* 84, 1-35.

The Himalaya passive margin should be separated into the Indian Himalaya and the Pakistan Himalaya, divided by the Nanga Parbat-Haramosh basement uplift in the northwestern syntaxes. The Indian passive margin shows a complex history involving splitting of microcontinents off the northern Gondwana margin from early Paleozoic times until the Jurassic. In contrast, the Pakistan Himalaya formed part of the stable Indian shelf until separation from Africa started in the Jurassic. Each margin has a distinct stratigraphic history until the mid-Mesozoic after which they show similar histories until the Tertiary.

The Himalaya mountains in India consist of three distinct tectonic units juxtaposed during the Neogene by southward thrusting of the northern Indian Precambrian to Mesozoic passive margin. The Lesser Himalaya on the south forms a late Precambrian passive margin usually directly overlain by late Cretaceous to Tertiary clastics: its stratigraphy is closest to that of the Indian Shield. In contrast, the High Himalaya has a thin Ordovician to Carboniferous shelf sequence deposited after early Ordovician deformation and granite intrusion. Above this, thick Permian and Mesozoic shelf sequences mark the separation of continental blocks off the northern Indian margin and the opening of the Neotethys ocean. The North Himalaya formed the slope and basin of this ocean and consists of reactivated Paleozoic gneiss domes overlain by thick Mesozoic sediments which pass, in the northeastern Himalaya, into an enormously thick sedimentary sequence resting on oceanic crust.

Paleomagnetic and structural evidence indicates at least 500 km of southward thrusting along the Main Central Thrust between the Lesser and High Himalaya. This thrusting, together with a further 250 km of erosion at the front of the nappes, has removed the entire inner shelf of the Himalaya passive margin and can explain the startling contrast between the High and Lesser Himalaya stratigraphic sequences. But there are still discrepancies, particularly in the eastern Himalaya, where Precambrian basement is juxtaposed with the North Himalaya Mesozoic slope. These discrepancies can be partly resolved by strike-slip movements roughly parallel to the Himalaya which have removed parts of the northern Indian passive margin. Such faults of the requisite orientation, displacement and age occur in southeast Asia where their cumulative displacements can add up to several thousand kilometres. Similar faults, of undoubted pre-Tertiary age, occur in the Pakistan Himalaya. Here, the passive margin shows a much simpler history of Jurassic to Miocene subsidence.

B/247. Brookfield, M.E., 1998. The evolution of the great rivers systems of southern Asia during the Cenozoic India-Asia collision: rivers draining southwards. *Geomorphology* 22, 285-312.

During uplift of the Tibetan plateau and surrounding ranges, tectonic processes have interacted with climatic change and with local random effects (such as landslides) to determine the development of the major river systems of Asia. Rivers draining southward have three distinctive patterns that are controlled by different tectonic and climatic

regimes. In central and southern Afghanistan, the rivers have moderate gradients and fan out from northeastern sources to disappear into arid depressions. Anti-clockwise rotation of southern Afghanistan, caused by differential compression and right-lateral shear, cut the rivers on the north, while increasingly arid conditions developed on the south as arc accretion in the Makran separated sources from the coastal rains. In Tibet and southeast Asia, the rivers are widely separated and have low gradients on the Tibetan plateau, higher gradients as they turn southwards into close and parallel gorges, before they fan out southeast to enter different seas. Differential shear and clockwise rotation between the compressing Tibetan plateau and Southeast Asia determined the great sigmoidal bends of this river system which was accompanied by increasing aridity, with truncation of river systems in the north and river capture in the south. In the Himalaya and southern Tibet, the main rivers have steep gradients where they cut across the Himalayan range and occasionally truncate former rivers with low gradients on the Tibetan plateau to the north. Southward thrusting and massive frontal erosion of the Himalaya caused progressive truncation of longitudinal rivers on the plateau, accompanied by river capture, and glacial and landslide diversions on the south. The drainage history of southern Asia can be reconstructed by restoring the gross movements of the plates and the tectonic displacement, uplift, and erosion of individual tectonic units. Most important changes in drainage took place in Pliocene to Quaternary times.

B/249. Brookfield, M.E. & Reynolds, P.H., 1981. Late Cretaceous emplacement of the Indus Suture Zone ophiolitic mélange and an Eocene-Oligocene magmatic arc on the northern edge of the Indian Plate. *Earth and Planetary Science Letters* 55, 157-162.

We report three $^{40}\text{Ar}/^{39}\text{Ar}$ dates (on stratigraphically located samples) of 82 ± 6 Ma from a syenite cutting the Indus suture zone ophiolitic mélange and about 39 and about 45 Ma from granodiorite intrusions north of the suture zone. Sedimentological observations indicate Eocene to Miocene deposition of coarse clastics by very large braided and meandering streams in a continental back-arc setting. These observations suggest that the ophiolitic mélanges of the Indus suture zone were emplaced in the late Cretaceous, shortly after a major change in plate motions in the Indian Ocean: they further suggest that an Andean-type magmatic arc developed on the northern edge of the Indian plate during the Eocene and Oligocene.

Key words: Ophiolites, Indus Suture Zone, mélange, magmatic arc, Indian Plate, Late Cretaceous collision.

B/250. Brookfield, M.E. & Reynolds, P.H., 1990. Miocene $^{40}\text{Ar}/^{39}\text{Ar}$ ages from the Karakoram Batholith and Shyok Mélange, northern Pakistan, indicate Late Tertiary uplift and southward displacement. *Tectonophysics* 172, 155-167.

The magmatic arc of the Karakorum Mountains is separated from the Cretaceous-Tertiary Kohistan arc sequence by an ophiolitic mélange-the Shyok Mélange. Two views of the age of the Shyok Mélange and Karakorum arc are: (a) that they represent a mid-Mesozoic arc-trench complex which collided with the Kohistan arc in the Cretaceous before the closure of the main Tethys ocean to the south; and (b) that they represent a late Tertiary arc-trench complex which closed in the late Miocene, representing final subduction of Tethyan sea-floor. Whether final destruction of ocean crust took place in the Mesozoic or Tertiary has important implications for current models of the development of the Indian-Asian collision zone. Here are reported ages of between 20 and 8 Ma, suggesting that final assembly and uplift did not occur until the late Tertiary; and that the Shyok Mélange is the structural equivalent of the Main Central Thrust of the Himalaya to the east. Like the Main Central Thrust, the Shyok Mélange appears to mark intraplate continental subduction which is mainly responsible for Tertiary granitoid intrusion, deformation and uplift in the High Himalaya and Karakorum to the north.

B/252. Broughton, R.D., Windley, B.F. & Jan, M.Q., 1984. Reaction isogrades and P–T estimates in metasediments on the edge of the Karakorum plate, Hunza, N. Pakistan. *Abstracts, First Geological Congress, Lahore*, p.58.

The Hunza area of North Pakistan contains a metasedimentary sequence on the southern margin of the Karakorum Plate. The sequence is largely pelitic with carbonate layers, cut by amphibolite and granitic sheets, and is bounded to the N E by the Karakorum batholith, and to the S W by the Northern Suture at Chalt. The grade of metamorphism increases from S W to N E and this is marked by variation in mineral chemistry, and changes in mineral assemblages at a series of reaction isograds, which separate zones in which stable mineral pairs are; garnet - chlorite, chloritoid-biotite, staurolite-biotite, kyanite - biotite and sillimanite-biotite from S W to N E respectively. A reaction isograd marked by the paragenesis; forsterite-diopside-calcite-dolomite occurs in the siliceous dolomites. The northeasterly dip of the isograds indicates that the zones are inverted. At Hunza, maximum metamorphic conditions given by pelitic rocks are 632° C and 5.5 kb. The temperature obtained from calc-silicate rocks is 669°C at 5.5 kb, with CO₂, F1 0.66. The inversion of the metamorphic zones was associated with major southward thrusting during collision of the Karakorum Plate with the Kohistan Arc.

Key words: Isogrades, P-T estimates, metasediments, Karakoram, Hunza.

B/253. Broughton, R.D., Windley, B.F. & Jan, M.Q., 1985. Reaction isogrades and P–T estimates in metasediments on the edge of the Karakorum plate, Hunza, N. Pakistan. *Geological Bulletin University of Peshawar* 18, 119-136.

The Hunza area of N. Pakistan contains a metasedimentary sequence on the southern margin of the Karakorum Plate. The sequence is largely pelitic with carbonate layers, cut by amphibolite and granite sheets, and is bounded to the N. E. by the Karakorum Batholith, and to the S. W. by the Northern Suture at Chalt.

The grade of metamorphism increases from S. W. to N. E., and this is marked by variation in mineral chemistry, and changes in mineral assemblages at a series of reaction isograds, which separate zones in which stable mineral pairs are: garnet-chlorite, chloritoid-biotite, staurolite-biotite, kyanite-biotite and sillimanite-biotite from S. W. to N. E. respectively. A reaction isograd marked by the paragenesis, forsterite-diopside-calcite-dolomite occurs in the siliceous dolomites, and the northeasterly dip of the isograd indicates that the zones are inverted.

At Hunza, maximum metamorphic conditions given by pelitic rocks are 669 °C and 5.5 kb, with XCO₂, F1=0.66. The inversion of the metamorphic zones was associated with major southward thrusting during collision of the Karakorum Plate with the Kohistan Arc.

B/256. Brozovic, N., Burbank, D.W. & Meigs, A.J., 1997. Climatic limits on landscape development in the northwestern Himalaya. *Science* 276, 571-574.

The interaction between tectonism and erosion produces rugged landscapes in actively deforming regions. In the northwestern Himalaya, the form of the landscape was found to be largely independent of exhumation rates, but regional trends in mean and modal elevations, hypsometry (frequency distribution of altitude), and slope distributions were correlated with the extent of glaciation. These observations imply that in mountain belts that intersect the snowline, glacial and periglacial processes place an upper limit on altitude, relief, and the development of topography irrespective of the rate of tectonic processes operating.

The rock fall secree slope model in which there is a size difference down slope on sacress formed by rock fall processes was shown to apply to Karakoram screes. These simple relationships were shown to be disturbed by subsequent mass movement processes to produce distinctive patterns of stripes, festoons and scallops. The patterns are described for large and small screes and scallops. The patterns are described for large and small screes and various processes. Considerable differences in grain size are caused by dry grain flow, shallow sliding and mudflow or debris avalanche.

B/264. Buchroithner, M.F., 1980. An outline of the geology of the Afghan Pamirs. *Tectonophysics* 62, 13-35.

In the Great Afghan Pamir (Pamir-e Kaland) the following formations can be distinguished, from bottom to top: Wakhan Fm. (3000–4000 m thick anchimetamorphic slates and sandstones with frequent intercalations of quartzites and rare beds of crystalline limestones; conodonts of Lower Triassic); Qala-e Panja Tonalite (epimetamorphic, cataclastic); Qal'a-e Ust Gneiss (meta- and orthogneisses); Issik Granodiorite (batholite of the Afghan Pamirs, equivalent to Baba Tangi-Lunkho Granodiorite; xenoliths, flow structures and diaphtoritic portions; Upper Jurassic to Eocene). The tectonics are determined by the Peripheric Southern Fault of the Pamirs and the Wakhan Fault, showing vertical dislocation up to 1000 m and sinistral thrusting in connection with the Western Himalayan Syntaxis. Late Variscan and Alpine deformations and an intensive middle Alpine metamorphism can be observed. Interpretations of satellite pictures lead to an insertion of the regional tectonic features into the model of plate tectonics of the Himalayan arc. The paper is of interest for those working in Chitral because some of the Pamir rocks extend there through Wakhan.

B/273. Buksh, M.N. & Mohammad, F., 1963. Preliminary survey and chemical investigation on iron ore of Khyber Agency. Pakistan Journal of Scientific and Industrial Research 6(1), 21-24.

Iron ore outcropping at several localities near Jamrud and elsewhere was found to be too siliceous for profitable beneficiation. The occurrences are briefly described, and the hematitic ore at Lashoora is described in greater detail because of its larger size and relatively high iron content.

Key words: Iron ore, Khyber Agency.

B/274. Bunch, T.E. & Okrusch, M., 1973. Al-rich paragasite. American Mineralogist 58, 721-726.

Two Al-rich amphiboles were found in a corundum- and spinel-bearing calcite marble together with minor phlogopite, margarite, anorthite, and sphe or rutile. Microprobe analyses give half their unit cell contents as:

Amphibole AA-5, $\text{Na}_{0.54} \text{K}_{0.16} \text{Ca}_{1.99} \text{Mg}_{3.35} \text{Fe}_{0.01} \text{Ti}_{0.16} \text{Al}^{\text{vi}}_{1.47} \text{Al}^{\text{iv}}_{2.26} \text{Si}_{5.74} \text{OH}_{1.4} \text{F}_{0.40} \text{Cl}_{0.07}$;

Amphibole HA-1/2, $\text{Na}_{0.67} \text{K}_{0.17} \text{Ca}_{1.99} \text{Mg}_{3.62} \text{Fe}_{0.07} \text{Ti}_{0.27} \text{Al}^{\text{vi}}_{1.12} \text{Al}^{\text{iv}}_{2.25} \text{Si}_{5.75} \text{OH}_{1.05} \text{F}_{0.55} \text{Cl}_{0.02}$.

Amphibole AA-5 is the most aluminous yet found in nature (22.6 wt percent Al_2O_3) and contains essentially no Fe (total iron as FeO : 0.05 wt percent).

Both amphiboles are too rich in Al^{iv} (viz, high Al_2O_3 , combined with low SiO_2) to consider them as mixed crystals strictly intermediate between pure pargasite and pure tschermakite. Al-rich pargasite appears to be a suitable name for amphiboles of this composition, owing to the fact that more than 50 percent of their structural formulae can be recalculated in terms of a hypothetical end-member molecule Al-pargasite, $(\text{Na},\text{K})\text{Ca}_2\text{Mg}_3\text{Al}^{\text{vi}}_2 \text{Al}^{\text{iv}}_3 \text{Si}_5\text{O}_{22}(\text{OH},\text{F})_2$, which conforms to the limiting $\text{Al}^{\text{iv}}/\text{Al}^{\text{vi}}$ ratio of Ca-amphiboles statistically evaluated by Leake (1965, 1971).

The water determination and X-ray powder data are given for one of the amphiboles but not for the other owing to insufficient material. Conditions for the crystallization of the Al-rich amphiboles are briefly discussed.

Key words: Mineralogy, amphiboles, Hunza.

B/275. Bundschun, J., 1992. Hydrochemical and hydrogeological studies of groundwater in Peshawar Valley, Pakistan. Geological Bulletin, University of Peshawar 25, 23-37.

In September 1988 a comprehensive three months program for hydrogeochemical groundwater investigations in Peshawar Valley in the North West Frontier Province (NWFP) of Pakistan was carried out. Its main aim was to classify the groundwater chemically in order to limelight the regional differences and highlight problems related to drinking and irrigation water in the region. About 100 water samples were collected from wells and analyzed. The elevation of the groundwater table in Peshawar Valley is < 5 m deep, except in areas near the mountains and in the southeast where it ranges from 5 to > 30 m. There is a general groundwater flow towards the center of the basin from where the discharge is towards the Indus Valley. It has been noticed that the electrical conductivity (EC-values) increases from < 800 S/cm near the mountains to a maximum of 7800 S/cm in the center of the basin. Similar is the case of mineralization.

The groundwater has been classified according to PIPER. In Peshawar Basin predominantly low mineralized groundwaters of the type "normal alkaline earth freshwater prevailing hydrogencarbonatic" and "normal alkaline earth freshwater with higher contents of alkalies prevailing hydrogencarbonatic" are present. These groundwaters are of good quality. Only in its central part highly mineralized groundwater of the type "alkaline freshwater either hydrogencarbonatic or sulfatic-chlorotic" are found. This high mineralization in combination with the low depth of the groundwater table causes salification of the soils in the center of Peshawar Basin, i.e. Risalpur and its surroundings. It is concluded that the use of such highly mineralized drinking and irrigation water should be abandoned as soon as possible because of the expected hazards to human health and irrigation. It is highly recommended that deeper wells should be drilled to find low mineralization groundwater in this area.

B/276. Burbank, D.W., 1982. The chronologic and stratigraphic evolution of the Kashmir and Peshawar intermontane basin, Northwestern Himalaya. Ph.D. Thesis, Dartmouth College, Hanover, New Hampshire, USA, 291p.

Consult the following account for further information.

Key words: Chronology, stratigraphy, intermontane basin, Kashmir, Peshawar, Himalaya.

B/277. Burbank, D.W., 1983a. The chronology of intermontane-basin development in the northwestern Himalaya and the evolution of the northwest syntaxis. Earth and Planetary Science Letters 64, 77-92.

The Northwest Syntaxis delineates a complex zone where the northwesterly trending Himalayan Ranges meet the northeasterly trending Hindu Kush and Indus Kohistan Ranges. The southern margin of the Hindu Kush-Himalayan collisional belt is delineated by a series of imbricate thrusts that transect the northern edge of the modern Indo-

Gangetic foredeep. The Kashmir and Peshawar Basins are embedded in this still-developing thrust belt and are symmetrically oriented about the Northwest Syntaxis.

Consideration of chronologic, stratigraphic, structural, and geophysical data from the syntaxial zone permits the construction of a model for intermontane-basin development and the evolution of the Northwest Syntaxis during the Late Cenozoic. The formation of the Kashmir and Peshawar Basins results from the transfer from the north of the locus of thrusting and uplift to the southern margins of the basins. During the Pliocene, the morphotectonic emergence of the ancestral Pir Panjal and Attock Ranges along the southern margins of the two basins coincides with changes in the patterns of sedimentation and deformation both within the basins and in the bounding foredeep to the south. Contrasting styles of tectonic deformation on opposite sides of the Syntaxis are interpreted as a response to differences in the strength of sediment-basement coupling across the Syntaxis.

B/280. Burbank, D.W., 1991. Models of aggradation versus progradation in the Himalayan Foredeep. *Geological Society of America, Special Paper* 232, 113-128.

A frequent goal of decompaction analysis is to reconstruct histories of basin subsidence and tectonic loading. In marine environments, eustatic and paleobathymetric uncertainties limit the resolution of these reconstructions. Whereas in the terrestrial basins, these ambiguities are absent, it is still necessary to account for depositional slopes between localities in order to analyze three-dimensional patterns of subsidence. We define two end-members for depositional surfaces: aggradation and progradation. The relative importance of either end-member is a function of the interplay between the rate of net sediment accumulation and the rate of basin subsidence. The models predict the patterns of major drainages (transverse versus longitudinal) and the way in which provenance should be reflected within different portions of a basin. Consequently, paleocurrent and provenance data from the ancient stratigraphic record can be used to distinguish between these endmembers. The subhorizontal depositional surfaces that dominate during times of aggradation provide a well-defined reference frame for regional analysis of decompacted stratigraphies and related subsidence. Depositional slopes during progradation cannot be as precisely specified, and consequently yield greater uncertainties in reconstructions of subsidence. These models are applied to the Mio-Pliocene foreland basin of the northwestern Himalaya, where sequences of isochronous strata have been analyzed throughout the basin. These time-controlled data delineate a distinctive evolution from largely aggradational to largely progradational depositional geometries as deformation progressively encroaches on the foreland. Such a reconstruction of past depositional surfaces provides a well constrained reference frame for subsequent integration of subsidence histories from throughout the foreland.

Key words: Aggradation, progradation, foredeep, Himalaya.

B/281. Burbank, D.W. & Beck, R.A., 1989a. Synchronous sediment accumulation, decompaction and subsidence in the Miocene foreland basin of northern Pakistan. *Geological Bulletin University of Peshawar* 22, 11-24.

Previous magnetostratigraphic studies in northern Pakistan provide a tightly constrained temporal framework within which to analyze the sediment accumulation history of the northwestern Himalayan foreland basin. Paleocurrent and provenance data indicate that a longitudinal drainage system flowing to the ESE persisted through much of the middle and late Miocene deposition. The subhorizontal cross-sectional surfaces defined by the paleodrainage configurations provide a reference frame for analyzing subsidence histories. Six magnetic sections in the Potwar Plateau have been decompacted as a function of burial depth and lithology to provide both accumulation and subsidence records. These records demonstrate consistently higher amounts of accumulation and subsidence in the northern portions of the basin, but also indicate that events of tectonic loading were experienced synchronously across the basin. Inflections in the curves of tectonically induced subsidence suggest that an important interval of thrust loading began ~ 11.5 Ma and terminated ~8 Ma.

B/282. Burbank, D.W. & Beck, R.A., 1989b. Early Pliocene uplift of the Salt Range; Temporal constraints on thrust wedge development, northwest Himalaya, Pakistan. In: Malinconico, L.L. & Lillie, R.J. (Eds.), *Tectonics of the Western Himalayas*. Geological Society of America, Special Paper 232, 113-128.

Recent chronologic and stratigraphic studies in the northwestern Himalayan foreland basin have led to better constrained deformational and depositional histories. In order to test the hypothesis that considerable pre-Pleistocene uplift occurred in the Salt Range of northern Pakistan, the stratigraphic record adjacent to the central and eastern Salt Range has been examined. Unconformities, paleomagnetically documented tectonic rotations across these unconformities, and changes in the paleocurrent directions, provenance, and rates of sediment accumulation serve to delineate an interval of early Pliocene uplift of the Salt Range, as well as several late Pliocene-Pleistocene uplift events in thin range and adjacent structures. Stratigraphic, reflection seismic, and structural data indicate that these uplift events resulted from thrusting related to the salt- lubricated Potwar detachment. When considered in conjunction with the chronology of deformation in other parts of the foreland, these data clearly indicate that out-of-sequence thrusting has occurred on a large scale (>100 km) during the past 6 m.y. This pattern of deformation supports the concept that an irregular spatial and temporal distribution of shortening should be expected to occur within an advancing thrust wedge.

Key words: Structure, Pliocene, Salt Range.

B/283. Burbank, D.W., Beck, R.A. & Mulder, T., 1996. The Himalayan foreland basin. In: Yin, A. & Harrison M. (Eds.), *The Tectonic Evolution of Asia*, Cambridge University Press, 149-189.

Tectonic loading during the Cenozoic growth of the Himalaya created the Indo-Gangetic foreland basin, a flexural depression that is the largest terrestrial foreland basin on the earth's surface. Stratigraphic, chronologic, petrographic, sedimentological and structural data from across the foreland are synthesized here to produce an overview of the Cenozoic evolution of this basin. Within the foreland, variations in crustal rigidity along the strike and the presence of long-lived basement faults have modulated its width and large-scale subsidence patterns. During most of the Cenozoic, the rates of migration of the distal basin pinch-out and of the foreland depocenter suggest that about 20% of the Indo-Asian convergence has been accommodated by thin-skinned thrusting within the foreland, often related to detachments localized at the top of the basement or in incompetent foreland strata, and by thrusts with hanging walls more than 4-10-km thick along its proximal margin. Episodic southward relocation of these basin-margin thrusts has served to define large intermontane basins.

Although the early foreland deposition is poorly documented, ≥8-km of Paleogene strata have accumulated in proximal locations and show clear Himalayan derivation. Neogene deposition encompasses the Siwalik Group strata of Miocene and younger age. In northwestern Pakistan and parts of India and Nepal, excellent time controls derived from magnetostratigraphic studies permit detailed correlations, analyses of accumulation and subsidence patterns, and delineation of the interrelationships between deformation and deposition. During early and middle Miocene times, axial rivers, fed by numerous oblique tributaries, appear to have followed southeastward from northwestern Pakistan into the Ganges drainage. In northwestern Pakistan, a major stratigraphic change occurred at about 11 Ma: Accumulation rates increased 30-200%, sandstone abundances doubled, fluvial discharges increased fivefold and a major influx of detritus occurred, attributed to unroofing of the Kohistan island-arc. Upward coarsening and accelerated accumulation also prevailed in India and Nepal. Those changes are interpreted as having resulted from

initial motion and loading by the Main Boundary Thrust at about 11 Ma, approximately 5 m.y. earlier than previously documented.

Proximal portions of the foreland are more abundantly represented within the preserved Upper Neogene strata. As deformation encroached on the foreland, depositional environments and regimes of accumulation and erosion became increasingly heterogeneous. On the basis of scale, petrology, and dispersal patterns, often four river systems can be delineated within the foreland as it became structurally disrupted: an axial river, large transverse rivers with hinterland catchments, and rivers sourced on newly created intra-foreland uplifts. Late Miocene-Pliocene growth of the Salt Range at the southern limit of a 100-km wide salt-lubricated detachment in northwestern Pakistan initially created a large piggyback basin that localized the ancestral Indus River. Continued shortening caused diversion of the Indus to the southwest, coinciding with rapid accumulation and southward pinch-out migration in the Trans-Indus region. Large-scale out-of-sequence thrusting occurred in northwestern Pakistan between 6 Ma and 1 Ma, coeval with deposition Plio-Pleistocene intermontane basins ponded behind major basin-bounding thrusts. Across the foreland, records of initial conglomeratic strata indicate highly diachronous progradation (ranging from >8 to <1 Ma) that was strongly influenced by fluvial interactions with local folds and thrusts. Whereas tectonic loading appears to continue to control depositional patterns in the Indus foreland, changes in the position of the axial river and in cross-sectional stratal geometries suggest that erosional unloading during the past 4-5 m.y. has become increasingly important in the Himalaya adjacent to the Gangetic foreland. This may be a response to expanding glacial climates. In contrast, the inferred strengthening of the Asian monsoon at about 7-8 Ma does not appear to have led to an increased detrital-sediment flux to the foreland.

Major unresolved problems in the Himalayan foreland included the following: our poor understanding of its Paleogene history; sparse reliable chronologic control in the central and eastern foreland; absence of clear “fingerprinting” that could tie foreland strata to specific hinterland source areas; inadequate seismic analysis of foreland structure; poorly understood climatic influences on deposition and erosion; and uncertainties regarding strain partitioning and its variation along strike within the foreland.

B/284. Burbank, D.W., Beck, R.A., Raynolds, R.G.H., Hobbs, R. & Tahirkheli, R.A.K., 1988. Thrust and gravel progradation in foreland basins: A test of post-thrusting gravel dispersal. *Geology* 16, 1143-1146.

The use of gravels as syntectonic indicators of thrusting has recently been questioned by foreland-basin models that assign gravels to a post-thrusting interval of progradation, except in very proximal areas. On the basis of precise temporal control provided by magnetostratigraphically dated sections, the history of gravel progradation after a major thrusting and uplift event in the northwestern Himalaya is shown to be a virtually syntectonic phenomenon. Despite considerable crustal subsidence driven by a thick-skinned thrust, gravels prograded ~ 70 km during a 1.5-m.y.-long thrusting event. By 3 m.y. after the start of thrusting, gravels extended more than 110 km into the basin. Although delayed gravel progradation appears appropriate for many Rocky Mountain foreland basins, it is clearly not valid for the Himalaya. We attribute the difference in depositional response between these basins to differences in the quantity of sediment supplied to them (sediment starved vs. overfilled), the availability of resistates in the source area, and the size of the antecedent drainage.

B/286. Burbank, D.W. & Johnson, G.D., 1983. The Late Cenozoic chronologic and stratigraphic development of the Kashmir intermontane basin, northwestern Himalaya. *Palaeogeography, Palaeoclimatology Palaeoecology* 43, 205-235.

The intermontane basin of Kashmir developed within the thrust-faulted, southern margin of the Himalayan Range. Detailed lithostratigraphies, magnetic-polarity stratigraphies, and fission-track dates on enclosed volcanic ashes were determined at four separate localities in order to develop a chronology of the Late Cenozoic evolution of the Kashmir Basin.

The results indicate that sedimentation had commenced by about 4 m.y. ago. Since then, over 1300 m of sediments have aggraded at inferred average rates varying from 16 to 64 cm per 1000 yr. Lacustrine and deltaic sediments dominate the Kashmiri sequences and appear to respond sensitively to tectonic events along the basin margins. Conglomerates shed from the faulted basin margins at about 1.7, 2.1, 2.7, and 3.0–3.5 m.y. ago punctuate the predominantly low-energy, fluviolacustrine depositional record. Paleocurrent analyses indicate a switch from northeasterly derived conglomeratic facies to southwesterly derived ones about 1.7 m.y. ago. This transition reflects enhanced activity along the Main Boundary Thrust complex to the southwest and an apparent diminution of faulting along the northeastern margin of the basin. In the Pir Panjal Range, 1400–3000 m of uplift at inferred rates of up to 10 mm yr⁻¹ have terminated widespread sedimentation within the Kashmir Basin since the middle Pleistocene.

The topography of tectonically active mountain ranges reflects a poorly understood competition between bedrock uplift and erosion. Dating of abandoned river-cut surfaces in the northwestern Himalayas reveals that the Indus river incises through the bedrock at extremely high rates (2–12 mm yr⁻¹). In the surrounding mountains, the average angles of hillslopes are steep and essentially independent of erosion rate, suggesting control by a common threshold process. In this rapidly deforming region, an equilibrium is maintained between bedrock uplift and river incision, with landsliding allowing hillslopes to adjust efficiently to rapid river down-cutting.

B/288. Burbank, D.W. & Raynolds, R.G.H., 1984. Sequential Late Cenozoic structural disruption of the northern Himalayan foredeep. *Nature* 311, 114-118.

Chronologies for the Siwalik molasse and intermontane basins along the southern margin of the Himalaya and Hindu Kush Ranges constrain the timing and pattern of facies migration and structural disruption of the Indo-Gangetic foredeep. This synthesis indicates that quiescent intervals are punctuated by pulses of rapid deformation as thrusting migrates in a stepwise fashion across the foredeep.

B/291. Burbank, D.W. & Tahirkheli, R.A.K., 1985. The magnetostratigraphy, fission-track dating, and stratigraphic evolution of Peshawar intermontane basin, northern Pakistan. Geological Society of America, Bulletin 96, 539-552.

The Peshawar basin is situated along the junction of the northern margin of the Indo-Gangetic foredeep and the southern margin of the Hindu Kush-Himalayan Ranges. During the late Cenozoic, southward encroachment of tectonic disruption into the foredeep terminated molasse deposition and delineated the Peshawar intermontane basin through uplift of the Attock Range along the southern margin of the basin. In this study, magnetostratigraphy, fission-track dates on volcanic ashes, and stratigraphic data are used to define the chronologic and stratigraphic evolution of the basin.

Following a late Miocene to Pliocene interval of folding and thrusting of the preexisting molasse sediments, deposition began in the Peshawar basin by at least 2.8 m.y. ago. Subsequently, >300 m of basin-filling sediments accumulated at rates averaging 15 cm/1,000 yr. Northward progradation of alluvial-fan deposits from the uplifted basin margin had begun by 2.6 m.y. ago and continued at an inferred rate of 2 cm/yr. Proximal to the Attock Range in the south, alluvial-fan facies persisted until 0.6 m.y. ago. Contemporaneous sediments closer to the basin center demonstrate the presence of rapid facies transitions to extensive floodplain and shallow-lacustrine depositional environments. Widespread intermontane-basin sedimentation was terminated by accelerated uplift of the Attock Range after ~0.6 m.y. ago. Subsequently, during the Brunhes chron, catastrophic floods have periodically inundated the Peshawar basin. Continuing tectonic deformation of the basin is indicated by uplifted flood deposits, offset terraces, and modern seismicity.

B/292. Burchfield, B.C. & Royden, L.H., 1985. North-South extension within the convergent Himalayan region. *Geology* 13, 679-682.

Recent work by Burg et al. (1984) indicates the presence of east-west-striking, gently north-dipping normal faults in the Higher Himalayas and southern Tibet that formed during postcollisional convergence of India and Tibet. These faults extend for at least 800 km along strike. We interpret these normal faults as probable late(?) Miocene extensional features with perhaps several tens of kilometres of down-to-the-north displacement. A simple elastic model suggests that these normal faults may have formed during gravitational collapse of the Miocene topographic front between India and Tibet. In this interpretation, gravitational collapse occurred by southward motion, relative to India and Tibet, of a wedge of crustal rocks bounded above by gently north-dipping normal faults and below by thrust faults that probably dip north. North-south extension produced in this way is probably confined to upper crustal levels only and does not reflect regional extension of the entire lithosphere.

The Jijal and Chilas complexes have been interpreted previously as the lower level of the layered Kohistan Island Arc, in Pakistan. We provide petro-structural evidence for melt-consuming reactions between mantle rocks and infiltrated, volatile-rich magmas in both complexes. Precipitate minerals in Jijal and Chilas suggest that melt-rock reaction occurred at higher pressure in Jijal than in Chilas. The early appearance of orthopyroxene in Chilas and the spatial relationship of the ultramafics rocks with quartz-bearing norites indicate that the reactant melt was more silicic. We argue that the Jijal complex includes the intra-arc crust/mantle boundary and that ultramafics associations of the Chilas complex are apices of possibly younger, intra-arc mantle diapirs.

B/295. Burg, J.P., Bodinier, J.L., Chaudhry, N., Hussain, S.S., Dawood, H. & Garrido, C.J., 1999. Mantle-crust transitions in the Kohistan Arc Complex (Pakistani Himalaya). Terra Nostra 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 16-18.

The Kohistan complex is an island arc obducted during the Mesozoic onto India along the Indus Suture. We have recognized two units containing ultramafic rocks in this complex: (1) the Jijal unit, which is the lowermost part of the exposed arc and (2) the Chilas unit, which configures the core of the arc. Our observations indicate that the ultramafic rocks are exhumed mantle rocks that record distinct evolution and different depths of equilibration. The Jijal unit includes the arc crust-mantle boundary and contains mantle rocks equilibrated in the Arieigite subfacies. The Chilas ultramafic associations are apexes of intra-arc mantle diapirs with ultramafic rocks equilibrated in the plagioclase peridotite facies.

The lower part of the Jijal section ('the mantle section') is dominated by dunites and wehrlites interlayered with subordinate pyroxenites. The presence of harzburgites, with a high-temperature tectonite microstructure, indicates that peridotites were part of a residual 'arc mantle'. Flames of dunite in websterites indicate that these rocks have replaced peridotites through magma-consuming melt-rock reactions, at P-T conditions close to the peridotite solidus. The proportion of mafic rocks (websterite and minor hornblendites and garnetites) increases up-section, up to a sharp intrusive contact between ultramafic rocks and overlying garnet granulites. The latter facies is derived from garnet gabbro. The contact dips gently to the north, parallel to the pyroxenite-peridotite layering. We interpret this boundary as the exhumed petrological arc-'Moho'.

The Chilas section includes a series of ultramafic bodies and gabbro norites. Gabbro-norites display magmatic/cumulitic textures. Ultramafic rocks, however, show microstructure typical of mantle rocks, notably, porphyroclastic textures in wehrlites and harzburgites and coarse-grain textures in plagioclase-bearing dunites. The contact between ultramafic rocks and gabbro-norites is steep and underlined by strongly metasomatised rocks, such as hornblende and/or plagioclase pyroxenites. This metasomatic aureole is indicative of extensive reaction between peridotites and infiltrated melt, implying that the mantle rocks were intruded at high, near-solidus conditions within partially consolidated norites. Interstitial plagioclase and diffuse impregnations of gabbro-norite are further indications of magma percolation in peridotites. Thereafter, upon cooling, the peridotites were fractured, intruded by magma dikes and eventually brecciated and finely dispersed in the gabbro-norite. These final evolutionary stages are exemplified by the occurrence of steeply dipping, intrusive gabbro-norite layers in peridotites, blocks of peridotites in gabbro-norites and olivine xenocrysts in graded cumulate layers. These cumulate layers describe a large antiform. To integrate small (reactional and intrusive contacts) and large (antiformal) scale observations, we interpret the Chilas ultramafic bodies as pieces of intra-arc mantle diapirs. These mantle diapirs indicate rifting of the Kohistan arc during a major tectonic event that should be considered in any collisional model of the area.

B/296. Burg, J.P., Chaudhry, M.N., Ghazanfar, M., Anczkiewicz, R. & Spencer, D.A., 1996. Structural evidence for backsliding of the Kohistan arc in the collisional system of NW Pakistan. *Geology* 24, 739-742.

In the Naran region of the Pakistan Himalayas, a regionally distributed second generation of folds results from northward-directed shear deformation. These folds are collapse structures associated with back sliding of the hanging wall, namely the Kohistan paleo-island arc. They are explained by a geometrical model that combines coeval vertical and horizontal shortening. Accordingly, they are synconvergence collapse features that indicate at

least 5-km of vertical shortening of the imbricate thrust slices derived from the Indian continent in the northwest Himalayas.

B/297. Burg, J.P. & Podladchikov, Y., 1998. Bending of syntaxes: consequences. In: Hamidullah, S., Lawrence, R.D. & Jan, M.Q. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 39-41.

Syntaxis areas where orogenic structures seem strongly bent around a vertical axis are fundamental features of modern collisional orogens. The still active Himalayan mountain belt is one example that terminates at both ends into nearly transverse syntaxes. The West and East Himalayan syntaxes (named after the Nanga Parbat and Namche Barwa, respectively) are crustal antiforms in which granitic and migmatitic rocks yield Cenozoic to very recent apparent ages.

The first part of this talk will emphasise that both syntaxes present remarkably similar thermo-mechanical evolution of basement rocks overprinted by Himalayan metamorphism and Pliocene-Pleistocene high-grade metamorphism and anatexis. Both straddle the same Neogene time span and have undergone rapid denudation, which links their still going growth to the uplift that produced Tibet in the last few million years. A rise of the Moho level is recorded under the Nanga Parbat. No information on the topic seems available beneath the Namche Barwa. In Pakistan, the Hazara-Kashmir Syntaxis is the southern continuation of the Nanga Parbat Syntaxis. In the Arunachal Himalaya, the Siang antiform appears as the southwestern continuation of the Namche Barwa syntaxis. All interpretations point to crustal scale folding as the driving mechanism that has produced these orogenic structures.

Folding and buckling instabilities as a response to layer parallel shortening are well-investigated features in geodynamics. Classical theories are restricted to initial stages of the instability development and to linear viscous, elastic and visco-elastic rheologies. Recent theoretical developments extend to waning stages of folding and to non-linear visco-plastic rheologies. However, gravity plays a fundamental role at a crustal or lithospheric scale, which means that new methods are needed to model folding of the oceanic and continental lithospheres. We employ 2-Dimension FEM modelling to study shortening of the continental lithosphere driven by far field motions of relatively rigid plates over an inviscid substratum (asthenosphere). Features of the model are:

Visco-elasto-plastic rheology. Viscous deformation is power law creep. Plastic yielding is according to Mohr-Coulomb plasticity.

There are three compositional layers, upper felsic crust 25 km, lower mafic crust 15 km, subcrustal olivine lithosphere 70-140 km. Boundary conditions are free surface, erosion and zero temperature at the top; zero differential stresses and fixed temperature at the bottom, compressional velocity and no heat flux at the lateral boundaries. Erosion is modelled according to linear diffusion equation.

Second order implicit FEM is used to discretise the momentum and heat transfer equations. Because of the number of parameters controlling the style of folding we do not attempt any systematic study. We restrict ourselves to a particular example of continental shortening - the West and East Himalayan "syntaxes".

Modelling yields the following results:

Only cold (strong) lithospheres exhibit buckling with a wavelength of ca. 200-km. Significant amplification is achieved in the overall strain range of 10-25%.

Topography due to buckling is up to 5-10 km. Exhumation is limited by fold locking and the typical amount is ca. 20 km.

After locking up the first anticline, lateral fold propagation occurs.

The Moho is uplifted beneath crustal antiforms and one can define several Mohos at strongly deformed stages.

High heat fluxes are detected within the antiforms whilst tectonic overpressure as high as twice of the lithostatic value may build in limb areas.

There are broad small amplitude depressions around the growing anticline.

We extend point 6 to discuss the development of synformal basins on both sides of crustal antiforms. We propose that the Peshawar and Kashmir basins are such structural depressions. The synclinal Peshawar basin to the west is readily seen on any geological map as a structural analogue of the synclinal Kashmir basin to the east of the Hazara-Kashmir Syntaxis. This relationship and the possible correlation between these two synformal depressions were noted by. Like the Karewas of Kashmir, the Peshawar basin has a thick Plio-Pleistocene to recent fill of alluvial sediments that began around 4 My. ago. We note that both basins have the same beginning age as the syntaxis and that sedimentation developed in both basins, although their bulk history is that of surface uplift. Our interpretation explains the location of both basins, which a ramping interpretation does not.

The kinematic model involving crustal folding to explain the Himalayan syntaxes is verified by our FEM dynamic modelling. In addition, first order features of the "cold model" of lithospheric folding fit well geological observation. We conclude that buckling is a basic response of the continental lithosphere to shortening. We emphasise that dominant geological and physiographic features of Northern Pakistan formed during the last 4 Ma have been controlled by the growth of the Nanga Parbat syntaxis. This is true also for the less known eastern Himalayan Syntaxis.

B/298. Burg, J.P. & Podladchikov, Y., 2000. From buckling to asymmetric folding of the continental lithosphere: numerical modeling and application to the Himalayan syntaxes. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 219-236.

The eastern and western Himalayan syntaxes are large-scale, coeval antiforms developed late in the history of India-Asia collision. We use two-dimensional finite element models of lithospheric folding to develop a mechanically plausible structural interpretation. The models mimic the coeval development of adjacent synformal basins, analogous to the Peshawar and Kashmir basins on either side of and adjacent to the western syntaxis. Pure-shear thickening and symmetric buckling accommodate shortening until, at a certain strain, an asymmetric thrust-like flow pattern occurs on a crustal to lithospheric scale. Similarities between geological data and calculated models suggest that lithospheric buckling is a basic response to large-scale continental shortening. To generalize these results, we suggest that a typical shortening history would include: (1) locking of an early thrust system in hinterland regions, followed by (2) pure shear shortening and symmetric buckling of the shortened lithosphere, and (3) loss of symmetry leading to the formation of an asymmetric fold in which a new thrust system will nucleate.

1. The Question under Discussion.

The plains of Northern India consist of alluvial deposits brought down by the Rivers Indus and Ganges. These plains conceal from our view a deep trough that has been formed in the solid rock of the Earth's crust. The trough is bounded on the north by mountains of the tertiary age and on the south by an ancient pre-tertiary tableland. North of the trough the Earth's crust has undergone continual compression, disturbance, and uplift since the beginning of the tertiary age ; south of the trough it has remained undisturbed since the close of the paleozoic era. On Fig. 1 are shown the Indo-Gangetic trough, the mountainous area on its north, and the tableland on its south.

From the writings of Suess, the Indo-Gangetic trough has come to be called the Himalayan foredeep. In this paper is proposed to consider one question only, namely, the origin of the Himalayan foredeep

2. The Zone of Low Density in the Crust,

In 1912 I published a paper in which I endeavoured to show that a zone of low density underlies the Indo-Gangetic alluvium and skirts the southern foot of the Himalaya Mountains. The existence of this line of low density in the crust has not been disputed. Its significance lies in the fact that it furnishes an argument against Prof. Suess's theory of Himalayan formation. Prof. Suess held that the mountains of Tibet and Persia are advancing southwards in a great series of folds. Mr. Hayden, Director of the Geological Survey of India, writes that the great series of folds in Central Asia are supposed to have been caused by a horizontal thrust from the north.⁵

B/304. Burrard, S.G., 1930. The Himalayan ranges and Godwin Austen's map. *Geographical Journal* 75, 35-37.

There were one or two points in your article on the Indian Border, G.J., September, p. 274, which were not quite fair to the Survey of India. You are quite mistaken in thinking that the ideas of Godwin Austen have dominated the survey for fifty years or that our maps are dependent on geology. I have never seen that map in any Indian drawing-office, I have never heard it quoted, and have never used it myself. The reason that the successive maps of Tibet from Walker's downwards all resemble one another is that they are all based on the same topographical data, the later maps having additional data. All our maps of Tibet are purely topographical; geology does not enter; there have been no geological surveys, and if there had been, we never use geology in topographical maps.

In all branches of knowledge generalization is necessary and difficult. Geographers are obliged to generalize, and to produce diagrammatic maps of complicated mountain systems. These diagrams are required as index maps, and for bird's-eye views. If we plot all the known peaks above 16,000 feet, the points on our charts arrange themselves in curvilinear alignments. I am no advocate of "ranges"; as a geologist Hayden was opposed to long ranges, because the eastern part of the Himalayan range was of a different age from the western. But Hayden, like myself, could not but see that the high points of Tibet insisted on grouping themselves in curvilinear arrangements, and a "range" is merely an abbreviation for curvilinear arrangement. We have to keep quite separate the question of the continuity of ranges from east to west, and the continuity of their names throughout their lengths. As to the continuity of ranges the topographical data lead to the idea that the plateau of Tibet is traversed from west to east by long continuous ranges. If a range does sink into the plateau here and there, it seems to reappear on the same alignment a little farther on. Between the ranges the plateau seems to consist of level strips. There has been no topographical survey; but there have been scattered surveys from east to west and from north to south, and they all confirm the view of parallel ranges.

As to continuity of names across the plateau, everyone would like to find Tibetan names. No one wants to extend the name Karakoram east of the Karakoram region: it would be a mistake. The Map of Tibet, 1914, which you quote, had a very unfortunate error, which was not noticed by the scrutineer; the drawing-office was short-handed, and this mistake crept in. The draughts-man entered the name Karakoram too far east. This was a mere slip; there was nothing intentional about it. I have never heard any surveyor advocate the extension of the name Karakoram east of the Shyok basin. The name has not been limited in area with the same definite precision as a state boundary. But just as the name of this range is automatically changed to Hindu Kush, as it proceeds westwards into Afghanistan, so we may hope that it will one day take on a Tibetan name as it proceeds eastwards.

With regard to your remark about the Ladakh and Kailas ranges extending eastwards to 920, there is no doubt that these two ranges are very long alignments of elevated points. The apparent breaks in their continuity are mentioned on pp. 93 and 95, Part II (Burrard and Hayden's sketch). These breaks are probably only dips of the alignment below the high level of the plateau. The difficulties of naming these long ranges, when there are no Tibetan names, were painfully present to Hayden and myself in 1907. Our critics may say, "How absurd to extend the names Ladakh and

Kailas through so many degrees of longitude!" The names affixed to these two ranges were given in 1852-53 by Cunningham, a careful, scientific and erudite explorer; we followed Cunningham, and in the absence of Tibetan names we continued Cunningham's names throughout the eastern prolongations of his range- alignments. In taking this step and in avoiding inventions of new names, we were only actuated by the wish to leave the whole question open for final consideration when the time had become ripe. We thus saved our successors from the complications of having new names started which might prove unsuitable. I may say that in 1907 we consulted every known authority about these ranges, and we received the universal advice: "the time is not ripe; leave the question alone."

The ranges of Tibet seem to open like a fan, and to be squeezed together at the north-western end. But the same elevated alignments seem to persist even when squeezed and pushed north-west.

B/307. Butler, B.C.M., 1963a. An occurrence of nephrite jade in West Pakistan. *Mineralogical Magazine* 33, 385-393.

Two pebbles of good quality nephrite jade from the riverbed of the Teritoi, Kohat District, West Pakistan, are described. One pebble is pale greenish white and has specific gravity 2.954, and the other is spinach green with specific gravity 3.021. Under the microscope both consist of sub-parallel bundles of tremolite fibers. The discovery is of significance in relation to the problem of the origin of the raw material of Indian carved jade. The pebbles are thought to be derived from the Siwalik sediments.

B/309. Butler, B.C.M., 1965. Epidiorite-limestone contact relations at Burawai, Hazara district, West Pakistan. *Mineralogical Magazine* 34, 82-91, 2 Pl.

Mineral assemblages in calcareous rocks upto 6 ft from the contact of an epidiorite sill are interpreted as a result of regional metamorphism superimposed on an earlier thermal metamorphism in which potassium metasomatism occurred. The sill, originally a dolerite, is 70-100 ft thick and now consists of green amphibole, oligoclase, and sphene. The rocks 6 ft from the contact are impure calcareous rocks with microcline, epidote and zoisite, oligoclase,

pale green pyroxene, actinolite amphibole, and quartz. At 4 ft from the contact calcite, microcline, Ca-rich garnet (n 1.760), zoisite epidote, and pyroxene are the chief components. Nearer to the contact the abundance of garnet increases, but in the last foot of the contact garnet is absent and the assemblage is epidote-amphibole-calcite-quartz. Numerous model analyses are given.

B/311. Butler, R., Jones, C., Treloar, P. & Wheeler, J., 1991. Tectonic evolution of the Nanga Parbat massif insights from the central-southern segment. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Auris, France, 23.

The Nanga Parbat massif represents the northern-most continuous outcrop of the Indian continent within the Himalayan collision belt, exhumed from beneath the overriding Kohistan arc terrane by young thrust activity. Recent work has concentrated on the uplift neotectonics, effect which are concentrated on the western margin of the massif.

The internal structure of the Nanga Parbat massif is schematically represented as antiformal, with the early high strain contact between Kohistan-Ladakh and Indian continental material (a possible MMT analogue) defining this structure. However, recent studies of the internal structure of the massif (Wheeler, Potts and Treloar) along the accessible Indus transect suggest otherwise. This work defined two major antiformal structures in foliation of the Nanga Parbat basement. In this contribution we present new results arising from two expeditions into the Nanga Parbat massif, both of necessarily of a reconnaissance nature: the Durham University geological expedition in 1998 and a NERC-funded trip in 1990.

Our studies in the heart of the massif to the south attempted to trace the composite antiformal structure determined on the Indus section. Our more recent work suggests a rather more complex arrangement. Foliation on the western side of the massif is concordant to the early high strain contact with Kohistan (subtracting the affects of local neotectonic faulting), consistent with the antiformal model. However, work along the Astor valley transect did not reveal a major antiformal closure. Rather the structure is of an asymmetric west-gaping synform with foliation on the eastern margin dipping steeply east, beneath Kohistan (Ladakh). The penetrative stretching lineation plunges N in the E and NE in the W with a gradual change in trend. Further insights from the Rupal transect allows a second major south-gaping closure to be mapped, with an apparently high strain upper limb (outcropping on the Rupal face and summit of Nanga Parbat). The lower, south-dipping limb, while also high strain, contains a south-plunge stretching lineation. We discuss the interpretation of these unexpected structures, specifically the relationship between position on large-scale folds, shear criteria and orientation of lineations. However, the age of some fabrics in the massif, despite the "Himalayan" trend of stretching lineations, is not necessarily Tertiary. A suit of biotite granite bodies, mineralogically distinct to the late two-mica leucogranite veins of the massif, crosscut fabric. Therefore we also discuss the problems of identifying Himalayan deformation from much earlier tectonics within basement of the Indian continent. Work is underway investigating these topics.

B/312. Butler, R.W.H., 1985. Relationships between crustal scale thrusting, subduction and lithospheric flexure on the NW margin of the Indian Continent. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

Data from magnetic anomaly stripes on the floor of the Indian Ocean suggest that 1500-2500 km of relative convergence has occurred between Indian and stable Asia since the abutment of the two continental masses in the middle Eocene. This has been accommodated by southward directed thrusting within the Indian crust together with other shortening processes in the Himalayan hinterland. To the west, oceanic subduction has continued throughout this period beneath the Makran forearc. This contribution explores the ways in which crust and mantle stacking varies within the Himalayan belt and links through the Makran region, together with the control these geometries on patterns of flexural basin development on the Indian Continent.

This study is underpinned by a balanced cross-section, constructed from the Punjab foreland to the main Mantle thrust in northern Pakistan. This restores upper crustal thrust systems to a width in excess of 720-km with an implicit shortening of at least 470-km. A further 150-km displacement on MMT, amounting to simple subduction of Indian lithosphere, preceded this shortening. Indian lower crust of the western Himalayas has been stacked beneath the Asian hinterland, possibly as far north as the Pamirs while in the central Himalayas whole crustal stacking occurs directly beneath the thrust belt. This has resulted in a greater topographic elevation in the central Himalayas and gravity modeling has suggested that this topographic load account entirely for the flexural depression of the adjacent foreland. However, in western Pakistan the lower Indus basin has a similar width (c. 300-km) and inner depth (c. 7-km) as the main Punjab-Gangetic foreland basin. Yet in these western regions the orogenic belt has a relatively low topographic elevation (average less than 2-km) so that an extra, subsurface load is required to drive the flexural basin. This can be provided by the adjacent oceanic lithosphere which has been subducted below the Peshawar basin which overlies thrust systems in northern Pakistan. These interpretations suggest that load stresses in the subducted oceanic lithosphere can be transmitted across the adjacent continental lithosphere, which must be coupled at depth. This argues against the concept of India behaving as a rigid indenter with respect to Asia but supports models of thrust continuity within the convergent plate system.

B/313. Butler, R.W.H., 1986. Thrust tectonics, deep structure and crustal subduction in the Alps and Himalayas. *Journal of the Geological Society of London* 143, 857-873.

The structural restoration of collision orogenic belts onto crustal templates provides important insights into the tectonic evolution, deep structure and amounts of plate convergence after the initial contact between two continental masses. Balanced cross-sections have been constructed, parallel to the local displacement directions, across the western Alps and western Himalayas and demonstrate very large amounts of crustal shortening above intra-crustal detachments. To achieve a balance, substantial volumes of lower crust must have been subducted beneath the two tectonic hinterlands. A model of eclogite metamorphism is invoked to facilitate this subduction and to explain the varying isostatic responses of the Alpine and Himalayan hinterlands. Patterns of eclogite metamorphism are controlled by the geometry of thrust profiles on a lithospheric scale: the development of crust-mantle detachments being of crucial importance. Such a profile is proposed for the Himalayas, suggesting that relatively small volumes of the footwall crust succumbed to eclogite metamorphism. In the Alps however, a steeper thrust profile apparently developed, emplacing mantle onto crust, causing wholesale eclogite metamorphism in the underlying Franco-Swiss crust. The resultant density increase would provide a mechanism of isostatic collapse and flexural subsidence in the Po plain region.

B/314. Butler, R.W.H., 2000. Structural evolution of the western margin of the Nanga Parbat massif, Pakistan Himalaya: insights from the Raikhot-Liachar area. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 51-75.

There are several competing interpretations of the structure of the margins of the Nanga Parbat massif: that the massif is bounded by original suture between the Indian continent and the Kohistan-Ladakh island arc-the Main Mantle Thrust; that the massif is entirely bounded by neotectonic faults; that it is bounded by a combination of early and late faults and shear zones. If the marginal structures of the massif are to be related to local and regional geotectonic evolution then their correct characterization is critical. The Raikhot Bridge area on the western margin of the massif is useful in this regard, as it provides accessible and near-continuous outcrops. This contact, sometimes called the Raikhot Fault, is composite. Sheared metagabbros of the Kohistan arc are juxtaposed tectonically against metasediments and orthogneisses of the Nanga Parbat massif along an early ductile shear contact, developed under amphibolite facies conditions. In this regard it may be a preserved segment of the Main Mantle Thrust. However, this ductile shear zone has been strongly modified, flattened and rotated, and is cut by younger shears and faults. The original kinematics of the shear zone has been largely overprinted by these subsequent deformations. The younger structures include NE-SW striking, dextral strike-slip faults and a major top-to-NW thrust and shear zone. A sequence of metamorphism, deformation and igneous emplacement may be used to study the history of structural evolution within the massif. The use of a single name (e.g. Raikhot Fault) for the present-day map contact between

the Nanga Parbat massif and neighboring Kohistan is misleading. The early contact (termed here the Phusparash Shear Zone, possibly the northeastern continuity of the Main Mantle Thrust) is modified by the Buldar Fault Zone (dextral strike-slip) and the Liachar Thrust Zone (top-to NW carriage of the Nanga Parbat massif across the Phusparash Shear Zone and onto Kohistan). The activity of the Buldar Fault and Liachar Thrust Zone continued during exhumation of the massif, through amphibolite facies to the Earth's surface. The interaction between these structures is at present unknown. However, establishing these and similar interactions within the Nanga Parbat area remain central to establishing the role of regional NE-SW dextral transpression in the modern structure of the massif.

B/315. Butler, R.W.H. & Coward, M.P., 1989. Crustal scale thrusting and continental subduction during Himalayan collision tectonics on the NW Indian plate. In: Burchfiel, B.C. & Sengor, A.M.C. (Ed.), *Tectonic evolution of Tethyan Regions Proceedings*. NATO ASI, Kluwer, Dordrecht C259, 387-413.

Following the subduction of Tethyan oceanic lithosphere beneath Asia and Kohistan the continued convergence between the upper plate and the Indian continent led to thrust stacking of Indian crust to form the Himalayas. This lasted from Oligocene to Recent times and in an attempt to evaluate displacements, a series of balanced cross-sections have been constructed across the belt. In Pakistan these illustrate that over 600km of relative convergence between India and the Kohistan complex north of the Eocene suture zone has occurred by SSE-directed thrusting. This deformation only involves Indian upper crust at present outcrop levels so that the lower crust and remaining lithosphere must have been subducted beneath Kohistan and Tibet. The northern edge of the Indian lower crust may lie beneath the Pamirs. Similarly large amounts of shortening (several hundred kilometres) are implied by other balanced crustal sections through the central Himalayas and western Pakistan. The continuity of thrust systems around the NW margin of the Indian continent is proposed so that thrusts which stack continental crust step off into oceanic lithosphere in the west. This thrusting mechanism accounts for a substantial fraction of the total, 1200–2000km relative convergence between stable India and Asia. Further shortening in the Tibetan region which developed after the Eocene continent-continent collision must be added to the displacements on thrusts which stack Indian lithosphere. Deformation within the entire collision zone approximates more closely to an essentially vertical plane strain model rather than to a process of lateral expulsion of Tibet towards the east.

B/317. Butler, R.W.H., George, M., Harris, N.B.W., Jones, C., Prior, D.J., Treloar, P.J. & Wheeler, J., 1992. Geology of the northern part of the Nanga Parbat massif, northern Pakistan and its implications for Himalayan tectonics. *Journal of Geological Society of London*, 149, 557–567.

The northern outcrop termination of Indian continental crust lies at the Nanga Parbat massif, from where this contribution presents new field data. The tectonic contact with the structurally overlying Kohistan island arc is concordant and ductile, is associated with interleaving of Nanga Parbat and Kohistan lithologies, and may be correlated with the Main Mantle thrust found elsewhere in the NW Himalayas. This ductile shear zone is locally overprinted by cataclastic faults associated with exhumation of the massif but overall, the northern outcrop termination of the massif is controlled by erosion through a gently, northward-plunging antiformal structure. This folds both the Main Mantle thrust and the underlying, concordant 'Layered Unit' of the Nanga Parbat basement. Thus there is no indication that the massif acted as a promontory to the Indian continent during collision nor that it is a structure entirely bound by neotectonic faults. Ductile shear fabrics associated with the 'Main Mantle thrust' are

cross-cut by leucogranite sheets and pegmatites. These may represent the stockwork to a significant crustal-melt granite body described here in the northern massif. This Jutial granite shows many geochemical characteristics in common with similar bodies in the High Himalayas which are consistent with anatexis of the buried Indian continental basement rocks. However, the granite is enriched in heat producing elements (particularly Th: 22 ppm) and shows extremely high $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (>0.88). The high concentrations of radiogenic Sr are also an attribute of a suite of hitherto enigmatic leucogranitic pegmatites that laces the Nanga Parbat massif, suggesting that these may represent a stockwork to a largely buried body of which the Jutial granite is a small exposure. The enrichment in heat-producing elements within the granite may reflect similarly high heat production in the source Indian continental crust requiring in turn a fundamental re-examination of the thermal evolution of this crust during Himalayan metamorphism and exhumation.

B/319. Butler, R.W.H., Harris, N.B.W. & Whittington, A.G., 1997. Interactions between deformation, magmatism, and hydrothermal activity during active crustal thickening: A field example from Nanga Parbat, Pakistan Himalayas. *Mineralogical Magazine*, 61, 37–52.

The Nanga Parbat massif is a rapidly eroding, thrust-related antiform that is distinct from other regions of the Himalayan orogen in being both intruded by Late Miocene-Pliocene anatectic granites and permeated by a vigorous hydrothermal system. Exhumation is achieved by erosion during thrusting along the Liachar thrust in the apparent absence of extensional tectonics. At depths in excess of 20 km, small batches of leucogranitic melt have been generated by fluid-absent breakdown of muscovite from metapelitic lithologies. These melts ascend several kilometres prior to emplacement, aided by low geothermal gradients at depth and by interaction with meteoric water as they reach shallow levels. At intermediate depths (approximately 15 km) limited fluid infiltration is restricted to shear zones resulting in localised anatexis. Within the upper 8 km of crust, magmatic and meteoric fluid fluxes are channelised by active structures providing a feedback mechanism for focusing deformation. Leucogranite sheets show a range of pre-full crystallization and high-temperature crystal-plastic textures indicative of strain localisation onto these sheets and away from the country rocks. At subsolidus temperatures meteoric fluids promote strain localisation and may trigger cataclastic deformation. Since near-surface geothermal gradients are unusually steep, the macroscopic transition between distributed shearing and substantial, but localised, cataclastic deformation occurred at amphibolite-facies conditions (approximately 600 degrees C). Even with the greatest topographic relief in the world, the meteoric system of Nanga Parbat is effectively restricted to the upper 8 km of the crust, strongly controlled by active structures.

B/320. Butler, R.W.H., Owen, L.A. & Prior, D.J., 1988. Flash floods, earthquakes and uplift in the Pakistan Himalayas. *Geology Today*, 4, 197–201.

Catastrophic flooding of parts of the frontal plains of the Pakistan Himalayas has occurred throughout the historical past. The largest recorded flood (1841) originated from an earthquake triggered landslide from the flanks of Nanga Parbat, which blocked the Indus river for six months. The earthquake probably occurred on the Liachar thrust, which has been responsible for uplifting the amphibolite facies Nanga Parbat gneisses to the Earth's surface in the last 10 million years. These movements raise serious problems for hydroelectric engineering project in this and other active mountain belts.

B/321. Butler, R.W.H. & Prior, D.J., 1988a. Tectonic control on the uplift of the Nanga Parbat Massif, Pakistan Himalayas. *Nature* 333, 247-250.

Cenozoic mountain belts like the Himalayas contain regions that experienced rapid uplift in comparison with the areas around them. Whether this uplift occurred by buoyant rebound of previously thickened crust or during the crustal thickening process itself is uncertain. Here we show, however, that the 7 mm yr⁻¹ Recent uplift of the Nanga Parbat massif, Pakistan Himalayas, was accomplished during NW-directed thrusting located along its western margin. This 3-km-wide Liachar thrust zone operated from amphibolite facies to the present topographic surface and accommodates substantial crustal shortening. The adjacent Indus river valley, itself cut by seismogenic faulting, completely transects the massif, showing that erosion keeps pace with geologically rapid thrust uplift.

B/323. Butler, R.W.H., Prior, D.J. & Knipe, R.J., 1989. Neotectonics of the Nanga Parbat Syntaxis, Pakistan, and crustal stacking in the northwest Himalayas. *Earth and Planetary Science Letters* 94, 329-343.

The northwest termination of the Himalayan arc is marked by two large antiformal structures, termed syntaxes, and a NW-SE zone of intermediate depth earthquakes which have yielded both strike-slip and thrust-sense fault-plane solutions. This contribution presents new structural data from the Nanga Parbat area, the northern syntaxis, one of the fastest rising portions of the orogen (7 mm yr⁻¹). Our studies show uplift related to syntaxis growth to be accommodated by structures located along its western margin. Fault kinematics in the southern part of the margin indicate NW-directed thrusting along a shear zone and high level cataclastic faults, termed the Liachar thrust zone. This carries amphibolite facies basement rocks out onto Quaternary sediments. Further north along the western margin active faults are dominantly dextral strike-slip, oriented north-south (e.g. the Shahbatot fault). Overprinting relationships suggest that the strike-slip fault zone has migrated southwards into the NW-directed thrust zone. These relationships are consistent with the northwest termination of the arcuate Himalayan thrust belt at a lateral tip generating folding and radial thrust directions. Faulting patterns at Nanga Parbat suggest that this tip zone has migrated southwards. Active faulting is now concentrated in the northwest continuation of the Hazara (southern) syntaxis, along a seismogenic strike-slip and thrust zone. These deep level tips lie on the crustal stacking thrusts which cut through the higher level, SSE-directed thrusts of Pakistan.

B/324. Butler, R.W.H., Wheeler, J., Treloar, P.J. & Jones, C., 2000. Geological structure of the southern part of the Nanga Parbat massif, Pakistan Himalaya, and its tectonic implications. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 123-136.

The Nanga Parbat massif lies in the core of the major north-south trending, broadly upright antiform that marks the NW syntaxis of the Himalayan arc. However, this antiformal structure is not evident in the trend of foliation and banding within the central and southern parts of the massif. Reconnaissance field studies in this region (Astor, Rama and Rupal areas) have delineated an important shear zone with top-to-the-south overthrust kinematics. This Rupal Shear Zone carries the migmatitic core of the massif onto non-migmatitic metasediments locally termed the Tarshing Group. The shear zone traces north into a broad high strain zone of steep foliation with gently plunging mineral elongation lineations with no consistent sense of shear. A tentative model is proposed whereby top-to-the-south overshear in the Rupal area passes northwards into a steep belt of apparently constrictional N-S elongation. This type of large-scale transpression may record the early growth of the syntaxis. However, relating these structures to Himalayan orogenesis and the amplification of the NW syntaxis is problematic. The Nanga Parbat massif displays a long and complex history of polyphase deformation, metamorphism and magmatism, as might be expected of a terrane derived from the basement of the Indian sub-continent. Although at least the alter part of the constrictional

steep belt developed with syn-kinematic leucogranite intrusions (<10 Ma), the old age limit on the Rupal Shear Zone remains unconstrained.

Key words: Stratigraphy, Abbottabad, Hazara.

B/326. Butt, A.A., 1969. A note on the Cretaceous Tertiary boundary in Hazara, West Pakistan. Geological Bulletin, Punjab University 8, 73-78.

Middlemiss (1896, pp. 39-40) described grey limestone (proposed as Kawahgar Formation by the Stratigraphic Committee of Pakistan, 1969), of doubtful age, which underlies the Paleogene formations in the Hazara District of West Pakistan. Latif (1962, p. 57) pointed out that the limestone belongs to the Upper Cretaceous age because of the presence of foraminifera Globotruncana, Heterohelix, Rugoglobigerina and Pseudotextularia, which he identified by examining thin sections of the rock from certain localities, namely, Darband, Dungagali and Khan.

If we consider the lithological characteristics of the Kawahgar Formation in the district, we find that the formation is present, as a hard and very fine-grained, well-bedded, light grey limestone for which reasons the foraminifera can only be examined under thin sections. However, at some localities, for example at Changlagali (1" 43 G/5) along the Murree-Nathiagali road, which is regarded here as one of the reference sections; nearly 13 miles east of the Jabri Forest Rest House along the Lora-Maqsood road (1" 43 G/1), this formation is predominantly represented by very thinly-bedded pale weathering marls which, on treatment with peroxide, yield loose fossil specimens. It is from the latter locality that the foraminifera, because of their better preservation, mentioned below are discussed and illustrated (Coll. Aftab, 1966, sample 9125) for the first time.

The boundary between the Kawahgar Formation and the overlying dense grey, nodular limestone, the Lockhart Limestone (name proposed by the Stratigraphic Committee of Pakistan, 1969) is marked by a laterite band of few feet in thickness. This band is very conspicuous in the field and can be used as a marker bed for the purpose of mapping.

The sampling from the marls of the Kawahgar Formation from the above mentioned localities, has shown the presence of well-preserved globotruncanids. The species/subspecies encountered are Globotruncana limelano, G. fornicata, G. ventricosa and G. concavata carinata. Moreover, Heterohelix globulosa, H. reussi and Rugoglobigerina rugosa also form part of the planktonic association. Rugoglobigerina rugosa, recorded here as few specimens, however, has not been illustrated. This assemblage suggests that the Kawahgar Formation ranges from Coniacian up to the Campanian.

Reviewing the Cretaceous-Tertiary succession in Hazara, we find that the Kawahgar Formation marks the end of the Cretaceous period. The Paleocene begins with a new transgressive phase which is represented by nodular limestone, the Lockhart Limestone that overlies the Kawahgar Formation. The Lockhart Limestone shows an abrupt change in lithology as well as in the faunal composition. The pelagic foraminiferal association of the Kawahgar Formation is entirely absent and the fauna is now composed of the benthonic larger foraminiferal species such as Lockhartia haemei, Miscellanea miscella, Ranikothalia soldadensis (= R. sirdensis), Daviesina khatiyohi and Discocyclina ranikotensis suggesting an Upper Paleocene age. At this stratigraphic level, similar lithologic as well as paleontologic changes have been observed by the author in the Kala Chitta and the Samana Ranges pointing towards a similar stratigraphic break. Further research is, however, in progress to discuss, in detail, the foraminiferal assemblages of these regions and their stratigraphic implications.

B/331. Butt, A.A., 1987a. The Paleogene stratigraphy of the Kala Chitta Range, Northern Pakistan. *Acta Mineralogica Pakistanica* 3, 97-110.

The geology of the Kala Chitta Range is an integral part of the structural units of the Kohat-Hazara region, northern Pakistan. The sedimentary geology of the Kala Chitta Range has similarities with the adjoining areas. However, there are certain differences in the stratigraphy and the geology history. The structural evolution of the Kala Chitta Range began in the Mesozoic time and attained its maximum by the end of the Eocene time. The deposition of the Upper Cretaceous (Coniacian-Campanian) Kawagarh Formation in a narrow belt along the northern part of the Range, intergradation of the Upper Paleocene (Thanetian) sedimentary facies, the continuity of the stratigraphic and the paleogeographic pattern from north to south by a southward trend of younging of strata, especially during the Middle Eocene, are some of the salient geological features of this structural entity. First major stratigraphic break between the Upper Cretaceous Kawagarh Formation (Coniacian-Campanian) and the Upper Paleocene (Thanetian) Lockhart Limestone is marked by a ferruginous pisolite. The second major break between the Middle Eocene Kohat Formation and the Miocene Murree Formation is marked by a pebbly deposit-the Fatehjang Member. An attempt is made to review the stratigraphic, biostratigraphic as well as the paleogeographic setting of the region in the context of basin analysis framework.

B/332. Butt, A.A., 1987b. The Ranikothalia Sindensis zone in Late Paleocene Biostratigraphy. *Acta Mineralogica Pakistanica* 3, 111-115.

The foraminiferal genus *Ranikothalia* characterizes the Upper Paleocene (Thanetian) succession of Pakistan and elsewhere in the world, but does extend rarely into Lower Eocene. A closer examination of several Upper Paleocene species from various world localities demonstrates that the open spiral complanate forms may be identified as *Ranikothalia sindensis* (Davies), which has been illustrated here from the Upper Paleocene Lockhart Limestone of the Kala Chitta Range, northern Pakistan. In view of its stratigraphic value, it is strongly advocated that the *Ranikothalia sindensis* Zone be incorporated within the Upper Paleocene (Thanetian) in the Paleogene stratigraphic correlation scale of Cavelier and Pomerol (1983). This would be one step forward towards refinement of the Paleogene biostratigraphy on the basis of benthonic larger foraminifera.

Key words: Stratigraphy, biostratigraphy, *Ranikothalia*, Late Paleocene.

B/333. Butt, A.A., 1988a. Upper Cretaceous foraminiferal biostratigraphy of Pakistan. *Acta Mineralogica Pakistanica* 4, 90-95.

The Upper Cretaceous succession of Pakistan covers a time interval from Cenomanian to Turonian but largely, Coniacian to Campanian and a Maastrichtian interval. Deposition of the Kawagarh Formation in northern Pakistan and correspondingly the Parh Limestone in southern Pakistan (Coniacian to Campanian in age) is the result of a major transgression along the north-western margin of the Indian Plate, whereas the Maastrichtian interval records a major regression, marked either by the complete absence of the Maastrichtian deposits in northern Pakistan or by the development of a regional blanket of regressive facies of the shallow-water Pab Sandstone in southern Pakistan. Uninterrupted succession argillaceous deposits, the Korara Shale, across the Cretaceous-Tertiary boundary in the Kirthar Range (Gaj River section) containing Maastrichtian and Danian planktonic foraminifera in continued sedimentary environments, is among the very few world-wide examples of continuous section across the boundary.

Key words: Biostratigraphy, Cretaceous, foraminifera.

B/334. Butt, A.A., 1988b. Some geological aspects of the Hazara arc, Northern Pakistan. *Acta Mineralogica Pakistanica* 4, 147-150.

B/335. Butt, A.A., 1991. Plate tectonics and the upper Cretaceous stratigraphy of Pakistan along the northwestern margin of the Indian Plate. Abstracts, 1st Postgraduate Training Course in Plate Tectonics, Punjab University, Lahore, 13-14.

In terms of sedimentary geology, global marine transgression (sea-level rise) has been expressed as an episode of active plate movement, drowning the margins and many inland depressions of the world continents with shallow epicontinental seas. This significantly expanded the world oceanic environments favourable for flourishing of marine organisms, whereas global marine regression is an episode of slow plate movement causing major lowering of the sea-level. It means that the epicontinental seas and much of the continental shelf areas were periodically drained, thereby reducing world oceanic environments considerably. The shrinking of world oceanic environments caused extinction of marine organisms.

The Upper Cretaceous stratigraphy of Pakistan is interpreted to fit into this concept along the northwestern margin of the Indian Plate. The deposition of the Upper Cretaceous (Coniacian-Campanian) Kawagarh Formation in northern Pakistan and correspondingly Parh Limestone in southern Pakistan, has been interpreted as a result of active plate movement causing major regional flooding (marine transgression) along the northwestern margin of the Indian

Plate, thus causing expansion of marine environments favourable for the flourishing of the marine organisms. This is manifested by the presence of varied age-diagnostic globotruncanid fauna in these stratigraphic units.

The Maastrichtian time interval envisages a major episode of "draining off" regression the northwestern margin of the Indian Plate - a period of destruction of marine environments creating limited shallow-water living space, which amounts to a major extinction of the marine organisms.

The reduced marine environments in northern Pakistan are, therefore, refloated by the complete absence of the Maastrichtian sediments (total "drain off" of the shelf areas), while there is a development of regional blanket of regressive clastic facies in southern Pakistan --- the shallow-water Pab Sandstone resulting from the lowering of sea-level. This created a sedimentary facies almost barren of marine organisms except for a very rare reported occurrence of a Maastrichtian orbitoidal foraminifer *Lepidobitoides minor* (Vredenburg, 1908). The rare occurrence, however, is in harmony with respect to the shrinking environments

Key words: Plate tectonics, stratigraphy, Cretaceous, Indian Plate.

B/336. Butt, A.A., 1992. Geological framework of the Hazara arc. Abstracts, First South Asia Geological Congress, Islamabad, p.8.

The Hazara Arc forms part of the western limb of the Hazara-Kashmir Syntaxis and the closely situated geological segment of the Azad Kashmir from the towns Balakot to Muzaffarabad appears to form an integral part of the Hazara Arc. This interpretation gains support on the basis of following criteria: 1. The structural configuration of the Hazara Arc and, in its immediate neighborhood, the presence of dislocated lobe shaped geological segment of Azad Kashmir between the towns Balakot and Muzaffarabad. The dislocated junction between the geological segment of Azad Kashmir and the Hazara Arc can be visualised as a result of structural complexities caused by the Nathiagali Thrust merging further into the Main Boundary Thrust.

2. The extension of the stratigraphic units of the Hazara Arc into the neighbouring geology of Azad Kashmir, 3. The location of the town Balakot at the northern tip of the Hazara Arc.

Our interpretation based upon the structural setting, stratigraphic framework and the geographical location appears most appropriate for the definition of the Hazara Arc. Major geological events which occurred in the Hazara Arc can be summarized as follows: 1. A major Paleozoic stratigraphic gap crossing over to the Triassic. 2. Cretaceous-Tertiary unconformity (Maastrichtian-Danian interval) marked by residual deposits. 3. Marked southward depositional shift during the Middle Eocene Kuldana Formation towards the adjoining Potwar Basin. 4. A major depositional break from Upper Eocene to Oligocene which marked an end to the maximum stratigraphic and structural evolution in the Hazara Arc. 5. Creation of the Hazara arc as a hinterland to the adjoining actively subsiding Potwar Basin during the Miocene. This structural framework brought prominence to the Miocene sedimentation (Murree Formation) to the actively subsiding Potwar Basin, while it formed a southernmost bordering belt of the Hazara Arc.

Key words: Balakot, Muzaffarabad, Hazara Arc.

B/339. Butt, G.D., 1993-95. Study of Geo-aspects of barrage and its related structures of Ghazi Barotha Hydropower Project. M.Sc. Thesis, Punjab University, Lahore, 81p.

Ghazi Barotha Hydropower project is named after the village Ghazi near Tarbela and near Attock. It is basically a hydropower project which consists of second biggest channel of the world. This project was started in 1989. It is eight year project, and was expected to complete in 1997 to 1998. Due to some financial constraints and political problems for land acquisition, the project is delayed by 4-5 years. The project is a joint venture of five different companies in which two of these are national and three companies are international named as:

- * Pakistan Hydro Consultants (P.H.C.)
- * National Engineering Services of Pakistan (NESPAK) (Pvt.) Ltd.
- * Associated Consulting Engineers (A.C.E.) (Pvt.) Ltd.
- * Binnie and Partners (Overseas) Ltd.
- * Ghazi Barotha Contractors (G.B.C.)
- * Ewbank Preece Ltd.
- * Harza Engineering Company International. ,

The project is started on the idea that the overflow water from Tarbela should be reused for electricity. A concrete line channel is proposed on the left side of the area, 7 km down stream of Tarbela. It follows a gentle slope up to Attock and then a sharp head difference of about 250 feet is available at Barotha providing a suitable head for hydropower generation.

Key words: Engineering geology, Ghazi Barotha, Hydropower, Hazara.

B/340. Butt, I.H., 1997-98. Geological mapping of Rawalakot Area with special emphasis on engineering characteristics of soils. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 40p.

A number of static and dynamic tests have been performed in order to investigate the basic nature of the natural soils during testing. The samples tested cover a large variation in composition and dynamic behaviour. The test enables to study how the tests can be applied for land use. Void ratio, laboratory consolidation history settlement history can be established.

Clays, silty clays and inhomogeneous soils including consolidated soft clays, a slightly overconsolidated silty clays and a stiff overconsolidated clays were tested. The results indicate that the bearing capacity directly depends on the load. For foundations on clay soils the pore pressure is a good parameter, for the pore pressure dissipation and redistribution can easily be measured. The liquid limit, plastic limit, compaction and grain size distribution are within the ASTM specifications. The results indicate that most of the soils are firm and are good for sale construction of local purposes. The key parameters in the stress-strain relationship is the shear stress and the effective stress which are still to be investigated.

Key words: Soil, engineering geology, Rawlakot, Kashmir.

B/341. Butt, K.A., 1981a. Hydrothermal phenomenon associated with Lahor pegmatoid granite complex, Kohistan. Geological Bulletin, University of Peshawar 14, 85-93.

Pb-Zn-Mo and uranium mineralization spatially associated with Lahor pegmatite / granite complex and enclosing metasediments is examined in the light of new data on ore minerals. Several ore paragenetic associations are described and it is concluded that polyphase mineralization processes are responsible for the ore associations described.

Key words: Hydrothermal process, mineralization, granite, pegmatoid, Besham.

B/342. Butt, K.A., 1981b. Pyrochlore group minerals in carbonatites from Loe-Shilman, Khyber Agency, NWFP, Pakistan. Geological Bulletin University of Peshawar 14, 111-122.

Metamict, partially metamict and non metamict species of pyrochlore group minerals have been identified from a sheet like carbonatite complex in Loe-Shilman, Khyber Agency. Microscopy, X – ray diffractometry and partial chemical analyses are reported which indicate a chemical and structural variability between various species of pyrochlore. A multiplicity of intrusive activity is considered to be responsible for the variations described.

Key words: Mineralogy, carbonatite, Loe-Shilman, Khyber Agency.

B/343. Butt, K.A., 1983a. Komatiitic Affinities of Ultramafic Rocks, Serpentinites and ultramafic amphibolites in the amphibolite belt of Northern Pakistan. Kashmir Journal of Geology 1, 43-48.

A review of komatiites is presented and the existing chemical and petrographic data on amphibolites of Dir, Swat, Kohistan, Thak Valley, Nanga Parbat and Astor is re-evaluated. This study suggest that the association of amphibolites, ultramafic rocks, serpentinites, talc-carbonate rocks with occasional occurrence of pillow structures and ultrabasic volcanic breccias, all suggest komatiitic to tholeiitic affinities. Much of the ultrabasic material occurring within the amphibolite belt is interpreted to be submarine ultramafic to high MgO basaltic volcanic flows and minor intrusions. An oceanic crustal model proposed for this belt (Butt et al. 1979) is therefore further substantiated.

Key words: Petrography, komatiite, amphibolite belt, Kohistan.

B/344. Butt, K.A., 1983b. Tectonic environments for Ni and Pt group elements sulphide deposits in northern Pakistan. 2nd National Seminar on Development on Mineral Resources, Peshawar, 1, 21–24 May, 8p.

Nickel mineralization reported from Swat and Dir Districts are described with reference to their immediate geological and tectonic environments. Two types of environment of the ultramafic rocks hosting Ni mineralization have been distinguished; Synvolcanic and Alpine type. The significance of these environments with respect to their potential as hosts for sizable Ni and platinum group element sulphide deposits is discussed.

Key words: Ni-Pt group sulphides, tectonics, Swat, Dir.

B/345. Butt, K.A., 1983c. Petrology and geochemical evolution of Lahor pegmatoid/granite complex, northern Pakistan, and genesis of associated Pb-Zn-Mo and U mineralization. In: Shams, F.A. (Ed.), *Granites of Himalayas, Karakorum and Hindu Kush*. Institute of Geology, Punjab University, Lahore, 309-326.

The study describes a detailed account of the geology of Lahor pegmatite-granite complex. Field relations, texture, major and trace element chemistry are used to arrive at conclusion that the complex formed by in situ melting of pre-existing metamorphites. Metallic mineralization associated with the complex is interpreted to have been mobilized by hot fluids produced during anatexis but the source of metals probably lay in the metamorphites. Lahor pegmatoid complex is correlated with the Nanga Parbat-Haramosh migmatites and their significance at the plate-scale is discussed.

Key words: Hydrothermal process, granite, pegmatoid, Lahor.

B/346. Butt, K.A., 1988. Geology of Koh-i-Sufaid Mountain, north of Parachinar and its correlation with other areas of comparable geology and mineralization. *Geological Bulletin*, University of Peshawar 21, 57-69.

Geology of Koh-i-Sufaid imbricate zone, North of Parachinar is described and compared with similar occurrences in Thakot-Besham and Nanga Parbat-Haramosh area. Ductile deformation exposed in the migmatitic rocks of these areas is interpreted to be due to structurally up thrown block of deep seated rocks along the older strike slip faults which have developed a significant vertical component during their re-activation under the influence of Himalayan orogeny.

Key words: Tectonics, structure, Koh-i-Sufaid, Parachinar.

Key words: Radioactive minerals, uranium, metamorphic rocks.

B/348. Butt, K.A., 1989b. Release of uranium through cataclastic deformation of Mansehra granite gneiss and its precipitation in the overlying montane basin in northern Pakistan. In: *Uranium Deposits in Magmatic and Metamorphic Rocks*. Proceedings of the Technical Committee Meeting, Salamanca 29, 1986. IAEA, Vienna, Austria, 155-166.

The Mansehra pluton belongs to a discontinuous belt of two mica granites of the Lesser Himalayas. The Mansehra granite is generally foliated except in the area around Mansehra. Several phases of granitic activity have been reported from the Mansehra complex. Shams and Rahman have demonstrated that the younger phases tend to be enriched in Na₂O. The northern edge of this sheet-like granitic mass has undergone extensive cataclastic deformation, resulting in the formation of shear zones, mylonites and cataclasites. A chemical comparison of crushed granite with granite outside the shear zone suggest little chemical reconstitution in terms of major elements during cataclastic deformation. A huge shear zone in albited granite gneiss has yielded secondary uranium minerals at water seepage, suggesting a liberation of uranium. Hydrogeochemical survey of the crushed granite and adjoining areas suggest that uranium from crushed granite was easily leachable in comparison with rocks outside the

shear zone. The uranium thus liberated was trapped in a Pleistocene sequence of clays and unsorted fluvial sand overlying the granite and country rock metamorphics.

Key words: Economic geology, uranium mineralization, cataclastic deformation, Mansehra Granite.

B/349. Butt, K.A., 1990. Ultrapotassic hypabyssal rocks from Khyber Agency. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, p.23.

Ultrapotassic rocks of a possible subvolcanic hypabyssal environments are described from Khyber Agency. These rocks contain sanidine as a major rock forming mineral. Other minerals include calcite, phlogopite, sodalite, fluorite, zircon and zeolites. Textural data suggest that these rocks crystallized under high-T conditions characteristic of high level subvolcanic environments. A predominance of K₂O over Na₂O is characteristic of these rocks. On the basis of chemical data presented, these rocks have been classified as LAMPROITE of "GROUP III" (Foley et al. 1987). Petrogenetic models for the origin of these rocks are discussed.

Key words: Ultrapotassic rocks, petrography, Khyber Agency.

Pegmatite rocks associated with Oligocene two-mica granites of the Asian plate as well as pre-Cambrian granites of the Nanga Parbat Haramosh Massif on the Indo-Pak plate have been investigated for their Li content. The pegmatites are of two distinct metaklogenic types, one showing enrichment towards lithium and the other to REE.

Key words: Lithium mineralization, pegmatites, Nanga Parbat-Haramosh.

B/352. Butt, K.A., 1997. An assessment of uranium favourability of granitic rocks of Indo-Pak plate in northern Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

An assessment of the granitic rocks of Indo-Pakistan plate for their favourability to host uranium deposits is presented. Mathews (1978) arrived at a set of recognition criteria including tectonic setting, host rock lithology, host rock texture, mineralogy, chemistry, alteration, geometry of mineralization and rock associations. Comprehensively compatible data on all these aspects of granitic rocks of Indo-Pakistan plate is not available. This paper, however, is an attempt to present a compilation of the available geological data along with more than 400 new chemical and petrographic analyses in order to arrive at a preliminary assessment of favourability of the granitic rocks of Indo-Pak plate.

Three groups of granitic rocks have been identified from the Indo-Pak plate in North Pakistan. Only one group has been interpreted to be favourable for hosting uranium deposits. This assessment would result in a substantial reduction in the size of the target area for uranium exploration in these granitic environments.

Key words: Uranium, granite, Indo-Pak plate.

B/353. Butt, K.A., 1997. Ruby mineralization at Nangi-Mali upper Neelum valley, Azad Jammu and Kashmir. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

Regional geological set-up and detailed local geology of Nangi-Mali ruby occurrence is described. Based on geology petrography and mineralogy of the occurrence a genetic model for the mineralization is proposed potential of this model's applicability in prospection of ruby in the higher Himalayan region of Pakistan is discussed.

Key words: Gems, ruby, petrography, Neelum valley.

B/354. Butt, K.A., Arif, A.Z., Ahmed, J., Ahmed, A. & Qadir, A., 1989. Chemistry and petrography of the Sillai Patti carbonatite complex, north Pakistan. *Geological Bulletin, University of Peshawar* 22, 197-215.

Detailed geology, petrography and chemistry of Sillai Patti sheeted carbonatite complex is presented. The complex is an anastomosing set of dykes intruding metamorphics of possible Proterozoic age. The complex is interpreted to be a product of multiple intrusions. The early phase of the intrusion is represented by peralkaline ultrabasic rocks (pyroxenites). This was followed by the intrusion of carbonatites and its attendant fenitization. There is a considerable petrographic and chemical variability in the complex, which is considered to be a function of varying degree of fenitization and hybridization of the earlier ultrabasic rocks by the carbonatite dykes.

Key words: Geochemistry, petrography, carbonatite, Sillai Patti, Malakand Agency.

B/355. Butt, K.A., Chaudhry, M.N. & Ashraf, M., 1980. An interpretation of Petrotectonic Assemblage West of Western Himalayan Syntaxis in Dir District and adjoining areas in Northern Pakistan. *Geological Bulletin, University of Peshawar* 13, 79-86.

A review of the geology of areas west of western syntaxial bend of Himalayas in Dir district and adjoining areas of northern Pakistan is presented. Several geotectonic regimes have been recognized and it is proposed that the well-known Indus ophiolite suture in this area is represented by amphibolite/ophiolite belt of Dir. These ophiolites are thought to have generated in an ocean and that their emplacement involved initially an ocean-continent type of plate interaction followed much later by continent-continent collision.

Key words: Tectonics, petrology, amphibolite, ophiolite, Dir, Himalaya.

B/356. Butt, K.A., Chaudhry, M.N. & Ashraf, M., 1985. Evidence of an incipient Palaeozoic ocean in Kashmir, Pakistan. *Kashmir Journal of Geology* 3, 87-102.

The Himalayas are interpreted to have formed by continent-continent collision between Indo-Pak plate and Asia. This event has been dated to be Eocene. Prior to the collision however, tectonics of the passive northern margin of the Indian plate has rarely been examined although these older rocks constitute a significant part of the Himalayan region especially the southern Kohistan ranges of Yeats & Lawrence (1984). Geochemistry of the Panjal volcanics is used to demonstrate that these represent an incipient ocean floor which lay between the Gondwana and Kashmir-Hazara microcontinent prior to the break-up of India from Gondwana.

Key words: Paleozoic, oceanic rocks, Panjal volcanic, tectonics, Kashmir.

B/357. Butt, K.A., Chaudhry, M.N. & Ashraf, M., 1987. Evidence of an incipient Paleozoic ocean in Kashmir, Pakistan- A reply. *Kashmir Journal of Geology* 5, 127-132.

Geochemical data presented in the paper Butt et al. (1985) is shown to be comparable to the data published by other authors on Panjal volcanics. Repeat analysis of 40 rock samples (to be published elsewhere) confirm high Al_2O_3 and low to moderate TiO_2 and low MnO_2 values.

The treatment certainly does not prove that Panjal basalt are MORB and the same was never claimed. Similarly the problem of these rocks being tholeiitic, alkaline or otherwise is also apparent from data of Gupta et al (1983) and Pareek (1983). Instead a transitional nature of these basalts was suggested which may have formed in an incipient ocean. The first stage in the evolution of an ocean is widely accepted to be an "Intracontinental rift" and successive developmental stages from a rift to an oceanic environment must involve an evolutionary process of development of oceanic crust between these two end members. The transitional nature of these basalts was proposed in this study.

Key words: Paleozoic, oceanic rocks, Panjal volcanic, tectonics, Kashmir.

B/358. Butt, K.A. & Khalid, M.M., 2001. Interpretation of satellite image to delineate the lineaments and natural drainage in and around Islamabad and their impact on environment. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.42.

Islamabad capital city of Pakistan is situated at the foothills of Margalla, which are considered to be in close proximity of Main Boundary Thrust (MBT).

Satellite image interpretation reveals that a number of lineaments abutting with MBT pass through the well-planned city of Islamabad. Most of the civil structures have been made in close proximity to these lineaments without any consideration for a special foundation design due to which cracks have been reported to develop in these buildings.

The streams originating from the hills surrounding Islamabad have also been blocked by manmade structures, which obstruct the natural seepage during rainfall and cause maximum surface runoff. This tremendously increased in the runoff input of water to Nala Lai. Due to this fact intensity of flood in Lai Nala has been increased in recent years.

Key words: Remote sensing, drainage, Islamabad.

B/359. Butt, K.A. & Khan, T.M., 1992. Uraniferous black shales of Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.8.

The graphitic-metapelites of NW Pakistan and Azad Kashmir are exposed in a zone of thrust tectonics, and are scattered in the form of continuous beds and lenses in various nappes. These are highly radioactive at places but the equivalent chemical uranium is found to be lower than its radiometric equivalents. Based on petrography and X-Ray diffraction studies a classification of black shales of Pakistan is presented. The chemical composition of the graphitic-metapelites indicates that the rocks from Tarbela area are more siliceous and contain more organic C compared to the rest of the exposures of the graphitic-metapelites. Due to their fine-grain-size, dark colour and Fe oxidation along fractures the rock types are classified as black shales. According to this classification the graphitic-metapelites from Tarbela area are siliceous and the graphitic-metapelites from other areas are dominantly argillaceous-siliceous with high normative quartz. Uranium and other associated elements are concentrated in the upper parts of the graphitic-metapelites. Compared to the metal rich black shale deposits elsewhere in the world, these rocks are enriched in U, V, Ba and Pb. Precipitation of these elements from saline waters is suggested rather than normal seawater. However, sulphidization of Fe by hydrogen sulphide has played some role in the concentration of elements from saline waters. Precipitation of the elements has taken place in oxygenated waters in a transitional environment close to the continent. The black shales were deposited in multiple basins characterized by different sources of supply of the elements to these basins.

Key words: Mineral exploration, petrography, XRD, black shale, uranium, Kashmir, Thakot, Tarbela..

B/360. Butt, K.A. & Mahmood, K., 1983. Munirite, naturally occurring sodium vanadium oxide hydrate, a new mineral. *Mineralogical Magazine* 47, 391-392.

Munirite was found in the sandstones of Siwaliks formation of mid-Miocene to Pleistocene age. It occurs as small globular clusters of acicular crystals (2 to 3 mm long). Analysis gave V₂O₅ 67.46, N₂O 22.91, and H₂O 10.26%. The X-ray powder diffraction pattern shows remarkable similarity to a synthetic compound NaV₃O₁₀ · 1.9H₂O (Lukacs and Strausievici, 1962). The new mineral was collected from Siwalik sandstones in Bhimber area, Azad Kashmir, Pakistan.

It crystallizes as radiating fibrous aggregates on outcrops as well as on the walls of exploratory trenches. The new mineral has been named after Mr Munir Ahmad Khan, Chairman of the Pakistan Atomic Energy Commission, who instituted the Mineral Research Laboratories in the Commission. The name and data have been approved prior to publication by the Commission on New Minerals and Mineral Names, IMA. Type material has been deposited with the Hard rock Division, Atomic Energy Minerals Centre, PO Box 734, Peshawar, Pakistan, and the British Museum (Natural History).

Key words: New mineral, sandstone, siwaliks, Azad Kashmir.

B/361. Butt, K.A. & Mahmood, K., 1986. Unit cell dimensions of uraninites from various geological environments in Pakistan. *Acta Mineralogica Pakistanica* 2, 47-52.

B/362. Butt, K.A., Malik, R.H. & Khan, A., 1997. Geology of gem bearing complex pegmatites from upper Neelum Valley Azad Kashmir. Geological Bulletin, Punjab University 31 & 32, 127-132.

Geology of Janawai-Folowai area in upper reaches of Neelum valley, Azad Kashmir is presented. The geology of the area is divided into two units. A migmatitic basement complex consisting of high grade pelitic gneisses, migmatites and sheet granites thrust on to the high grade dominantly calcareous metasediments. This area is the host of a number of lithium and rare earth enriched complex pegmatites. These pegmatites have been reported to contain gem bearing cavities. This study suggests a tectonic classification of the pegmatites of this area and it is proposed that this classification has a potential in discriminating between Li, rare metal and Gem producing pegmatites from barren pegmatites.

Key words: Gems, pegmatites, Neelum valley, Azad Kashmir.

B/363. Butt, K.A. & Qadir, A., 1987. Discovery of lepidolite from Shengus area, Gilgit, Pakistan. Geological Bulletin, Punjab University 22, p.153.

Several pegmatite localities in Gilgit and Chitral were sampled in a bid to investigate their Lithium content.

There are a few unpublished previous reports about pink micas from northern area i.e. Ruby mines of Hunza area etc. Some of these samples were analysed and were found to be rose muscovite (Nawaz, Personal Comm.). Kazmi et-al. (1985) reported an occurrence of lepidolite from Bulechi area in Gilgit. However they did not produce supporting mineralogical or chemical data.

Mica samples of various colours were collected from Chitral areas and analysed for Lithium. It has been observed that pink, greenish, smoky and colourless micas from these pegmatites contain anomalously high Lithium but do not approach the Li_2O concentration to be classified as Lepidolite.

Garam Chashma area in Chitral contains micas with highly anomalous Li_2O content of the order of 0.45% Li_2O . Associated white micas within a single body of pegmatite clearly fall in two categories in terms of their Lithium content.

(i) Lithium rich micas, 0.45% Li_2O

(ii) Lithium poor micas, 0.008% Li_2O

None of the muscovite analysed from this area approached lepidolite.

Similar sampling was carried out in Shingus (Gilgit) area. Once again associated micas gave two populations:

1. Lithium rich micas 4.24% Li_2O

2. Lithium poor micas. 0.05% Li_2O

Lithium rich micas of shingus area can be classified as Lepidolite. Considering the similarity of Lithium distribution patterns in the two areas, it is concluded that the complex pegmatites in Chitral also hold a good potential for the discovery of Lithium minerals. It may be added that this is the first report in Pakistan wherein the occurrence of Lepidolite has been confirmed on the basis of chemical data.

Key words: Lepidolite, Shengus, Gilgit.

B/364. Butt, K.A. & Shah, Z., 1985. Discovery of blue beryl from Ilum granite and its implications on the genesis of emerald mineralization in Swat District. Geological Bulletin, University of Peshawar 18, 75-81.

Geological mapping of toposheet 43 B/6 in Buner Valley, District Swat is presented. Petrographic and mineralogical data on veins associated with Ilum granite have revealed a complex assemblage produced by multiphase hydrothermal activity. Some of these veins have been cataclastically deformed along with the granite body, whereas others show minor or no cataclasis and are hosted in post-cataclasis joints.

A genetic relationship between the granite and associated veins is proposed from field criteria. Hydrothermal veins associated with Ilum granite contain blue beryl. A granitic source forms the beryl and possibly for spatially associated emerald mineralization is postulated.

Key words: Gemstones, beryl, emerald, granite, Ilum, Swat.

B/370. Butt, M.H. & Latif, A., 1992. Production of major minerals of Pakistan 1947-1989. Geological Survey of Pakistan, Information Release 512, 28p.

The term mineral is used for any of the large group of natural inorganic substance having homogeneous structure, a specific chemical composition, uniform physical characteristics and usually a definite form of crystal. In broader terms it refer to all products (solid or liquids) derived from the mineral kingdom including energy raw materials.

It is felt generally by all those concerned with and interested in mineral development that essential information regarding the minerals sector is not accessible easily, hence the pace of mineral development is restricted, which is extremely important for industrial development of the country. As a result, if on one hand exploitation of indigenous mineral resources has not expanded rapidly, on the other hand extent of their industrial utilization has remained rather restricted, so this foreign exchange deficient country is importing a lot of common mineral based commercial products, which can easily be available to the consumer in the coal currency.

Geological Survey of Pakistan (GSP), an attached department of the Federal Ministry of Petroleum and Natural Resources, is also aware of this situation and since its establishment (i.e. 1947), it has tried to find the new minerals by the application of most modern techniques and knowledge. A lot of new discoveries have been made by this organization, starting from Coal Copper, fluxes, Fertilizer, China clay, Silica Sand, Bauxite, Lead zinc, Manganese, Uranium to the latest discovery of high grade iron ore in Chiniot-Sargodha area.

It is the joint effort of private and public mineral enterprises, supplemented by the mineral-surveying national organization that the mineral sector share in the Gross National Product of Pakistan rose from Rs. 793 million in

1947 to Rs. 14767 million in 1987-88, a nineteen fold increase in real terms and in percentage share to GNP, it rose from 0.75% in 1947 to 2.27% in 1987-88, a threefold increase.

The aim of present report is to highlight the production of major minerals of Pakistan from 1947-1989 and represent these figures in the form of graph to tell the reader at a glance about the ups and downs of a particular commodity. For interested readers it also gives the physical properties, diagnostic features, occurrence and uses on the opposite page.

A geological map is presented at a scale of 1:25000 covered by topo sheet No. 43 F/1 issued by the Survey of Pakistan. The rock sequence in the project area is the part of eastern Jijal and Pattan Complexes. The Jijal Complex in the project area is thinned out due to the intersection of MMT and Pattan faults as compared with the western part of the Jijal Complex. It is relatively fresh and massive on the KKH section, but in our project area the Jijal Complex has imprints of metamorphism but is the least metamorphosed among series of meta-plutonic complexes. The Pattan Complex (lowest part of the so called Kamila amphibolites) is considered here as a metamorphosed basic plutonic complex. The rocks of the complex exhibit relic igneous textures, at places but the mineral assemblages correspond to the low pressure metamorphic assemblages from green schist to granulite facies. Field and petrographic studies show that the Jijal Complex is formed within a separate magma chamber and is predominantly igneous in nature. The Jijal rocks are considered younger than overlying metamorphosed series of plutonic complexes (earlier known as Kamila amphibolites). The plutonic complexes have been metamorphosed under low pressure dynamothermal metamorphism during the development of northern suture (MKT).

C/9. Caldeira, K. & Kerrick, D.M., 1995. Uplift and chemical weathering in south-central Asia, the carbon cycle and Cenozoic climate. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

It has been proposed that the general cooling trend through the Cenozoic has been largely due to the enhancement of silicate-rock weathering rates associated with continental uplift in south-central Asia (i.e., the Himalayan and related orogens, and the Tibetan Plateau). One of the primary pieces of evidence cited to support this proposal is the Cenozoic strontium isotope curve, which has been interpreted as indicating progressively increasing silicate-rock weathering rates associated with continental uplift in this region.

Uplift, by increasing the exposed surface area of fresh rock exposed to chemical weathering, may enhance the ease with which rock is weathered, and hence may have an impact on atmospheric CO₂ content and climate. However, if this mechanically weathered rock is rapidly transported to and buried in river deltas, enhanced mechanical erosion need not induce enhanced chemical weathering. Enhanced silicate-rock weathering on a global scale requires an enhanced supply of CO₂, else the atmospheric and oceanic reservoirs of CO₂ would be rapidly depleted. We have constructed a preliminary carbon budget for the Cenozoic, and have shown that the interpretation of the strontium isotope curve in terms of enhanced chemical weathering rates is inconsistent with both inferred rates of CO₂ degassing from the solid Earth and the inferred timing of uplift in Tibet, Himalayas and related orogens. Furthermore, the strontium in rivers draining the Tibetan plateau and the Himalayas is insufficient to account for the observed Cenozoic change in oceanic ⁸⁷Sr/⁸⁶Sr ratios.

Furthermore, we have conducted a preliminary field study examining the Himalayan and Karakorum orogens as a potential metamorphic CO₂ source to the atmosphere. Our initial results indicate that metamorphic CO₂ releases associated with the India-Asia collision would not have been sufficient to supply the CO₂ required to account for proposed increases in chemical weathering rates.

C/11. Calkins, J.A. & Ahmad, M., 1969. Geology of the Tarbela damsite area, Peshawar Division, West Pakistan. USGS/GSP, Information Release PK-47, 17p.

About 80 square miles in the vicinity of the Tarbela damsite was mapped in order to relate the geology of the damsite proper to larger regional geologic features. The rocks in the area are chlorite-mica-quartz schist, marble and calcareous schists, and calcareous graphite schists of the Salkhala Formation (Precambrian); slate and phyllite schists of the Hazara Formation (Precambrian to Early Paleozoic); quartzite of the Tanawal Formation (Silurian or Devonian); dolomite of the Abbottabad Formation (Carboniferous to Permian); and small intrusive bodies of Tertiary age. Unconsolidated surficial deposits include reworked loess, river alluvium, and terrace deposits.

The main structural feature is a strike-slip fault, called the Darband fault, which passes down the Indus River through the damsite, and separates the Salkhala and Tanawal Formation on the west bank from Hazara and younger formations on the east bank. East of the Darband fault large northeast-trending folds plunge northeast. On the west bank, west of the Darband fault, large folds are not evident in the Salkhala Formation, but most small-scale folds are parallel to the large folds east of the fault.

In the northern part of the mapped area quartzite of the Tanawal Formation forms a large east-trending anticline overturned to the south. The southern overturned limb has moved relatively southward over the Salkhala rocks along a north-dipping thrust fault. The geological feature of greatest potential concern relative to the Tarbela dam is the Darband fault, which passes through the damsite. This fault is considered to be inactive, however, and may be too deeply buried by river alluvium to promote leakage. The schistose rocks in the west abutment area are weak, permeable, and cut by numerous shear zones.

The dolomite rocks of the Abbottabad Formation in the east abutment area, although much jointed. Are rigid and relatively impermeable in comparison with the rocks in the west abutment area.

Key words: Dams, Tarbela, Peshawar

C/13. Calkins, J.A., Jamiluddin, S., Bhuiyan, K. & Hussain, A., 1981. Geology and mineral resources of the Chitral-Partsan area, Hindukush Range, northern Pakistan. USGS Professional Paper 716-G, 33p.

This report is based upon field investigations covering an area of about 1,400 square miles (3,626 sq km) in the Hindu Kush Mountains of Chitral State in northern Pakistan and also includes a discussion of geological questions relating to an area of about 8,000 square miles (20, 720 sq km) in the Chitral-Gilgit area. The area is extremely rugged; local relief is more than 8,000 feet (2,438 meters) over most of the area and commonly reaches 10,000 feet (3,048 meters). Many peaks are higher than 17,000 feet (5,182 meters), and Tirich Mir, 8 miles (12.9 km) north of the mapped area, is 25,263 feet (7,700 meters) high. The mapped area includes the following units: Devonian unit; Sarikol Shale (Devonian to Carboniferous); a broad belt of metamorphic rocks of Devonian to Jurassic age; Reshun Formation, a volcanic greenstone unit, a limestone and phyllite unit, a greenschist unit, and the Chitral Slate-all of Cretaceous age. Elongate bodies of granite (Cretaceous) underlie large parts of the area. Of stratigraphic interest are (1) the lateral facies change of the Reshun Formation from fossiliferous conglomeratic red shale and phyllite at Reshun, to marble in the Kafiristan area, and (2) the determination of a Cretaceous age for the Chitral Slate, which formerly was considered to be of Paleozoic age.

Structurally, the mapped area is characterized by a system of folds overturned toward the east and south. This fold pattern marks the regional trend of the Hindu Kush Range, from north in the southwestern part of the area to east-northeast in the eastern part. Several reverse and thrust faults separate belts of rocks of Cretaceous age from belts of older rocks. Metallic deposits in the area include (1) veins containing antimony, lead, and copper with associated gold, silver, and tin; (2) copper localities in mafic rocks and greenschist; and (3) miscellaneous showings, mainly of copper. Antimony has been mined on a small scale at Krinj since 1939. The places of high mineral potential are the vein-type deposits along the fault zones in the Awireth Gol-Shoghot-Madashil area, the Krinj mine area, and in the Shishi Valley area. Along these faults the largest showings of copper, lead, and antimony are found, and in the Awireth Gol locality the lead ore contains large amounts of gold and silver.

Nonmetallic mineral deposits include limestone, marble, dolomite, granite, pegmatite, and talc. No commercial limestone industry exists in the Chitral area. However, limestone and marble are used locally for building stone. Granite is also used locally for building stone. Mica and beryl are mined on a small scale from pegmatites 15 miles (24 km) northwest of the mapped area.

The work also includes a geological map of the area at a scale of 1:96000 along with two cross-sections, a regional geological map of the Gilgit-Chitral area at a scale 1:250,000 scale and a table of chemical analyses for metallic minerals.

C/14. Calkins, J.A. & Matin, A.S.A., 1968. The geology and mineral resources of the Garhi Habibullah quadrangle and Kakul area, Hazara district, West Pakistan. Geological Survey of Pakistan/USGS Project Report, Information Release PK 38, 55p.

The mapped area occupies about 250 square miles in the southern Himalayas of northern Pakistan and western Kashmir, rugged mountainous country characterizes the area; maximum topographic relief is about 7500 feet between Lachi Khan (9473 ft) and the lowest elevation of 2000 feet.

The oldest rocks are the slates and phyllites of the Hazara Formation, considered to be of Precambrian (?) age. Quartzose schists of the Tanawal Formation (Silurian? Or Devonian?) overlies the Hazara Formation. Succeeding rock units in the area include: dolomite of the Abbottabad Formation (Carboniferous to Permian), red shales of the

Galadanian Formation (early Jurassic), Daulatmar Limestone (Jurassic), Spiti shale and Glumal sandstone (Upper Jurassic and lower Cretaceous), Sattu Limestone (Upper Cretaceous), chhalpani Formation (Paleocene and Eocene), and the Murree Formation (Miocene). Correlation of the Carboniferous to Eocene sequence of rocks in this area has been established with rocks of the Kala Chitta hills west of Rawalpindi, and with rocks of the Kohat area south of Peshawar.

C/16. Calkins, J.A., Offield, T.W., Abdullah, S.K.M. & Ali, S.T., 1975. Geology of the southern Himalaya in Hazara, Pakistan and adjacent areas. USGS Professional Paper 716-C, 29p.

Geologic mapping and mineral investigations were conducted from 1961 to 1965 by the Geological Survey of Pakistan and the U.S. Geological Survey in the Hazara district, Pakistan, and part of western Kashmir, as part of a cooperative mineral exploration and development program. The area covers 2,000 square miles in the southern foothills of the Himalaya between the Jhelum River on the east and the Indus River on the west. Rugged mountains and deep canyons characterize most of the area. Altitudes range from 1,100 feet on the Indus River near Tarbela to more than 16,000 feet on the Kashmir divide; the Indus, Siran, Kunhar, Kishanganga, and Jhelum Rivers all flow in deep gorges through the area. The geologic formations range in age from Precambrian to Quaternary and include sedimentary, igneous, and metamorphic rocks and unconsolidated material. The oldest rocks belong to the Salkhala Formation of Precambrian age. Above it are the Hazara Formation (Precambrian(?)) and possibly lower Paleozoic, Tanawal Formation (Upper Ordovician(?) to Devonian (?)), Panjal and Kingriali Formations and "Agglomeratic Slate" (Carboniferous to Triassic), Datta Formation (Lower Jurassic), Samana Suk Limestone (Jurassic), Chichali Formation (Upper Jurassic), Lumshiwal Sandstone (Upper Jurassic to Lower Cretaceous), Kawagarh Limestone (Upper Cretaceous), Kala Chitta Group (Paleocene to Eocene), and the Murree Formation (Oligocene(?) to Miocene). The Mansehra Granite was intruded in Late Cretaceous to early Tertiary time, apparently in the form of one or more sheetlike bodies. Contact-metamorphic effects around the granite generally are not pronounced; however, wollastonite occurs at one locality. Regional metamorphism and accompanying penetrative deformation increase in intensity northward. The regional metamorphism was synchronous with or postdates the granite, because the granite itself is involved in the deformation. The structural pattern in the mapped area consists of two northward-projecting loops or reentrants the larger Hazara-Kashmir syntaxis and the smaller Indus reentrant connected by a broad arcuate belt, called the western arc. The Hazara- Kashmir syntaxis, which is the pivot point of the great regional arc of the northwest Himalaya, is oriented slightly west of north and contains younger rocks in its core or axial zone; successively older rocks wrap around the periphery. A system of boundary faults also wraps around the syntaxis and helps to define it. The southern part of the western limb of the syntaxis is divided into three structural blocks separated by major faults which show combined strike-slip and vertical displacement.

The structural development of the Hazara-Kashmir syntaxis is believed to be related to the great regional arc of the Himalaya 150 miles to the north. Southward tectonic transport moving perpendicular to this great arc would converge on the axial zone of the Hazara-Kashmir syntaxis, which is at the pivot point of the arc. The present syntaxial structure would be the natural result of such movement. Late-stage westward countermovement of the rocks in the axial zone resulted in the present westward overturning of the folds along the southern segment of the western limb of the syntaxis.

The Indus reentrant, as with the Hazara-Kashmir syntaxis, also is interpreted to be the result of smaller scale tectonic convergence towards its present axial zone. Between the Hazara-Kashmir syntaxis and the Indus reentrant, the rocks moved south to form the southward bulge of the western arc. In terms of large-scale tectonics the Himalayan mountain system has southward asymmetry, which has been interpreted in two ways: (1) radial spreading out southward of middle Asia and (2) continental drift of India against Asia. The latter view has gained credibility recently as a result of new data and ideas on global tectonics. The earliest known indications of the Himalayan

orogeny are found at Hindubagh, near Quetta, where ultramafic rocks were emplaced after Cretaceous but before Eocene time. The widespread episode of folding and mountain building began in Miocene time in the mapped area.

C/17. Callegari, E. & Zanettin, B., 1960. Chimismo di rocce vulcaniche plutoniche del Karakorum centro meridionale. Memoir Institute of Geology and Mineralogy, University of Padova, Mem., vol. xxi, 38p.

The Karakoram Range contains large number of plutonic rocks, as well as volcanic rocks along its southern margin. This is a report of the geochemistry of the rocks collected during the Italian expeditions led by Ardito Desio.

Key words: Geochemistry, volcanic, plutonic rocks, Central Karakoram

C/18. Campbell, E., 1917. Notes on the rock specimens collected by the Bullock Workman Expedition 1911–12 in the Bilaphond and Kondus basins, and on the Khondokoto and Masherbrum Glaciers. Appendix. In: Two Summers in the Ice–Wilds of Eastern Karakorum. Workman, F. Bullol and Workman, W.H. (Eds.), Fisher Unwin, London.

Three specimens were collected in the Ghyari nala below the Bilaphond glacier: two of these are white crystalline limestone containing a little tremolite; the third is a serpentine (chrysotile). These were the only specimens actually collected. Dr. Longstaff had previously recorded granite as abundant in the moraines.

Some interesting material was collected at the head of the Dong-Dong glacier. One is a coarse white crystalline limestone like those collected in the Ghyari nala. Another is a fairly coarse-grained white biotite-granite, with garnets reaching 4 mm in diameter; it is very poor in ferromagnesian minerals, containing only a little biotite and a trace of muscovite. Quite the most interesting specimen from this locality is a fragment showing large plates of pale green actinolite: some of these show rough crystal outlines, the outer zone of the crystal being brown. They are associated with portions of finer grain consisting of diopside and tremolite, and some fragments of aplite are also adhering to the specimen. This rock is evidently a product of contact metamorphism due to a granitic intrusion.

Several specimens were collected on the central moraine of the north-east branch of the Kaberi glacier. Here occurred white, pink, and purple limestones similar in texture to those of the Siachen; while a light coloured moraine at the head of the glacier yielded abundant slabs of white marble similar to that collected on the Tarim Shehr.

With the limestones of the central moraine occur masses of tetrahedrite, with malachite and azurite, and a curious mass of black pisolitic concretions cemented and impregnated with pyrites and apparently passing into a kind of pisolitic ironstone.

The east wall of the Khondokoro glacier yielded a fine-grained hornblende-biotite-gneiss and also a typical felspar-amphibolite. From the moraines of the same glacier came a muscovite-biotite-granite containing small garnets and showing a tendency towards granulitic structure. This rock occurs as a fine-grained granite, but in some specimens the plates of muscovite may measure half an inch across. The garnets never seem to exceed 1 mm. in diameter. This type was also found by Sir Martin Conway in the Astor valley.

The Masherbrum glacier yielded four specimens: two are white fine-grained dolomite, one is serpentine, the other is an augen of quartz, apparently from a chlorite schist. An interesting rock was collected at the junction of the Khondokoro and Masherbrum nalas. It is a fine-grained granite-gneiss consisting of quartz, stained yellowish brown, oligoclase and some microcline, with fairly abundant patches of biotite. Sphene and epidote occur as accessories. The oligoclase frequently shows patches of inclusions of biotite and sphene, and also a secondary development of muscovite and epidote. There is some micrographic intergrowth with quartz at the borders of the felspar crystals, and in places a marked tendency towards granulitic structure.

C/20. Caporali, A., 1992. Recent gravity measurements in Karakoram. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 11.

Two new gravimetric profiles have been observed in Karakorum as part of the activities of the Ev K2 CNR Project led by prof. Ardito Desio. One profile, established in 1988, starts from Bazar Dara (China), north of the Aghil range, and covers the portion of the Shaksgam valley between the confluence of the Urdok-Gasherbrum glaciers to the SE and, along the Shaksgam River, Tek ri-Sughet Jangal to the NW. The second profile, done in 1990, starts from Skardu and ends in Gilgit via the Biafo Hispar glaciers. During both expeditions we established a number of astrogeodetic stations for the measurement of the deflection of the vertical, using the satellites of the Global Positioning System to determine reference geodetic coordinates. Two astronomic stations were done in 1988 and fourteen in 1990,

The geographic location and overall quality of the observations indicate that they provide an interesting addition to the collected by Marussi and coworkers from 1964 to 1979. In the course of our surveys a number of the Marussi points were checked to ensure consistency.

The paper contains a preliminary analysis of the Marussi plus our 1988-1990 data. To remove low frequency trends in the anomalous gravity field we make use of predictions based on the spherical harmonics expansion of the global earth gravity field produced by the Ohio State University (model OSU91A). This representation is complete to degree and order 360 and is particularly interesting as it includes for the first time Chinese gravimetry.

Key words: Geophysics, gravity, GPS, Karakoram.

C/21. Caporali, A., 1993. Recent gravity measurements in the Karakoram. In: Treloar, P.J. & Searle, M.P. (Eds.), Himalayan Tectonics. Geological Society of London, Special Publication 74, 9-20.

Two new gravimetric profiles have been obtained in the Karakoram as part of the activities of the Ev-K2-CNR Project. One profile, established in 1988, starts from Bazar Dara (China), north of the Aghil range, and covers the portion of the Shaksgam valley between the confluence of the Urdok-Gasherbrum glaciers to the SE and, along the Shaksgam river, Tek ri-Sughet Jangal to the NW. The second profile, carried out in 1990, starts from Skardu and ends in Gilgit via the Biafo Hispar glaciers. During both expeditions a number of astrogeodetic stations were established for the measurement of the deflection of the vertical, using the satellites of the Global Positioning System (GPS) to determine geodetic reference coordinates. Two astronomic stations were established in 1988 and fourteen in 1990. The new data, when added to those collected by Marussi and co-workers from 1954 to 1979, improve the coverage north of the Main Karakoram Thrust, where the Bouguer anomalies attain their largest negative values. For all available data Bouguer and Airy isostatic corrections have been computed using the ETOPO5 height grid. A mean crust density of 2.85 g cm^{-3} , a density contrast of 0.3 g cm^{-3} and a normal thickness $T = 30 \text{ km}$ have been assumed, so that the surface of isostatic compensation locally best fits the Moho. Two profiles have been selected, one continuing northward of the Nanga Parbat - Haramosh massif the deep seismic sounding profiles done in the 1970s. The other is such that it crosses the Indus Suture Zone, the Main Karakoram Thrust and the Karakoram Fault nearly at right angles. In both profiles, from Pakistan to China, the horizontal gradients of the Bouguer anomalies are in the interval -1.5 to -2 mgal km^{-1} , comparable to gradients found in the region between the Indo-Gangetic Plains and the Himalaya. A marked steepening of the Moho is implied here with increased detail. Isostatic anomalies underneath the Karakoram are found to be more negative than those computed in the earlier work of Marussi, who made different assumptions of density and density contrast. Clearly the new data do not uniquely constrain the local structure of the lithosphere but may be of help in better understanding non-negligible deviations from isostatic equilibrium.

Key words: Geophysics, gravity, GPS, Karakoram.

C/22. Caporali, A., 1995. Gravity anomalies and the flexure of the lithosphere in the Karakoram, Pakistan. *Journal of Geophysical Research* 100 B(8), 15075-15085.

The negative correlation between gravity anomalies in mountain regions and the topographic height implies a mass deficiency beneath the range and adjacent regions. Classical compensation schemes in which roots of constant

density form at a depth proportional to the topographic height (Airy scheme) or individual columns of laterally variable density develop to a constant depth (Pratt scheme) enable only part of the anomalies to be modeled and provide a “static” description of the structure of the crust and upper mantle, regardless of the vertical and horizontal motions associated with the origin and evolution of mountain belts. Early studies of isostatic anomalies across the Karakoram range, in northern Pakistan, have shown that the region is not in isostatic equilibrium in the Airy sense and have pointed to the need of a more refined model of the forces and stresses shaping the lithosphere than classical isostasy. The concept that the lithosphere should respond by flexure to applied loads as a thin, elastic, semi-infinite plate buoyant on a denser, inviscid fluid is used here as the basis to compute model Bouguer anomalies, estimate by least squares the deformation of the plate, and constrain some of the plate's elastic parameters. It is assumed that the forces responsible for the deformation are the topographic load, the hydrostatic response, and the elastic stresses within the plate. The plate itself is assumed to be separated into an Indian and an Asian portion, each with its own equivalent elastic thickness. At the border between the two portions an empirical infracrustal point load is assumed to act vertically. Gravity anomalies are then computed along five profiles crossing the range, as a function of the abscissa of the border point, the load acting at this point, the elastic thicknesses of the Indian and Asian portions of the plate, and the density contrast across the median section of the plate. The corresponding numerical values and associated formal uncertainties are determined by a least squares fit of the model anomalies to the observed Bouguer anomalies, along each of the five independent profiles. The postfit residuals are found to have essentially zero mean and an rms (root mean square) dispersion of the order of 20 mGal, which is consistent with the expected overall accuracy of the “observed” Bouguer anomalies interpolated to the profiles. The distribution of the post fit residuals still shows systematic components at the level of a few tens of mGal, that are likely to be caused by local, shallow geological structures. Overall the peak-to-peak excursion of the residual anomalies is considerably smaller than the classical isostatic anomalies for the same region. It is found that (1) the line connecting the estimated abscissas of the border points on each profile follows closely suture lines which have been independently identified from geological data and could be associated with the center of mass of the Kohistan-Ladakh island arc considered as a buried load; (2) for all profiles the elastic thickness of the Indian plate is systematically less than for the Asian plate, typically 80–100 km for India and 100–120 km for Asia; (3) there is a tendency of the elastic thickness of both portions to increase moving NW, towards the Pamirs. The gravity data are thus consistent with a relatively rigid Asian plate in the Tarim basin, unlike the Central Himalaya where Tibet, being indented by India, has zero strength.

A ‘blank on the map’ only 60 year ago, the Karakoram Range has been explored and surveyed with greater difficulty than the Himalaya and Tibet due to its rugged terrain and extensive glaciation. In the past ten years we have succeeded in doubling the number of gravity stations. A substantial improvement in coverage and overall quality was obtained by concentrating on previously unsurveyed areas and by validating older data with more accurate measurements. Our data were merged with earlier data, converted to full Bouguer anomalies and gridded. The resulting Bouguer anomaly map defines very precisely the gravimetric low associated with the Nanga Parbat-Haramosh Syntaxis, and the huge negative values are now visible also in the Ghujerab-Khunjerab areas. Correlation of the topography and Bouguer anomaly shows that a plate of flexural rigidity with $D=2 \times 10^{21}$ Nm fits the coherence data in the Karakoram at all but two distinct frequency ranges centered at wavelengths of 80 and 300 km. In a rheologically layered lithosphere developing a buckling instability under horizontal compression, the observed spectral features of the topography and Bouguer gravity anomalies constrain the depth of the competent layers to be in the range 13-20 km and 50-75 km respectively.

The ophiolites of the Dras zone outcropping along the Suture between Indian and Eurasian continents are mostly made-up of lherzolite, gabbro and basalt. These are associated with Jurassic-Cretaceous sedimentary rocks (jaspers-radiolarite-shales-breccias), with the northern fault covering (Deosai plateau) and southern tectonic overthrust of the Tethyan calcareous dolomitic Triassic series. Amphibolitic prasinitic formations influenced by the Nanga Parbat Massif metamorphism and basic igneous masses developed near Astore on the western slope Deosai. They could represent the northern continuation of this Suture line. The ophiolitiferous series and the metabasites are briefly described, and hypotheses as to their origin are presented.

The formations crossed on a route travelled in the Ishkuman and Karambar valleys, along the profile of the Karakorum Geophysical project, are described. The section includes a plutonic core of granodioritic compositions surrounded by metamorphic rocks. In this body two batholiths can be identified, the northern one of which seems to constitute the axial batholith of the Karakorum. To the S of this structure there is development of metasedimentary and igneous rocks divided into two complexes; the greenstone complex with slates, phyllites, marbles, intrusives and middle-basic volcanics, and the clastic metasedimentary succession of turbiditic origin. To the N a thick sedimentary

sequence was observed, consisting of sandstones, limestones, dolomites, argillites, marls and conglomerates comprising terms from the Permian to the Cretaceous, never reported before.

C/45. Cervený, P.F., Johnson, N.M., Tahirkheli, R.A.K. & Bons, N.R., 1989. Tectonic and geomorphic implications of Siwalik Group heavy minerals, Potwar Plateau, Pakistan. In: Malinconico, L.L. & Lillie, R.J. (Eds.), *Tectonics of the Western Himalayas*. Geological Society of America Special Papers 232, 129-136.

Heavy mineral and paleocurrent direction data suggest that the ancestral Indus is an analog of the modern Indus River (Pakistan). During the past 18 m.y., the Indus has maintained a relatively stationary outlet position along the Himalayan Front. Sandstones from three sections of Siwalik strata have been sampled and their heavy mineral suites analyzed. These stratigraphic sections cover some 200 km in an east-west direction in the Potwar Plateau area. In the western and central Potwar Plateau sections, blue-green hornblende makes a conspicuous first appearance at 11 Ma, the boundary between the Chinji and Nagri Formations. Above this boundary, blue-green hornblende dominates the heavy mineral assemblage of Siwalik sand. In the Upper Siwalik beds the heavy mineral suite contains as much as 75 percent blue-green hornblende. Unroofing of the Kohistan Arc terrane is the most likely explanation for this detrital hornblende. In marked contrast, the eastern Potwar region does not show the same abundance of blue-green hornblende. Significantly, the modern river~ of the eastern Potwar do not carry abundant blue-green hornblende either; only the Indus River does. Paleocurrent measurements taken in the Chinji Village section near the center of the Potwar Plateau indicate a northwest-to-southeast flow direction, whereas those in the Trans-Indus 120 km west of Chinji Village indicate a northeast-to-southwest flow direction. These data indicate that the Siwalik sequence of northern Pakistan is configured as a large-scale alluvial fan with the ancestral Indus shifting course back and forth across the Potwar Plateau region with a frequency of 10^4 to 10^5 yr/cycle. River sinuosity varied systematically from side to side of this fan, with minimum sinuosity attained along a north-south axis. As indicated by the absence of blue-green hornblende, the ancestral Indus did not reach the eastern Potwar Plateau (Kotal Kund area, 100 km east of Chinji) during the past 11 m.y.

C/46. Cervený, P.F., Naeser, C.W., Keleman, P.B., Lieberman, J.E. & Zeitler, P.K., 1989. Zircon fission-track ages from the Gasherbrum diorite, Karakoram Range, Northern Pakistan. *Geology* 17(11), 1044-1048.

The Gasherbrum Peaks, in the Himalaya of Pakistan, reach elevations of >8000 m. The relief between the peaks and the adjacent valley (Baltoro Glacier) is in excess of 3000 m. Eight samples of the Early Cretaceous Gasherbrum Diorite at elevations between 4880 and 7165 m on Gasherbrum IV were collected for fission-track dating. Zircon fission-track ages from the Gasherbrum Diorite vary from Early Cretaceous to middle Tertiary in age. There is no consistent pattern between age and elevation. The Cretaceous ages indicate that these rocks were never deeply buried, i.e., heated to temperatures in excess of 175°C, to reset the zircons during Cenozoic time. These results also indicate that the uplift of this part of the Himalaya has been either very rapid and recent, or very slow since Early Cretaceous time. This latter possibility is not consistent with the high relief at Gasherbrum and what is known about regional tectonics. Gasherbrum IV zircons, currently at ~4880 m, have never been at depths greater than 6 km, and less than 3 km of material has been removed from the top of the range by erosion since the Early Cretaceous. Rapid uplift has occurred very recently, and erosion rates have not been able to keep pace with this uplift.

C/47. Cervený, P.F., Naeser, N.D., Zeitler, P.K., Naeser, C.W. & Johnson, N.M., 1988. History and relief of the Himalaya during the past 18 million years: Evidence from fission-track ages of detrital zircons from sandstones of Siwalik Group. In: Kleinspehn, K.L. & Paola, C. (Eds.), *New Perspectives in Basin Analysis*. Springer-Verlag, Berlin, 43-61.

Fission-track dating of individual detrital zircon grains can be used to characterize both ancient and modern sedimentary provenance. Ages of zircons in the modern Indus River drainage system of northern Pakistan are controlled dominantly by uplift rates of the source rocks in the Himalaya. Young detrital zircons come from rapidly rising terrain, whereas old zircon ages imply slow or negligible uplift. Modern Indus River sands contain a distinctive population of young, 1 to 5 Ma, zircons that are derived from the Nanga Parbat-Haramosh Massif, an area of rapid uplift ($5 \text{ m}/10^3 \text{ yr}$). Sandstones of the Siwalik Group deposited by the ancestral Indus River over the past 18 million years contain zircons that are only 1 to 5 million years older than the depositional age of the sandstones. Therefore, young zircons have been a consistent component of Himalayan surface rocks for the past 18 million years. These ages imply that a series of uplifted blocks or "massifs," analogous to the contemporary Nanga Parbat area, have been continually present in the Himalaya since 18 Ma, and that over that time the elevation and relief of the Himalaya, on a broad scale, have been essentially constant.

C/50. Chamberlain, C.P., Jan, M.Q. & Zeitler, P.K., 1989. A petrologic record of the collision between the Kohistan Island Arc and Indian Plate, northwest Himalaya. In: Malinconico, L.L. & Lillie, R.J. (Eds.), Tectonics of the Western Himalaya. Geological Society of America Special Paper 232, 23-32.

Pressure-temperature (P-T) paths observed in pelitic schists on either side of the Main Mantle Thrust in northern Pakistan record the dynamics of the collision between the Kohistan Island-Arc and Indian plate. Geothermometry studies, mineral reaction textures, and thermodynamic modeling of zoned garnets suggest that the rocks in the Kohistan Arc and the Nanga Parbat-Haramosh Massif experienced different pressure-temperature histories as a result of imbrication of these two terranes during thrusting. Rocks in the Kohistan Arc followed decreasing pressure-temperature paths, with early garnet growth occurring at high pressures (9.5 kbar) and later garnet growth at lower pressures (8.5 kbar). Conversely, rocks in the Nanga Parbat-Haramosh Massif record an increasing P-T path history. The early P-T history within the massif was at low pressures (4.0 kbar) and low temperatures (450°C). Later, both pressure and temperature increased to a maximum of 7.5 kbar and 580°C. The contrasting P-T paths observed within these two terranes provide evidence for overthrusting of the Kohistan Arc over the Nanga Parbat-Haramosh Massif along the Main Mantle Thrust.

C/52. Chamberlain, C.P. & Zeitler, P.K., 1996. Assembly of the crystalline terranes of the northwestern Himalaya and Karakoram, northwestern Pakistan. In: Yin, A. & Harrison M. (Eds.), The Tectonic Evolution of Asia. Cambridge University Press, 138-148.

In northern Pakistan, the collision of three terranes proceeded sequentially, with an initial collision of the Asian plate with Kohistan at 70-100 Ma (Coward et al., 1986; Treloar et al., 1989a), followed by a later collision of Kohistan with the Indian plate at about 50 Ma (Klootwijk et al., 1991). The P-T-t data show that the assembly of these crystalline terranes was a complicated process. The collision of the Asian plate and Kohistan began with initial tectonic thickening and high-pressure, high-temperature metamorphism, followed by post-metamorphic southward-directed thrusting as rocks of the Asian plate were thrust over Kohistan. The timing of these events is poorly constrained, but they must have occurred before 37 Ma (Searle, 1991) and, most likely, during the early stages of collision in the middle to late Cretaceous.

The timing of events related to the collision between the Asian Plate/Kohistan terranes and the Indian plate is much better constrained. We know from U-Pb ages of syn-metamorphic granites (Zeitler and Chamberlain, 1991; Smith, 1993;) and Nd-Sm ages of eclogites (Tonarini et al., 1993) that at about 50 Ma the northern margin of the Indian plate underwent initial tectonic thickening and relatively high pressure metamorphism. Following metamorphism, in the interval from 45 Ma to 25 Ma the northern margin of the Indian plate underwent a period of rapid exhumation and uplift. We (Chamberlain et al., 1991) and others (Treloar, Rex, and Williams, 1991) have tentatively suggested that the rapid cooling was a result of extension of Kohistan slid northward along normal faults.

By 20 Ma, movement along the Main Mantle Thrust had ceased, and the Indian plate and Kohistan were locked into place, with much northern Pakistan subsequently undergoing simple post-orogenic uplift and erosion. However, we have discovered that some areas of northern Pakistan are presently undergoing extraordinarily rapid exhumation: the Nanga Parbat-Haramosh massif has experienced long-term denudation rates on the order of 1-km/m.y. over the past 10 m.y., and rates as high as 5-km/m.y. over the past 3m.y. During the recent exhumation, Indian-plate gneisses have undergone granulite-grade metamorphism, intrusion by abundant leucogranites, and intense hydrothermal activity. The cause of this most recent phase of active Himalayan tectonism is unknown.

C/53. Chamberlain, C.P., Zeitler, P.K., Barnett, D.E., Winslow, D., Poulson, S.R., Leahy, T. & Hammer, J.E., 1995. Active hydrothermal systems during the Recent uplift of Nanga Parbat, Pakistan Himalaya. *Journal of Geophysical Research* 100, 439-453.

During the last 10 m.y., the Nanga Parbat Haramosh Massif in the northwestern Himalaya has been intruded by granitic magmas, has undergone high-grade metamorphism and anatexis, and has been rapidly uplifted and denuded. As part of an ongoing project to understand the relationship between tectonism and petrologic processes, we have undertaken an isotopic study of the massif to determine the importance of hydrothermal activity during this recent metamorphism. Our studies show that both meteoric and magmatic hydrothermal systems have been active over the last 10 m.y. We suggest that the rapid uplift of the massif created a dual hydrothermal system, consisting of a near-surface flow system dominated by meteoric water and a flow regime at deeper levels dominated by magmatic/metamorphic volatiles. Meteoric fluids derived from glaciers near the summit of Nanga Parbat were driven deep into the massif along the transpressional faults causing $\delta^{18}\text{O}$ and δD depletions in the gneisses and marked oxygen isotopic disequilibrium between mineral pairs from the fault zones. The discharge of these meteoric fluids occurs in active hot springs that are found along the steep faults that border the massif. At deeper levels within the massif, infiltration of low $\delta^{18}\text{O}$ magmatic fluids caused $\delta^{18}\text{O}$ depletions in the gneisses within the migmatite zone. These low $\delta^{18}\text{O}$ fluids were derived from the young (<4 Ma), relatively low $\delta^{18}\text{O}$ granites (~8‰) that are found within the core of the massif. Geochronological evidence in the form of fission track and $^{40}\text{Ar}/^{39}\text{Ar}$ cooling ages and U/Pb ages on accessory minerals from the granites and gneisses provide a constraint on the timing of fluid flow in the surface outcrops we examined. Fluid infiltration in the migmatite zone rocks located along the Tato traverse was coeval with metamorphism, granite emplacement, and rapid denudation, in the interval 0.8–3.3 Ma. Finally, we infer from the presence of active hot springs that significant flow systems continue to be active at depth within the central portion of the Nanga Parbat-Haramosh Massif.

C/56. Chamberlain, C.P., Zeitler, P.K. & Jan, M.Q., 1989. The dynamics of a crustal suture in the Pakistan Himalaya. *Journal of Metamorphic Geology* 7, 135-149.

The pressure-temperature and temperature-time paths derived for rocks in the Kohistan arc and adjacent Nanga Parbat-Haramosh massif record the dynamics of the collision between the island arc and the Indian plate. Studies of P-T-t paths show that the Kohistan arc was thrust over the Nanga Parbat-Haramosh massif at least 25 Ma ago, but not more than 30–35 Ma ago. Rocks in the Kohistan arc followed decreasing pressure paths, with the early metamorphism beginning at high pressures (9.5 kbar) and later metamorphism occurring at 8.0 kbar. In contrast, rocks in the Nanga Parbat-Haramosh massif (Indian plate) experienced increasing pressure and temperature paths. Prior to thrusting, the massif was at low pressures (4.0 kbar) and low temperatures (450°C). Later, the pressure and temperature increased to 8 kbar and 580°C. The authors interpret the convergence (to approximately the same pressure and temperature) of the P-T paths in the two terranes as being the result of thrusting and thermal equilibration between the thrust sheets. $^{40}\text{Ar}/^{39}\text{Ar}$ cooling ages of hornblendes and other geochronological data suggest that the time of peak metamorphism and hence the completion of thickening was approximately 30–35 Ma ago. Temperature-time paths show that after thrusting, during the period 25–10 Ma, the Kohistan arc and Nanga Parbat-Haramosh massif were uplifted at similar rates (0.5 km Ma). However, in the past 10 Ma the Nanga Parbat-Haramosh massif has been uplifted more rapidly than the adjacent Kohistan arc. Rapid uplift has been accommodated by late faults along the edge of the massif.

C/58. Chambers, A., 1991. The effect of stratigraphic variation on structural style: examples from the western limb of the Hazara-Kashmir Syntaxis, N. Pakistan. *Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop*, Auris, France, 27-28.

An attempt is made to integrate stratigraphic and structural data in order to generate an evolutionary model of the Lesser Himalaya and Sub Himalaya of N. Pakistan. Field outcrops in the Potwar Plateau and Murree Hills and well data and seismic profiles from the Potwar Plateau constrain the stratigraphy. The regional stratigraphic variations are telescoped by Himalayan shortening, which exceeds 200-km in the external zones of Pakistani Himalaya. The true regional stratigraphic is evident only after the restoration of Himalayan structures.

Three stratigraphic cover series separated by major unconformities of base Permian and base Paleocene age is represented in the Potwar region. The crystalline basement is overlain by a series of Eocambrian-Cambrian age that comprises the basal Salt Range Formation and the Jhelum Group clastics and carbonates. The Permian-Cretaceous series represent an essentially shallow marine shelf environment, although the cycles of sandstone, carbonate and occasional laterite indicate transgressive pulses throughout this period. Flexure and erosion is associated with the widespread basal Paleocene unconformity. Erosion increases towards the southeast such that the Paleocene overlies the Cambrian in the eastern Salt Range whilst in the north the unconformity is negligible. Shelf conditions were reestablished in the lower Tertiary before molasse deposition commenced in Miocene times. The thick, but poorly-consolidated, alternating sands and shales of the Rawalpindi and Siwalik Groups form the youngest stratigraphic series.

These stratigraphic series have distinct rheological properties. The weak evaporitic Salt Range Formation forms a major basement-cover decollement throughout the Potwar Plateau. The Permian-lower Tertiary carbonate carapace acts as a rheologically competent unit that deforms brittly. Where it is thick the carapace forms large thrust sheets. However, the action of the Paleocene unconformity reduces the carbonate carapace to approximately 100m thickness, effectively juxtaposing the Eocambrian salt and the Tertiary molasse. The molasse behaves incompetently and collapses to form a series of pop-ups, boxfolds and breaching thrusts above the salt decollement. The western

and eastern Potwar therefore show different structural styles, the former being controlled by the carbonate carapace and the latter by the molasse.

During the south-southeastward propagation of the Pakistani thrust wedge two to major detachments have been exploited, the Hazara Detachment (or MBT) and the Salt Range Detachment (or MFT). The strongly deformed strata of the Murree Hills lie in the hangingwall of the Hazara Detachment. This thrust has been carried more than 80-km across the molasse basin, a process assisted by the presence of talcs and evaporites in the Hazara Slate Formation. Further displacement occurred by duplexing in the footwall of the Hazara Detachment, the floorthrust following the basement-cover contact until the Salt Range Formation was encountered. This decollement is still active today.

The timing of deformation can be dated using palaeomagnetic reversal methods in the molasse sediments of the Potwar Plateau. Dating of events in the Murree Hills is more loosely constrained by metamorphic cooling ages in the internal zones and thrust interference with the southwest-directed Kashmir thrust wedge.

C/59. Chambers, A. & Izatt, C., 1992. The evolution of the external Himalayas, N Pakistan: The Galiat and Eastern Potwar, Punjab. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 13.

During the last 10 Ma, the Miocene-Recent molasse series of the external Pakistan Himalayas and its sedimentary substratum has been shortened by over 200-km. This progressive shortening, which was concurrent with the rapid subsidence in the Potwar Basin, can be divided into four phases:

The imbrication of the hangingwall to the Hazara Detachment (or MBT).

Ramping of the MBT from the basement-cover contact (Hazara Formation) to an intramolasse (Murree Formation) and translation of the MBT thrust wedge across the molasse basin by over 80-km.

Collapse of the MBT footwall ramp to produce a duplex at depth. Initially displacement was transferred from the floorthrust within the Hazara Formation to the foreland-wedge MBT. As the duplex propagated southward the roofthrust became hinterland-vergent due to the loss of the competent MBT overburden. This is expressed by backfolding in the Hill Ranges and Northern Potwar, the duplex tip being marked by a frontal monocline.

Deformation of the Southern Potwar in the hangingwall of a salt detachment, the Potwar-Salt Range Detachment (SRT). An abrupt change in structural style is observed as the Himalayan sole thrust encounters the Hazara Formation-Salt Range Formation facies change from intertidal clastics to evaporites.

In this presentation the role of inherited pre-Himalayan stratigraphic variations upon the structural style of Himalayan deformation is emphasised-with particular reference to the evolution of the Potwar Plateau during the Pliocene. A combination of field and seismic data is used to demonstrate the relative control exerted by the three major lithostratigraphic series (Eocambrian evaporites series, the Cambrian-Eocene pre-orogenic "shell" series and the syn-orogenic molasse series) upon structural style in the Potwar Plateau.

It is concluded that, in addition to halotectonics and basement topography, the presence or absence of the Cambrian-Eocene carbonate carapace is paramount in controlling structural style in the Potwar Plateau.

C/60. Chandra, U., 1976. Fault plane solution and tectonic implications of the Pattan Pakistan earth quake of December 28, 1974. *Tectonophysics* 28, T1-T24.

A large destructive earthquake occurred on December 28, 1974 on the western bank of the Indus River near the village of Pattan. The earthquake reportedly killed 5,300 persons, injured 17,000 and left 60,000 people homeless. A seismicity map of the region is presented for the period January, 1963, to March, 1974 on a Mercator projection. Two main linear trends are recognized on the epicenter map. The northwest trend, beginning at 32.3°N, 76.6°E terminates at the southwest alignment of epicenters beginning at 36.0°N, 73.5°E and ending at 33.0°N, 71.0°E. The Pattan earthquake occurred near the junction of the two linear trends. A fault-plane solution for this earthquake has been determined from an analysis of teleseismic P-wave first-motion and S-wave polarization data. The strike and dip of the two nodal planes are N65°E, 68°SE and N50°E, 23°NW, respectively. The solution is compatible with and indicates underthrusting of the Indian plate in this region in the NNW direction along a thrust zone striking northeast.

C/61. Chandra, U., 1978. Seismicity, earthquake mechanisms and tectonics along the Himalayan mountain range and vicinity. *Physics of the Earth and Planetary Interiors* 16, 109-131.

The historical as well as recent seismicity data and the focal mechanism solutions for 48 earthquakes determined from the observations of world-wide standardized stations network (WWSSN) records, were used to investigate the tectonics of the Himalayan mountain system and vicinity. Seismicity maps of the region showing large earthquakes (magnitude 7.0 and above, and damaging earthquakes that caused fatalities) from the earliest time through 1976, and instrumentally located earthquakes for the period January 1963–March 1974 are presented. Eleven of these earthquakes are estimated to be of magnitude 8.0 and above. The earthquake epicenters generally follow the trend of the mountains with greatest concentrations of seismic activity occurring along the Hindu Kush and Pamir mountain ranges, and near the Quetta, Kashmir and Assam syntaxes. Throughout Tibet, however, the distribution of epicenters is rather irregular and no clear trends are apparent. Two aseismic lineaments, one west of the Sulaiman Range and the other in the Assam Valley, are identified. Also, seismic activity in the vicinity of the Counter Thrust (Indus-Tsangpo suture zone) is rather small. Based on the identification of these aseismic lineaments and from a consideration of the geometry and kinematics of the continental collision model, a hypothesis for the origin of the Himalayan syntaxes is presented.

Focal mechanism solutions confirm northward underthrusting of the Indian Plate along the Main Boundary Thrust and Main Central Thrust system, and eastward underthrusting along the Burmese Arc. Fault-plane solutions indicate left-lateral motion along the Kirthar-Sulaiman Range, right-lateral motion along the Karakoram Fault, left-lateral motion along the eastern extremity of the Himalayan flank of the Assam syntaxis, and right-lateral motion along the northern part of the Naga Hill flank of the syntaxis. These observations are in agreement with the expected sense of lateral (parallel to the collision boundary) mass movement for the continental collision model. Focal mechanism solutions for three earthquakes in east Afghanistan show NW-SE compression. A near-vertical orientation of the axes of tension in the solutions for two earthquakes in the Hindu Kush region is consistent with the sinking of a remnant slab of oceanic lithosphere. Normal fault-plane solutions showing NW-SE extension for two events near Gatok, Tibet, and for the recent Kinnaur earthquake are interpreted to indicate a possible subsurface northern continuation of the Aravalli Range of Peninsular India, and its involvement in the tectonic framework of the region. Focal mechanism solutions of three earthquakes near the southern edge of the Shillong Plateau suggest block uplift of the plateau as a horst along the Dauki Fault. The solution for one earthquake near the Yunnan Graben shows NE-SW extension.

C/64. Chatelian, J.L., Roecker, S.W., Hatzfeld, D. & Molnar, P., 1980. Microearthquake seismicity and fault plain solutions in the Hindu Kush region and their tectonic implications. *Journal of Geophysical Research* 85, 1365-1387.

The nature of the Hindu Kush intermediate seismic zone was studied in two microearthquake investigations in 1976 and 1977. By testing several sources of uncertainty the precision of about 600 earthquake locations was estimated to be about 5 km in epicenter and 10 km in depth. Projections of the earthquake locations from several perspectives reveal several regions of aseismicity as well as a highly contorted nature of the active regions. Very little seismicity was recorded in the crust from 0- to 70-km depth. The part of the zone southwest of about 37°N, 71.5°E and shallower than about 160 km is broad and seems to dip north at progressively steeper angles from west to east. Fault plane solutions for this region do not reveal a simple consistent pattern. This region is separated from another active region to the northeast by a curved gap that is nearly 50 km wide. Northeast of this gap the zone dips to the southeast. In the western portion there is an aseismic region around 160-km depth that separates the contorted shallower zone from a narrow (15–20 km wide), consistently steep, deeper zone. As in island arcs, the fault plane solutions for the deeper events show T axes generally lying within the plane of seismicity and P axes perpendicular to the plane. In contrast to island arcs the T axes in general are not parallel to the dip direction, and there seems to be greater variation in the orientation of these axes. The entire western zone plunges to the west at about 20°, and most of the T axes plunge steeply to the west. In detail, the earthquakes tend to occur in clusters that leave aseismic gaps between the clusters. There is a distinct gap of about 15-km width near 70.7°E. This gap seems to separate events with fault planes solutions that in the west have westward plunging T axes and in the east have eastward or vertically plunging T axes. Although many of these features were not detected in previous studies of this region, the data from those studies are consistent with the dips, changes in dip, gaps, and breadth of the seismic zone. Both the variations in dip and breadth of the active zones and, for one gap, the difference in fault plane solutions of earthquakes on either side of it, make the role of the gaps as boundaries clear and suggest their long-term existence. We infer that the configuration of the Hindu Kush seismic zone could possibly be the result of the subduction of oceanic lithosphere from two separate, small basins in opposite directions. The age of the subducted lithosphere is probably greater than 70 m.y., and subduction probably has occurred over a relatively short duration. The rate of subduction probably has been between 20 mm/yr and 48 mm/yr. Correlations of seismic trends with surficial features suggest that in the south the Hindu Kush suture zone lies along or somewhere between the Panjer and Kunar faults and that in the north the Pamir suture zone lies near the Darvaz-Karakul fault. Finally, it seems that the protrusion of India into Eurasia has been a major factor in developing the present configuration of the zone.

The present report is a geological study of nearly 30-miles² (Dhamtaur and Baghseri area) in southeastern direction of Abbottabad. The study includes a geological map on the scale 1:12500 (1cm=125m) and the stratigraphy of the area, from Precambrian to Upper Paleocene (Thanetian). The geological history of the Hazara Trough and the environmental deposition of the formation are reviewed. Structurally, the area is very complicated within which a generally complex folding and faulting predominates.

C/76. Chaudhry, M.N., Ahsan, N. & Ahmed, F., 2001. Petrography and environment of deposition of Lumshiwal Formation, Karlan Bazar, Nathiagali-Abbottabad Road, Hazara basin, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 25-26.

The studied section of the Lumshiwal Formation (Shah, 1977) is located near Karlan Bazar. It is composed of quartz arenites that are cemented by quartz, glauconite, clay, iron oxides and calcite. The amount of cements and their proportions to one or other vary considerably. These arenites are generally off-white, medium grey, yellowish grey to greenish grey in colour.

The quartz is the main detrital constituent of the Lumshiwal Formation (Chaudhry et al., 1998). The arenites are compositionally mature and texturally sub mature to super mature. The maximum development of glauconite is in the middle and upper part of the formation. The glauconite appears to have developed from clay therefore glauconite rich arenites might have initially been deposited as wackes (Ahsan and Chaudhry, 1999).

The grains of tourmaline, zircon and rutile within the arenites indicate a granitic/gneissic composition of the source rock. Microcrystalline quartz indicates derivation from the textured siliceous rocks. The heavy minerals such as tourmaline, sphene, epidote and zircon also occur as inclusions and their occurrence is restricted. The suite of heavy minerals indicates the S-type granitic or gneissic provenance. The other common accessory minerals are magnetite, haematite and limonite.

The formation contains belemnites, brachiopods, pelecypodes and rare ammonites. This formation overlies the Chichali Formation, which was deposited in reducing conditions (Chaudhry et al., 1998). The lower contact of the Lumshiwal Formation is transitional. The Lumshiwal Formation was deposited in marine subtidal conditions. The presence of relict haematite and films of pyrolusite strongly suggest halmyrolysis in the presence of O_2 and CO_2 . The evidence of progressive deepening in the upper part of the Lumshiwal Formation resulted in the deposition of the pelagic shelf sea, Kawagarh Formation (Ahsan and Chaudhry, 1998). The upper contact of the formation with the Kawagarh Formation is transitional.

C/78. Chaudhry, M.N., Ahsan, N., Chaudhary, M.M. & Gondal, M.M.I., 2001a. Chilas sand--fine aggregate for Bhasha Dam. Abstracts, 4th Pakistan Geological Congress, Islamabad, 42-43.

Bhasha Dam with a rated hydroelectric potential of 4500 MW and a storage capacity of millions of acre feet of water is proposed to be build near Bhasha about 40 km downstream of Chilas. This dam is very important for national economy since it will cater the needs of water and power requirements of the country.

Huge amount of coarse aggregate is available in the area. However, there is no mineable fine aggregate deposit around the site proposed for the dam. Our studies show that the nearest source of fine aggregate for the proposed Bhasha Dam is Chilas sand deposit. It was deposited on the Chilas norites. There is no interbedded component of glacial deposits. These sands are overlain by a thick sequence of well-rounded Indus gravel (Chaudhry et al., 1998) which in turn are overlain, at places, by glacial till. The beds of this deposit are nearly horizontal or gently dipping towards the Indus River and contain associated oversized material.

The coarse aggregate is composed of amphibolites (0.4% to 5.8%), diorite (8.5% to 41.2%), dunite (0-2. 1%), leucocratic fine-grained S-type granite (1.9% to 8. 1%), S-type granite mylonite (3.3% to 18.9%), pyroxenite (0-1.17%), greenstone (0-3.6%), norites (12.1% to 19.2%), S-type microgranite (14.7% to 35.6%) and vein quartz (0-1.2%).

The granite mylonite fraction of coarse aggregate is potentially deleterious and may cause Alkali Silica Reaction.

The sand component of this deposit is composed of diorite/tonalite/amphibolite (0.5% to 2.5%), dolerite (0.3% to 0.9%), granite/granitoids (5.8% to 36.5%), jasper* (0.2% to 0.3%), limestone (0-0.6%) schist/gneiss (8.6% to 42.7%), quartzite/polygrain quartz (2.7% to 5.2%), biotite/vermiculite (1.0% to 8.0%), epidote (0 to 2.1%), feldspar (3.8% to 8.7%), garnet (0 to 1.1%). These sands possess minor reactive rock fragments. However, a peculiar problem of Chilas sand is the presence of vermiculite that may expand in the cement concrete. The role of vermiculite as a deleterious constituent in the concrete is still debated. However, our observations of civil structures and rock exposures indicate that concrete structures subjected to hydraulic conditions and containing vermiculite may show expansion.

The engineering properties (BS.8 12, 1965) of Chilas sand are fairly good. It can be quarried and sieved to meet the desired gradation. However, some horizons are very fine grained but their gradation can be improved by adding manufactured fine aggregate. The mechanical and physical properties of the Chilas sand are comparable with Lawrencepur sand (Chaudhry et al., 1999), Ravi and Chenab sands (Ahsan et al., 1999) and Maira sand (Ahsan et al., 2000). The compressive strength of mortars is within the limits specified by CP-110.

Key words: Building material, aggregate, Bhasha dam, Chilas.

C/79. Chaudhry, M.N., Ahsan, N., Chaudhary, M.M. & Gondal, M.M.I., 2001b. Petrographic evaluation of Jalipur mollase as construction raw material. Abstracts, 4th Pakistan Geological Congress, Islamabad, 60-61.

The Jalipur valley fill is composed of glacial tillites mollassic sediments. The deposit is exposed along Karakoram Highway upstream of Chilas. It is a huge deposit with millions of cubic metres of reserves. The Jalipur mollase is older than 0.78 Ma but younger than 2 Ma (Oslo, 1982; Shroder, 1993). The lower tillite unit which is overlain by Jalipur mollase is indurated. The Jalipur mollase itself is indurated, folded and faulted. The mollase unit is overlain by younger tills. The Jalipur unit occurs only in valley sides and floor. Detailed petrographic studies of coarse as well as fine fraction of Jalipur unit clearly shows that no contribution was made to the Jalipur mollase by the Nanga Parbat gneisses. This indicates the fact that the Nanga Parbat —Haramosh massif was not uplifted at the time the Jalipur mollase was being deposited. This mollase had derived its components from Kohistan Island Arc. It represents a warm period during Shanoz Glaciation period (Shroder, 1993). Its thickness is more than 150m.

The Jalipur mollase was sampled near Jalipur and coarse and fine aggregates were evaluated petrographically. The mollase is cemented mainly by calcite.

The coarse aggregate was sieved through ASTM sieves 2 to No. 4. The retain of each sieve was analysed for rock types. The mollase is composed of amphibolite, diorite, granite, granite mylonite, mylonite, schist, vein quartz, tonalite, slate, quartzite, greenstone, rhyolite and siltstone (wacke). The percentage of rock types is given in Table 1.

The fine aggregate of Jalipur mollase was sieved through sieves of ASTM. The retain of sieve No. 8, 16, 30, 50 and 100 were analyzed under binocular microscope. It is composed of granite/granodiorite (1.1% to 24.6%), diorite/tonalite/amphibolite (0-32.8%), quartzite (8.1% to 21.8%), phyllite/slate (7.2% to 20.4%), greywacke group (0-0.4%), chert (0-0.8%), quartz mica schist (4.60/o to 8.50/o) and schist (0-7.1%). The mineral grains include quartz/polygrain quartz (22.1% to 53.6%), feldspar (4.4% to 8.3%) and amphibole (0.9% to 3.7%). The mineral grains include quartz/polygrain quartz (22.1% to 53.6%), feldspar (4.4% to 8.3%) and amphibole (0.9% to 3.7%). Biotite, muscovite, epidote, magnetite, garnet, tourmaline and zircon are the minor constituents.

The Jalipur coarse as well as fine aggregate contains unacceptable quantities of potentially deleterious reactive phases with Alkali Silica Reaction Potential if used in concrete with OPC. These phases are slate/phyllite, chert and greywacke. These aggregates may be used with low alkali cement or slag cement after testing. The aggregates may also be used with cement-pozzolana, cement-fly ash or cement-silica fume blends after testing.

Key words: Petrography, Jalipur Mollase, Kohistan.

C/80. Chaudhry, M.N. Ahsan, N. & Ghazanfar, M., 1998. A preliminary account of sedimentology of Hazara basin from Jurassic to Eocene. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 41-43.

The Mesozoic to Eocene Hazara Basin dominated by shelf carbonates is characterised by a distinct package of sediments punctuated by a number of diastems, hiatus and unconformities. The environment of deposition vary from supratidal to shelf edge (250m) and from open shelf to restricted circulation anoxic conditions as a consequence of plate movement. The average Rhified rates of sedimentation vary from 0.96mm to 83.30mm per 1000 years.

During upper Hettangian the Hazara landmass changed into a marine basin with the development of a transgressive shore line with the deposition of Datta Formation which overlies either Upper Proterozoic Hazara Formation or Cambrian Hazira Formation.

It was deposited during open marine, lower to upper shoreface, lagoonal to subareal regimes (Chaudhry et al., 1997; Chaudhry et al., 1996; Chaudhry et al., 1995). It is composed of lenses, sheets and layers of poorly sorted medium to coarse grained quartz arenites with rare grit and interlayers of carbonaceous shales, silty shales, marls and oolitic to

pelletoidal limestones. The average lithified rates of sedimentation were approximately 2mm/1000 years. Provenance studies show derivation from an igneous metamorphic sialic Indian plate. Source tong to the south.

The Samanasuk Formation represents an epicontinental intertidal environment with upper shelf ooidic-pelletoidat shoals deposited from Toarcian to Callovian. Cross bedding and burrows are frequent. The sediment are composed of ooidic-pelletoidal wackestones to grainstones, bioclastic limestones and dolomitic horizons. Rare caicirudites also occur. The oyster topped beds and hard grounds represent slow rates of deposition and subareal exposures. The average lithified rate of deposition was about 6mm/1000 years.

At the close of Callovian restricted anoxic environment prevailed and condensed pyrite rich and belemnite-bearing black shale-siltstone sequence represented by Chichali Formation of Oxfordian to Kimmeridgian age was deposited. The lithified sedimentation rates were about, 2.3mm/1000 years.

Strongly reducing conditions changed to mildly reducing conditions with better circulation in Tithonian during which the Lumshiwal Formation was deposited. It is mainly composed of glauconitic quartz arenites (Chaudhry et al., 1997, Chaudhry et al., 1994) with submarine hard grounds. These sediments are generally cemented with quartz, clay, Iron oxides or glauconite. The ubiquitous glauconite indicates slow rates of deposition in mildly reducing environments. The suite of heavy minerals once again indicates sialic igneous metamorphic provenance. The average lithified rates of sedimentation were about 0.96mm/1000 years.

In Cenomanian, the Hazara basin deepened (upto a maximum of 250m as shown by the presence of oligostigena (Ahsan et al., 1993, Ahsan et al. 1994, Chaudhry et al. 1992) during a major global transgression with deposition of Kawagarh Formation composed of. pelagic mudstones, wackestones and packstones. The upper beds (Maastrichtian in age) of Kawagarh Formation were exposed during a widespread regression due to initiate contact of the Indian with the Kohistan Arc at 67 ± 2 Ma prior to main India-Eurasia collision (Bard et al., 1979) at 50-55 ma. The average lithified rates of sedimentation of Kawagarh Formation have been estimated as 9mm/1000 years (Chaudhry et al., 1994).

The subareal exposure under subtropical conditions reworked the Maastrichtian sediments of the Kawagarh Formation into fire clay, pisolitic bauxite and laterite. The rate of accumulation of these residual sediments of Hangu Formation are about 1.77mm/1000 years.

The crustal bulge which developed due to initial Kohistan Arc-Indian Plate contact at 67 ± 2 ma (Bard et al. 179, Chaudhry et al., 1994) subsided by Thanetian and Hazara Basin once again changed into an open shelf to deposit nodular Lockhart Limestone in shallow shelf (subtidal) environments. The sediments of the Lockhart Limestone rich in benthic forams are composed of mudstones, wackestones and packstones. The average lithified sedimentation rates are worked out at about 30mm/1000 years.

The carbonate shelf developed into a siliciclastic basin with increased turbidity which suppressed deposition of carbonates and olive grey splintary shales of Patala Formation with occasional limestone bands were deposited. The average lithified rates of deposition of Patala Formation are about 30mm/1000years.

During Ypresian the siliciclastic basin developed into a carbonate platform and deposited the Margala Hill Limestone in upper subtidal to lower subtidal environments. It is composed of mudstones, wackestones and packstones with many intercalations. The average rates of sedimentation of the Margala Hill limestone are about 62.5mm/1000 years.

The Chorgali Formation is composed of shales, mudstones, wackestones and packstones. The same environment that deposited the Margala Hill limestone deposited the Chorgali Formation. The average lithified rates of sedimentation were about 83-3mm/1000 years.

At about 55-50 Ma main collision between India and Asia took place due to which during Lutetian the sea started retreating. In Hazara with brief episodes of transgression-The Kuldana Formation represents these changing conditions and is represented by red continental shale-siltstone beds with interactions of fossiliferous marine limestones. The average lithified rates of sedimentation of this unit are about 71.1mm/1000 years. Thereafter the Himalayas started rising with the deposition of continental Molasse represented by Murree Formation with a Himalayan rather than Indian Plate provenance.

The cement stratigraphy for carbonate sediments of Hazara Basin (except Samanasuk Formation) shows that non ferroan microcrystalline calcite was penecontemporaneous with deposition. The second stage involves that dolomitization of calcite and bioclasts. Replacement of dolomite and bioclasts by ferroan calcite is the third stage. The final stage is the silicification of groundmass, bioclasts and at places the dolomite rhombs. In Samanasuk Formation dolomite occurs as first stage supratidal cement and sparite as early burial cement.

In addition to submarine and very early calcite cement the following order in cement stratigraphy for the pre-Danian clastic units of the Hazara Basin has been worked out: i) thin rim early quartz cement, ii) kalonite cement, iii) early calcic cement, iv) dolomitic cement, v) ferroan calcite cement, vi) deep burial quartz cement and vii) lite diagenetic kaolinite cement.

Key words: Stratigraphy, sedimentology, Jurassic, Eocene, Hazara basin.

C/81. Chaudhry, M.N. Ahsan, N. & Majid, C.M., 1997. Engineering properties, mineralogy, alkali aggregate reaction potential and provenance of Lawrencepur sand Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 2p.

Lawrencepur sand is one of the most popular fine aggregate deposits of Pakistan. Detailed analysis of engineering characteristics, mineralogical composition and Alkali Aggregate Reaction (AAR) potential as well as the provenance of this deposit has been studied in detail.

The bulk densities of this sand vary from 82 lbs/cft to 86 lbs/cft. Its grading generally corresponds to the zone 3 or 4 of BS 882/1965 and is therefore considered an excellent fine aggregate for mixing with cement individually or as an additive with other fine aggregates of Pakistan. However, some sand layers contain oversize particles or other sizes larger than permissible limits for fine aggregates and therefore require sonic processing to meet the desired gradings. The Lawrencepur sand was tested in accordance with USBR Designation 14 to determine the organic impurities. The colour of the sand in 3% solution of NaOH was found to be lighter than the standard colour solution. This sand therefore, is free from organic impurities. Soundness test was carried out in accordance with ASTM Designation C88-76. The weight percentage losses range from 0.5% to 1.50% after five cycles of immersion. These results are lower than the maximum allowable limit of 12% (by Na₂ SO₄).

The Lawrencepur sand was tested petrographically for AAR potential with ordinary portland cement (OPC). It did not show Alkali Carbonate Reaction (ACR) potential. However, petrographic tests show that Lawrencepur sand ranges from innocuous to deleteriously reactive with respect to its ASR potential. These tests were carried out in accordance with ASTM Designation C33-81 and ASTM Designation C289-81. The chemical reactivity tests were carried out in accordance with ASTM Designation C289-8 1. These results range from innocuous to mildly deleteriously reactive.

Mineralogically the coarse sand is composed of lithoclasts as well as mineral grains. the average results and model analysis of coarse Lawrencepur sand are as follows:

quartz/quartzite 33.9%. granite/granodiorite 20.20%. amphibolite/foliated diorite 10.70%, feldspar 10%. mica 5.80%. graywacke group* 5.30%. amphibolite 4.60%, schist 4.0%, phyllite/slate* 3.300 a. iron ore 1.30%. sphene 0.30%. chert.* 0.20%, tourmaline 0.20%, apatite 0.10% and zircon 0.1 0%. The deleterious constituents are marked with an asterisk(*). The coarse sands are therefore generally potentially reactive with ASR potential. Some parts of this sand deposit specially the medium grained varieties are low in lithoclasts and deleteriously reactive constituents and are therefore innocuous.

The sand has been derived mostly from the Kohistan island arc and the Indian plate constituting the Higher arid Lesser Himalayas. Contribution from the Gawachi back arc basin and the Asian plate is negligible as far as lithoclasts are concerned.

Key words: Engineering geology, alkali aggregates, sand, Lawrencepur.

C/82. Chaudhry, M.N. Ahsan, N. & Majid, C.M., 2000. Alkali aggregate reaction potential and engineering properties of Indus aggregate from Skardu to Thakot, Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, 146-148.

The River Indus plays an important role in the industrial and agricultural economy of Pakistan. A number of dams are proposed to be constructed for water storage and power generation. The construction of these dams at Shyok, up and down stream of Kachura near Skardu, Raikot, Bhasha, Dasu and Patan will require millions of cubic metre of concrete. The (Chaudhry et al., 1999; Ahsan et al., 1999) aggregates of the River Indus for the Civil Engineering Projects. These aggregates were physically and petrographically evaluated for Alkali Aggregate Reaction (AAR) potential.

In the past, deleterious aggregates have been used in Tarbela Dam (Chaudhry and Zaka, 1994) and Warsak Dam (Chaudhry and Zaka, 1998). The aggregates used in Terbela and Warsak dams were considered safe but later on their inservice behaviour proved them deleterious with Alkali Silica Reaction (ASR).

The coarse and fine aggregates of Indus River meet the engineering characteristics as specified by ASTM or BS. The Los Angeles Abrasion Values are between 5.6 to 20.0 %. Specific gravity is 2.5 to 2.9 and water absorption is very low i.e. from 0.5% to 0.8%. The loss after 5 cycles of immersion in sodium sulphate solution ranges from 0.5% to 0.98%. The gradation of coarse and fine aggregates generally corresponds to BS 812: 1967, but at places they are

gap graded. The coarse aggregate of nine terraces of the Indus River from the Shigar Bridge, north of Skardu to Thakot Bridge were evaluated for Alkali Silica Reaction potential. The coarse aggregates were sieved through BS 2" to 3/16" sieves and retained fractions were separated for identification of rock types.

The rock types include greenstone, quartzite, dunite, leucacmtic fine grained S-type granite porphyritic S-type granitic gneiss amphibolite. S-type granite mylonite, norite, pyroxenite, peridotite, granodiorite, diorite, S-type microgranite, vein quartz, I-type granite, dacite, mica gneisses, microdiorite, schist/gneiss, andesite, rhyolite, black basalt, hornblendite, chert, greywacke, slate, phyllites, dolerite, greenschist, marble, quartzofeldspathic psammite, serpentinite, weathered schist, dacite, porphyry andesite porphyry and rhyolite porphyry. All these rock types may or may not be present in one sample. Moreover they vary from 0010 to as much as 63% on different sieves. The fine aggregates associated with the coarse aggregates were sieved through ASTM # 4 to # 200 sieves and rock types and minerals of each fraction were identified under the microscope. They include granite, granodiorite, diorite, tonalite, amphibolite, quartzite, slate, phyllite, greywacke, greenstone, basalt, norite, dolerite, quartz mica schist, gneiss, hornfelse, friable sandstone microfractured quartz, mica, greenstone, greenschist, polygrain quartz, feldspar, biotite, epidote, magnetite, garnet, tourmaline, sphene, zircon, calcite, rutile, barite, albite, plagioclase, clay lumps, acid to intermediate volcanics and diorite. All of these constituents may or may not be present in each fraction or deposit. The rock types indicated by asterish (.) are potentially deleterious. The coarse and fine material of these terraces was considered safe in the past. Petrographic studies, mon.ar bar tests and deterioration of concrete containing the Indus aggregates clearly show the deleteriously reactive nature of the Indus aggregates if used with Ordinary Portland Cement. Studies carried out on aggregates using low alkali cements, slag cements and using methods. Ahsan et al., (1999) and Chaudhry et al., (1999) have used Ravi and Chenab sands dilutants to minimize the ASR in the Lawrencepur sands of the Indus River. Experimentation and further studies to control the reaction by using silica fumes and dilution with innocuous aggregates are being carried out.

Key words: Engineering geology, alkali aggregates, sand, Skardu, Thakot.

C/83. Chaudhry, M.N., Ahsan, N., Mahmood, T. & Masood, K.R., 2001. Sedimentology of Margala Hill limestone, Neelum valley, Azad Kashmir, NW Lesser Himalayas. Abstracts, 4th Pakistan Geological Congress, Islamabad, 59-60.

The Margala Hill Limestone (Latif, 1970) at Chahla Bandi, Azad Kashmir (Ghazanfar et al., 1987) is composed of light grey to dark grey limestone. The formation at the base is thinly bedded. It is overlain by calcirudite that contains abundant pelecypode shells. Some shells are reworked. Highly fissile dark grey shale that overlies the shelly beds and contains marcasite nodules. The shale is followed by highly nodular limestone. The nodules are upto 30 cm x 50 cm x 13 cm and contain very thin shale partings. This zone is 29m thick. It is very dark grey in colour and gives very strong fetid smell. An argillaceous marly limestone that is 28 metres thick overlies the dark grey limestone. It is overlain by medium bedded to highly nodular limestone towards the top of the formation. This zone is grey and weathers to light grey.

On the basis of petrographic and field observations, the formation is divided into six facies. These facies from bottom to top include: a) Poorly developed nodular limestone facies, b) Calcirudite facies, c) Biostromic limestone facies, d) Highly nodular limestone facies, e) Argillaceous limestone facies, and t) Massive to nodular limestone facies.

After the collision of India-Asia (Bard et al. 1979; Chaudhry et al. 1994) a ramp (Ahsan et al. 2000) developed that received the Eocene sediments in Azad Kashmir. The formation started deposition in the middle subtidal zone on siliciclastic sediments of Patala Formation. It was followed by reworking of the facies (a) sediments and a brief period of subtidal exposure. Then a rapid transgression deposited kiohermal limestone facies. The many limestone facies was deposited in a relatively calm conditions followed by the deposition of massive nodular limestone. The groundmass of the microfacies is non-ferroan calcite that at places has been neomorphosed. Rare dolomite is associated with some horizon. Evidences of physical and chemical compaction are well preserved.

Palynological contents of the samples included moderate population of Dinoflagellates, Mycorrhizal spores and Acritarchs. Pollen, spores and cuticular fragments were rare to very rare. Most conspicuous were Ptenidophytic spores (PunctatLsporites, Lacinitriletes and Acanthotriietes) and Ccilpate pollen (Tricolpites).

Key words: Limestone, sedimentology, Margala Hills Limestone, Azad Kashmir.

C/84. Chaudhry, M.N., Ahsan, N., Masood, K.R., Baloch, I.H. & Spencer, D.A., 1997. Facies, microfacies, paleontology, depositional environment and economic potential of Datta Formation

of Early Jurassic age from Attock Hazara Fold and Thrust Belt, Lesser Himalayas (Salt Range, Pakistan). Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 133-134.

The Datta Formation (Danilchick, 1961; Shah, 1977) of Early Jurassic age is an important and persistent lithostratigraphic unit exposed in the Upper Indus Basin and Attock Hazara Fold and Thrust Belt of Pakistan. Its lithologies, thickness and environment of deposition vary widely. In the Hazara area, it unconformably overlies the Hazara Formation of Precambrian age. Here its basal part is a gritty sublithic arenite (Chuhan et al., 1990). The clasts were derived from the underlying slates during an Early Jurassic transgression (Chaudhry et al., 1994). The overlying package is composed of lenses and sheets of calcite and/or quartz-cemented quartz arenites. These are fine to coarse grained, generally sub-angular to sub-rounded, poorly to very well sorted, texturally sub-mature to mature and compositionally mature. This dominantly quartzose package also contains a few lenses of oolitic and pelletoidal limestones, marls, carbonaceous and silty shales. Diastems, at few places in this unit, are marked by hard-grounds.

The following order of cementation of stratigraphy for the Hazara area has been worked out: early submarine and calcite cementation followed by thin rim early quartz cementation followed by thin rim early quartz cementation => Kaolinite cementation => early calcite cementation => dolomitic cementation => ferroan calcite cementation => deep burial quartz cementation => late diagenetic Kaolinite cementation. The diagenetic events of the rock package in the Hazara area will be discussed in relation to the burial and uplift history of the basin. Submarine, early calcite cementation was followed by Kaolinite and thin rim quartz cements at shallow depths in the domain of meteoric or mixed meteoric-marine water circulation. This was followed at greater depths (under alkaline and mildly reducing conditions), by the precipitation of ferroan calcite. Transformation of Kaolinite to illite probably started at around 1000-meter depth. Extensive quartz cementation, suturing and reduction in porosity started at greater depth and was completed at depths of 4,000-4,200 meters at which the main phase of oil and gas maturation was completed. The late stage Kaolinite cement was formed during final stages of uplift by the alteration of surviving K-feldspar in the domain of meteoric circulation.

Zircon, tourmaline, epidote, sphene and biotite represent the heavy mineral suite for the Datta Formation and indicate an ultimate igneous metamorphic sialic source with minor basic/met basic component. The overall composition of sandstone, textural and compositional maturity, the restricted suite of heavy minerals, and their amounts and shapes, indicate a recycled origin for the sandstones of the Datta Formation. The granitoid component was S-type. Lack of kyanite, sillimanite and garnet suggests that high-grade gneisses were not exposed in the source area. This fact is further supported by the presence of indicolite, which indicates allochthonous granitoid intrusions in the epizone with thermal aureoles.

The environment of deposition of the Datta Formation varies from open marine, lower to upper shore face, lagoonal to sub-aerial. It was deposited along the northern edge of the Indian Plate along a mixed siliciclastic-carbonate shoreline during an overall transgression in Early Jurassic.

However, minor phases of off-laps and on-laps have been identified. The Datta Formation in the Western Salt Range is composed of fining-upward clastic fluvial sequences. Each cycle is composed of coarse-grained (often pebbly) sandstone or conglomerate lying on a scoured surface. This unit is interpreted as a channel lag deposit, which is overlain by cross-stratified sandstone interpreted as a point bar. This, in turn, is topped by overbank silt and clay deposits. The sequence also contains palaeosol horizons. The Datta Formation in the Western Salt Range represents fluvial deposits laid down by small shallow meandering streams subject to intense periodic flooding.

In the Attock region, to the west of Hazara, the Datta Formation is composed of three main horizons: the basal part is a thin and often discontinuous laterite bed; the middle part contains bauxitic clays composed of variable quantities of Kaolinite, boehmite and diasporite (Baloch, 1986); while the top unit is composed of variegated sandstones and shale of continental to transitional marine origin. This unit also contains recoverable amounts of rutile and anatase. In this area, the Datta Formation is composed of a continental residual deposit while in Hazara the unit is predominantly marine in origin. In the Hazara area small quantities of silica sand have been mined for the glass and chemical industries. Large quantities of refractory clays, high alumina clays, silica sand and small quantities of ochre are being mined from Attock, as well as parts of Kala Chitta and Salt Range. Our recent studies on the fire clays and high alumina clays have yielded encouraging results for recovering rutile and anatase from fire clays and high alumina clays of Attock. It is an important reservoir rock for hydrocarbons in the Upper Indus Basin.

Since the Datta Formation lacks diagnostic fauna, detailed palynological study of samples from the Salt Range and Hazara were carried out in order to constrain the age of this formation. The Datta Formation contains well preserved rich and diverse palynoflora, dominated by torate and auriculate miospores of Gleichenioidites (Ross) Delcourt and Sprumont and Triquitrites (Wilson and Coe) Potonie and Kremp types, respectively. Bisaccates were totally absent.

Cuticular fragments with sunken stomata and papillate outgrowths indicating a xerophytic habitat were observed in most samples. Some other important genera include *Leiotriletes* Naumova ex Potonie and Kremp 1954, *Todisporites* Couper 1958, *Calamospora* (Loose) Schopf Wilson and Bentall 1944, *Cyathedites* Couper 1953, *Granulatisporites* Ibrahim 1933, *Concavisporites* (Leschik) Nilson 1958 and *Verrucosisporites* potonie and Kremp 1954. *Triquitrites* and *Gelicheniidites* represent approximately 45% of the total microflora. Although the auriculate group was the most numerous, simple trilete miospores (*Leiotrites*, *Punctatisporites*, *Todisporites*) contributed an average of 5%. The most outstanding feature of the palynoflora was the persistent occurrence in the lower half of the Formation of any Early Jurassic marker pollen *Classopollis classoides* (Pflug) Pocock and Jansonius 1961.

C/85. Chaudhry, M.N., Ahsan, N., Zaka, K.J. & Majid, C.M., 1997. Alkali aggregate reaction potential of Indus gravel and sand between Raikot Bridge and Kalabagh. Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 2p.

Following River-Water Treaty with India. Pakistan lost rights over the waters of Sutluj and Ravi rivers. Therefore, the river Indus with its water and power potential is rightly regarded as the life line of Pakistan. A very large number of dams, barrages, bridges and other civil structures are likely to be built using sand and gravel of this river and its terraces. The amount of aggregate required is colossal. This warrants systematic studies of gravel and sand of the river Indus. A part of the work carried out on the Indus aggregates is presented in this paper.

The effects of deleterious alkali-aggregate reactions are often very profound and severely detrimental to concrete structures affecting their strength, stiffness, serviceability, safety and stability.

This paper for the first time, presents an overall preliminary evaluation of alkali-silica and alkali-carbonate reaction potential of coarse as well as fine aggregates of the Indus river between Raikot bridge and Kalabagh. Bulk aggregate samples were drawn from near Raikot bridge. Besham. Tarbela Dam. Attock. Lawrancepur. Harrow-Indus confluence and Kalabagh to study their deleterious alkali-aggregate reaction (AAR) potential as well as their physical and engineering characteristics.

In addition to petrographic evaluation of alkali-silica and alkali-carbonate reaction potential of these aggregates, their physical properties like water absorption (0.5 to 0.8%), bulk densities (80-90 Lbs/cft), specific gravities (2.60 to 2.85) and organic impurities for coarse and fine aggregates and mechanical properties such as aggregate crushing value (9% to 30%), aggregate impact value (6% to 25%), Los Angeles abrasion test (5 to 20%) and soundness test (1.50% to 10%) were also determined.

In addition to these, tests a detailed quantitative petrographic analyses of all the samples were carried out in order to determine their deleterious alkali-aggregate reaction potential. At many places these fine aggregates are gap graded. Metagraywackes, metasubgraywackes and metavolcanics were previously regarded as safe since they had undergone metamorphic reconstitution in low grade. We present theoretical bases for drawing a boundary line between reactive and non-reactive metagraywackes and acid to intermediate metavolcanics.

These studies show that while these aggregates possess excellent physical and engineering properties they show alkali-silica reaction potential. The reactive rock types identified are metagraywackes, metasubgreywackes, phyllites slates, acid to intermediate volcanics, granite mylonites and cherts. However, the reactive rock types and their amounts vary widely (Chaudhry et al. 1992; Zaka et al. 1995) between Raikot Bridge and Kalabagh. Not all the reactive rock types may be present at all these sites but nevertheless all these samples show deleterious alkali-aggregate reaction potential.

Chemical reactivity tests on these aggregates are inconclusive and molter bar tests over a period of six months to one year do not give unacceptable expansion. However extended mortar bar tests show unacceptable expansion. Inservice behaviour of Indus gravel and sand at Tarbela Dam and behaviour of similar aggregates in Warsak Dam has been found unsatisfactory. Evidence of alkali-silica reaction has been proved in these structures. Five possible preventive measures can be taken to avert alkali-silica reaction i.e. i) use of low alkali cement instead of ordinary portland cement. ii) use of silica fumes. iii) addition of fly ash, iv) use of slag cement and v) addition of pozzolana.

Since a large number of dams and other civil structures are planned to be built on the river Indus requiring huge quantities of cement, therefore on account of cost considerations, we do not recommend the use of low alkali cement. Silica fumes has a short history of application, therefore, its effectiveness in controlling alkali-carbonate reaction has not yet been proved under inservice conditions over extended period of time. At present we do not have large quantities of indigenous fly ash available. The use of this material therefore must wait till under-construction and planned coal fired power plants become operational. Slag cement can be usefully employed where settling time and quick attainment of peak strength is not required. The only other practical solution at the moment appears to be

manufacturing of pozzolana and producing suitably blended cements. We very strongly recommend this economical and effective solution where slag cement cannot be used.

C/86. Chaudhry, M.N. & Ashraf, M., 1977. Petrology of the Karak bentonite-Kohat District, NWFP, Pakistan. Geological Bulletin, Punjab University 14, 1-26.

A detailed petrographic, chemical, mineralogical and statistical study of the Karak bentonite is being presented for the first time. A total of 46 petrographic analyses, 47 chemical analyses, 6 X-ray analyses, 11 D. T. A. analyses and 11 spectrographic analyses have been discussed. The study shows it to be a mixed layered montmorillonite-illite with MgO in excess of CaO. It is originally thought to have been deposited as a montmorillonite which on a depth of burial of about 10000 feet and in the presence of K⁺ ions has been converted to a mixed layer montmorillonite-illite. The clay is transported and well stratified. It was deposited in a shallow undulating evaporitic basin with water reduced to nearly 1/3 of its original volume and varying slightly on either side.

C/87. Chaudhry, M.N. & Ashraf, M., 1980. The volcanic rocks of Poonch District, Azad Kashmir. Geological Bulletin, University of Peshawar 13, 121-128.

The volcanic rocks of the Poonch District are confined to the Pir Panjal Range of Upper Haveli, Poonch District. The volcanic rocks belong to two distinct ages. The Dogra Trap is basaltic and is confined within the Precambrian Dogra Slates. The Panjal Trap along with basal agglomeratic slates and Tuffs are Upper Carboniferous. The flows are mainly basaltic to andesitic. The pyroclasts occurring towards the top are intermediate to acidic in composition. The Panjal Trap is overlain by the 'Gondwana Group' of upper part of Upper Carboniferous to Permian.

This paper deals with the geology, petrography, chemistry and geochemistry of the Poonch volcanics. Map of the area on 1:50000 has been prepared. This is the first detailed petrological study of the Poonch Volcanics. A total of thirty nine petrographic analyses, thirty two chemical analyses and fifteen spectro-chemical analyses of the volcanics are presented.

Key words: Volcanics, slates, Pir Panjal Range, Poonch, Azad Kashmir.

C/88. Chaudhry, M.N. & Ashraf, M., 1981. Petrology of Middle Siwalik rocks of Kotri area, Azad Kashmir. Geological Bulletin University of Peshawar 14, 183-191.

Sandstones and shales of the Middle Siwalik of the Kotli area have been studied petrographically, chemically and spectrochemically. By comparing the overall compositions of these rocks and those of the rock fragments present in the constituent sandstones, it has been concluded that the Middle Siwalik rocks have been derived from igneous, metamorphic and sedimentary formations lying to the north and northeast of the area, towards the Pir Panjal Range.

C/89. Chaudhry, M.N. & Ashraf, M., 1984. Geology, petrography and spectrochemistry of Gondwana rocks of Poonch District, Azad Kashmir. Kashmir Journal of Geology 2, 11-18.

Geology, petrography and spectrochemistry of Gondwana metaconglomerates, quartzites and schists have been described and discussed. Ten modal analysis of Gondwana metaconglomerate bed, four modal analyses of Gondwana schists, five spectrochemical analysis of Gondwana metaconglomerate and two spectrochemical analysis of Gondwana schists are presented for the first time from Poonch. The geological and petrographic evidence supports the view (Wadia 1928) that the Gondwana Group of rocks were deposited under continental conditions. It has been further suggested that the environment of deposition varied from oxidizing to reducing. The upper Haveli Tehsil of Poonch with Agglomeritic slates and tuff, Panjal Trap and Gondwana Group rocks belongs to the Kashmir geologic province while the remaining part (with the Palaeozoic rocks missing) should be grouped with the Hazara province. The two contrasting provinces are separated by the great boundary fault.

C/90. Chaudhry, M.N. & Ashraf, M., 1985. Petrology of Murree Formation of Poonch District, Azad Kashmir. *Kashmir Journal of Geology* 3, 13-36.

A detailed petrographic, chemical and spectrochemical study of Murree Formation from Poonch Distt. of Azad Jammu and Kashmir is being presented for the first time. This study includes petrographic analysis of 22 sandstones, 31 shales and 13 limestones; chemical analysis of 23 sandstone, 6 shales and 13 limestones, chemical analysis of 23 sandstones, 6 shales, and 3 limestones and spectrochemical analysis of 10 sandstones, 8 shales and 4 limestones.

A comparison of the Murree Formation and Siwaliks of Poonch is presented to show similarities between the two. It is shown that the two have been derived from the same source.

The view held so far (following Wadia, 1928) that the Murree Formation has been derived from Dharwar and Cuddapah rocks of Peninsular India is dispelled. Instead, it is clearly shown that the Murree Formation like the Siwalik (Chaudhry and Ashraf, 1981) have been derived from the rising Himalayas.

In Poonch area it is shown that the Murree Formation are marine, while the middle and upper Murrees are of continental origin with local lacustrine conditions.

Key words: Petrology, geochemistry, Murree Formation, Azad Kashmir.

C/91. Chaudhry, M.N. & Ashraf, M., 1986. Petrology of ultramafics from Shangla-Alpuri-Malam Jabba area, Swat. *Kashmir Journal of Geology* 4, 15-33.

Chromite and chrome spinel bearing metamorphosed ultramafics occur south of the MMT within a eugeosynclinal assemblage composed of green schist, slices of blue schist and mafic lavas. The rocks originally peridotites are now composed of serpentinites, serpentinitised peridotites and a varied assemblages of talc-carbonates. The mineral assemblages show that the main metamorphic phase took place between 325 °C and 500 °C. That would correspond to low to very low grades of metamorphism. This paper presents petrography, chemistry and metamorphism of these rocks.

C/93. Chaudhry, M.N., Ashraf, M. & Hussain, S.S., 1980b. Preliminary study of Nickel mineralization in the Swat district, NWFP. *Contributions to Geology of Pakistan*, 1, 9-26.

Important areas of interest where significant reserves of Nickel ore may be expected are Shangla, Malam Jaba and Tutan Banda (Swat). Some minor occurrences are also found in Aspanr, Bar-Malakand and Ursak (Dir). Petrographically the nickel bearing rocks are ultramafics e.g. altered serpentinites (talc-carbonate rocks), sulphide bearing serpentinites and limonitic altered serpentinites, norites and allied rocks, studied so far by authors from the Swat-Dir areas, do not show nickel mineralization although these rocks deserve further study.

Chemical and spectrographic studies indicate higher values of nickel in the ultramafics than the background values (NiO in various rocks varies generally from 0.4 to 0.8% and the usual background value is less than 0.2%).

Key words: Nickel, mineralization, Swat.

C/94. Chaudhary, M.N., Ashraf, M. & Hussain, S.S., 1981. Petrology of Koga nepheline syenites and pegmatites of Swat District. *Geological Bulletin, Punjab University* 16, 83-97.

Detailed petrography, chemistry and petrogenesis of the Koga nepheline syenite intrusion is being described. A total of 70 petrographic modal analyses and 56 chemical analyses of various types of nepheline syenite and its associates were carried out. The data was processed on ISM 1130 computer using FORTRAN IV language, thus averages,

standard deviations and correlation co-efficients were worked out. The nepheline syenites show characteristics of miaskitic type. A generalised evolutionary sequence of the nepheline syenitic rocks is as follows; Pulaskite-nepheline syenite-foyaite-sodalite syenite-fenite-carbonatite.

The intrusion is a part of the alkaline province lying between Loe Shalman and Chamla. The province is composed of northern nepheline syenites, syenties and carbonatites and southern soda granites and soda porphyries. The extent of eastward extension of this province is not known. The province is associated with substantial dislocations.

C/95. Chaudhry, M.N., Ashraf, M. & Hussain, S.S., 1983. Lead-zinc mineralization of lower Kohistan District, Hazara Division, NWFP, Province, Pakistan. *Kashmir Journal of Geology* 1, 31-42.

Lead and zinc mineralization of galensphalerite type was discovered for the first time from Besham are of Kohistan. The mineralization is mainly of hypothermal to mesothermal vein type. Economically important deposits occur as veins within the igneous metamorphic zones formed by the interaction of Lahor granite and pelitic-calcareous metamorphics. Disseminated lead-zinc mineralization also occurs in skarns, altered granites, silicified granites and quartz veins. Petrography, ore microscopy, and chemistry of the mineralized rocks is presented and related to the field evidence to draw conclusions about the nature and origin of mineralization.

C/99. Chaudhry, M.N. & Chaudhry, A.G., 1974. Geology of Khagram area, Dir District. *Geological Bulletin, Punjab University* 11, 21-43.

A map of ninety square miles of the area is presented. Bojites, diorites, trondhjemite, norite, hypersthene gabbro, hypersthene diorite, pyroxenite, intermediate pegmatite and amphibolites occur in the area. Normal igneous

differentiation of two different magma types is postulated to be responsible for two different types of related rocks i.e., basaltic magma of andesite rhyolite association, which, resulted in the formation of bojite, diorite, tonalite and trondhjemite and the tholeiitic magma which gave rise to norite, hypersthene gabbro, hypersthene diorite and pyroxenite. The study suggests that the formation of complex progressed by independent intrusions of earlier basaltic magma of andesitic, rhyolitic association to latter of tholeiitic nature with subsequent differentiation.

C/100. Chaudhry, M.N., Chuhan, F.A. & Ghazanfar, M., 1994. Microfacies, diagenesis, environment of deposition and burial history of Datta Formation from Baraoter, District, Abbottabad. *Kashmir Journal of Geology* 11 & 12, 43-58.

Datta Formation of Early Jurassic age from Baraoter, Abbottabad-Nathiagali area, has been studied, for the first time from petrological/sedimentological point of view. The 11.37m thick section shows a marked vertical variation in lithology. The units included from bottom to top are medium grained kaolinite-illite and quartz cemented quartz arenite, fine grained glauconitic sandstone, medium to fine grained quartz and kaolinite-illite cemented quartz arenite, alternating bands of carbonate cemented medium to fine grained quartz arenite and oolitic pelletal limestone, medium grained ferruginous quartz arenite, coarse grained carbonate cemented quartz arenite, fine grained quartz and carbonate cemented quartz arenite, very fine grained arenaceous limestone, fine grained carbonate and quartz cemented quartz arenite, mudstone, and coarse grained arenaceous dolomite with streaks and layers of grit. There is a very restricted suite of heavy minerals, which include tourmaline, zircon, epidote and sphene. This suite indicates ultimate derivation from an igneous metamorphic sialic basement with subordinate basic/metabasic component. The granitic component was predominantly S-type. The diagenetic events have been interpreted with respect to the burial and uplift history. The maximum depth of burial is estimated at 4150m at which oil and gas maturation and reduction of primary porosity occurred. Kaolinite is the first cement to form followed by quartz and ferron carbonate cementation. At depth beyond 1000m, kaolinite transforms into illite. Kaolinite is early diagenetic as well as formed at the final stage. The environment of deposition is also highly variable from continental, subtidal, inter-tidal and supra tidal.

Geological set-up, geochemistry, petrography, petrogenesis and petrotectonics of Panjal greenstones from middle Kaghan Valley is presented for the first time. These greenstone ophiolites are tholeiites, alkali basalts and spilites of oceanic character. The Panjal volcanics which show pillow structures at many places were once considered subareal. Petrological and field evidence will be presented to show that they are in fact oceanic in character.

The sequence Panjal volcanics-Agglomeritic slate-Tanols taken together may mark the opening and then closure of an ocean (proto-Tethys), which developed on the rifted continental margin, what is now the Indo-Pak plate.

It is shown that the Panjal lavas are primary in nature and have been derived through a high degree of partial melting of pyrolite.

C/103. Chaudhry, M.N. & Ghazanfar, M., 1986. A third suture in northwest Himalayas. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, 23-24.

The MKT and MMT are two sutures so far identified in NW Himalayas and Northern Areas. In the region of Kaghan and Neelum Valleys the Main Boundary Thrust (MBT) constitutes an older Upper Palaeozoic-Lower Mesozoic suture-The Panjal suture.

The Panjal Volcanics - Agglomeratic slate-Tanol sequence tectonically is very significant and interesting and needs to be studied in greater detail. The Tanols which in Kashmir have Middle Palaeozoic age appear to indicate that the landmass of Kashmir-Hazara was developing series of disconnected basins marking the beginning of a phase of continental rifting which later led to the development of an incipient sea the Panjal sea.

The agglomeratic slate is a complex lithologic unit indicating a variety of environments including glacial and also containing an acid to intermediate volcanic suite representing a cratonic rift assemblage and an island arc affinity.

The presence of marine intertrappean limestones, pillow structures in Kaghan Valley and their tholeiitic to alkaline affinity indicates a suboceanic character for Panjal Volcanics.

The Tanol-Agglomeratic slate-Panjal sequence in the Kaghan Valley is enclosed between two major faults, which, together with others in between, constitute the Main Boundary Thrust (MBT) in this area. The MBT in Kaghan and Neelum Valley, Azad Kashmir, has therefore, acted as a suture along which representatives of a Palaeozoic incipient ocean floor developed in a rifted continental margin and were thrust onto the rocks of continental marginal affinity.

C/104. Chaudhry, M.N. & Ghazanfar, M., 1987. Geology, structure and geomorphology of upper Kaghan valley, Northwestern Himalaya, Pakistan. Geological Bulletin, Punjab University 22, 13-57.

The part of Kaghan valley between Batakundi and Babusar pass (nearly 900 sq. km has been geologically surveyed and mapped at 1 : 50,000 scale for the first time. Besides a detailed field description of rock units, brief petrographic description, comments on metamorphism, origin of migmatites, granite gneisses and granites of the area, description of structure and geomorphology are included. The Pre-cambrian metasediments of Sharda Group are mainly calc-pelites and marbles, with subordinate psammities and minor orthoquartzites. These rocks belong to the upper amphibolite facies of regional metamorphism. The associated syntectonically folded para-autochthonous garnet-tourmaline granite gneisses and migmatites are S-type and are formed due to high grade metamorphism and anatexis of pelites and psammities, feldspathic psammities and metatuffs (?) of Sharda Group. The minor undeformed Tertiary granites are from late-to post-tectonic S-type anatexites. The amphibolites are mainly mafic and pre-tectonic. Thin metasedimentary layers of amphibolite also occur associated with calc-pelites. Burawai Synform and Basal Antiform and Bela Synform are the major fold structures of the area. These have themselves been deformed further. These structures are large more like structural basins and elongated domes. Geomorphically the higher parts of the area close to Kaghan and Kohistan watersheds show Alpine sculpture with glacial troughs and associated cirques, lakes and moraines. Relatively infrequent and patchy signs of glaciation also persist along the trunk valley of River Kunhar down to Kaghan township.

C/108. Chaudhry, M.N. Ghazanfar, M. & Ahsan, N., 1994. Rates of sedimentation of Kawagarh Formation at Giah, Abbottabad-Nathiagali road and timing of uplift at K-T boundary in Pakistan. Pakistan Journal of Geology 2 & 3, 29-32.

It is postulated that lithified rates of sedimentation of Kawagarh Formation at Giah were on the average about 9 mm/1000 years, although Maastrichtian is not present at Giah section yet a substantial part of Maastrichtian is suppose to have been deposited but was removed through the process of lateritization. It is postulated that the Hangu Formation formed in upper most Maastrichtian, may have extended to lowermost Danian. Therefore, the Lockhart Formation is Danian in Age. The rapid regression resulting in the formation of Hangu Laterite started due to initial contact of Indian Plate with Kohistan Arc 67 ± 2 Ma prior to main collision between Indian and Asian Plate completely sandwiching Kohistan Island Arc at 55 Ma.

C/109. Chaudhry, M.N., Ghazanfar, M., Ahsan, N. & Masood, K.R., 1997a. Age, stratigraphic position and provenance of Murree Formation from Murree Hills and the syntaxial region. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, 9-10.

The red sandstone, siliciclastic molasse sequence of Murree Formation with subordinate rudites, rare mans and limestone horizons has for a long time been regarded as Miocene in age and derived from Cuddapah and Dharwar rocks of Indian Peninsula.

On the basis of plant and vertebrate fossils, Pilgrim (1910) assigned an to Middle Miocene age to this Formation in Kohat, Potwar and Salt Range. In the Syntaxial Region, Calkins et al., (1975) assigned a possible Oligocene age to the lower part of the Murree Formation on the basis of an apparent gradational contact with the underlying Eocene rocks of their "Kalachitta group".

However Bossart and Ottiger (1989) on the basis of larger benthic foraminifera studied from four richly fossiliferous marine calcareous zones from within the Murree Formation assigned a Late Paleocene to Middle Eocene age to the Murree Formation. Two of these four horizons have been shown as fault slices of "Kalachitta group" of Paleocene to Lower Eocene age by Calkins et al., (1975). Calkins et al. (1975) as well as Ghazanfar et al. (1986) have mapped and described Paleocene and Eocene formations lying stratigraphically below the same Murree Formation which has been assigned a Late Paleocene to Middle Eocene age by Bossart and Ottiger (1989).

We examined in detail these four richly fossiliferous marine calcareous horizons. They have distinctly sheared contacts, often with fault breccias and at places with tectonic melanges. Nowhere is there a transitional contact between these marine fossiliferous, calcareous and marly horizons and the enclosing maroon to deep red siliciclastic continental deposits. Around Chahla Bandi in Neelum Valley near Muzaffarabad part of the Syntaxial region, underlying the Murree Formation with a slight unconformity represented by calcirudites occurs a complete and well defined sequence of formations of Lower Paleocene to Middle Eocene age namely Lockhart Formation, Patala Formation, Margala Hill Formation, Chor Gali Formation and Kuldana Formation.

Near Kuldana village in Murree Hills as well as on Kummi Spur near Balakot in Kuldana Formation of Middle Eocene age grades upwards conformably into the Murree Formation. Therefore in this region we regard the Murree Formation as Upper Middle Eocene since the underlying beds of Kuldana Formation are Middle Eocene in age.

A preliminary palynological study of the Murree Formation carried out for this paper from the Syntaxial Region rules out a Paleocene to Lower Eocene age for the Murree Formation.

Prior to 1975, Murree Formation was supposed to have been derived from the Cuddapah and Dharwar rocks of Indian Peninsula (Wadia, 1926). However Calkins et al, (1975) were the first to suggest the possibility that the

Murree Formation of the Syntaxial Region was derived from the rising mountains to the North. Chaudhry and Ashraf (1985) on the basis of petrographic studies of Murree rocks with special emphasis on lithoclasts and heavy minerals from Poonch area of Azad Kashmir conclusively demonstrated a specifically Pin Panjal source region for these rocks. Bossart and Ottiger (1989) on the basis of microprobe analysis of spinals suggested "Kohistan Island Arc" as one of the source regions. Author on the basis of detailed petrographic studies on the lithic arenites of Murree Formation from Poonch, Kotli, Neelum and Murree areas furnished concrete evidence that Murrees were derived from the lower grade meta-sediments and allochthonous plutons to the north from rising Himalayas and Pin Panjal, but contribution of resistant heavy minerals including spinals from the Peninsular region is not ruled out.

C/110. Chaudhry, M.N., Ghazanfar, M., Ahsan, N. & Masood, K.R., 1997b. Age, stratigraphic position and provenance of Murree Formation of North West sub-Himalayas of Pakistan and Azad Kashmir. Proceedings of the third GEOSAS Workshop, GSP, 81-91.

The red shale, sandstone clastic sequence of Murree Formation with rare marls and limestone bands has for a long time been regarded as Miocene age and derived from Cuddapah and Dharwar rocks of Indian Peninsula. More recently age from Late Palaeocene to Middle Eocene have been proposed for the Murree Formation of Western Syntaxial region between Balakot and Kwat. It has also been proposed that the source area for the Murree Formation lay to the north in the rising Himalaya rather than to the south in the Indian Peninsula. On the basis of field studies and paleontological data, it is suggested that this time transgressive unit is neither Paleocene nor Lower Eocene in age anywhere in NW Himalayas in Pakistan and Azad Kashmir. Palynological studies of the Murree Formation from the Syntaxial region and Murree Hills clearly indicate an age from Eocene to Oligocene. We suggest that a complete sequence from Hangu Formation of Danian age to Kuldana Formation of Middle Eocene age are also present in the southern part of the western limb of the Hazara Kashmir Syntaxis. A Miocene age has been generally accepted for this formation in Kohat-Potwar region on the basis of fauna and flora. We therefore suggest that the overall age range for the Murree Formation is from Middle Eocene to Early Miocene. We provide further evidence to reinforce the proposition that the dominant source area lay to the north in the rising Himalayas but insist that subordinate contribution from the Indian Peninsula is not ruled out. The source area to the north was composed of a sedimentary to low-grade metamorphic cover with volcanic horizons (pierced by granitoids) and ophiolites.

C/111. Chaudhry, M.N., Ghazanfar, M. & Ashraf, M., 1984. A plate tectonic model for northwest Himalayas, Karakorum and Hindu Kush lying between and adjacent to MMT and MKT. Abstracts, First Pakistan Geological Congress, Lahore, 16-18.

A new plate tectonic model based on a petrotectonic approach is being presented for the first time.

Tahirkheli et al. (1979) and Bard et al. (1979) have expressed their thoughts on the sequence of tectonic events in the NW Himalayas in Pakistan. They have indicated an initial ocean - ocean collision leading to the formation of an island arc in the north of the Indo-Pak plate. Later, according to these authors, this area was sutured to the south with the Indo-Pak and to the north with the Asian continents, and that the sequence of rocks constituting this island arc system is now located between two thrusts, the Main Mantle Thrust (MMT) in the south, and the Main Karakorum Thrust (MKT) in the north. They have called it the Kohistan Island Arc sequence.

Field studies in the Section between Shewa and Chitral, however, revealed a different picture. The petrotectonic zones in the section between Shewa and Chitral and adjoining areas are more or less symmetrically disposed on either side of the central layered intrusions which represent oceanic lithosphere (and not granulites, as proposed by Jan et al. 1980) There are southern and northern melanges, southern and northern volcanic-sedimentary zones (arcs) and the trench zone (so far well established only on the southern side).

In other sections, due to extensive thrusting and transport of crustal chunks, the situation has become much more complicated. However, the identification of various petrotectonic elements and their interpretation shows that they represent elements of the above mentioned petrotectonic units plus chunks and protrusions of IndoPak and Asian masses. The present model is therefore considered applicable to NW Himalayas, Karakorum and Hindu Kush lying between and adjacent to the MMT and MKT.

Petrotectonic relations also indicate an initial subduction of Tethyan plate under the Indo-Pak continent. This is contrary to the currently postulated northwards subduction, only.

The central layered intrusions represent oceanic lithosphere as against the idea that they form lower part of the so-called Kohistan Island Arc sequence (or that they are granulites). This latter term i.e. Kohistan Island Arc' may be used only for a narrower zone south of the MMT. The huge succession that has been previously called the Kohistan Island arc actually comprises a number of distinct petrotectonic provinces viz, from south, southern island arc, southern mélange zone, central layered intrusions, northern mélange zone and the northern island arc of Asian plate affinity.

The presently mapped or postulated position of MKT also needs correction. It should be placed south of the northern island arc and not to its north. In this paper chunks of sheeted complex, pillow lava and the latest elements of Tethys's sediment in the area are related. Extrusive and intrusive elements on the Indo-Pak plate are identified. The existence of a tension related alkaline province on the Asian mass and a northern trench zone are predicted.

C/112. Chaudhry, M.N., Ghazanfar, M., Ashraf, M. & Baloch, I.H., 1989. Observation on Precambrian orogeny and the age of the metamorphism in Northwest Himalaya, Pakistan. *Kashmir Journal of Geology* 6 & 7, 19-22.

Presence of Tertiary granites in Himalayas has clouded the earlier metamorphic history of Northwest Himalaya. Evidence from the relationship of various rocks units throws fresh light on the chronology and intensity of older metamorphic events which go back to 1840 ma. In particular, a Late Precambrian event rose to amphibolite facies. A Permo-Trias event of much lower intensity is also indicated.

C/113. Chaudhry, M.N., Ghazanfar, M., Ashraf, M. & Hussain, S.S., 1984. Geology of the Shewa-Dir-Yasin area and its plate tectonic interpretation. *Kashmir Journal of Geology* 2, 53-63.

Regional Geology of a large area between Shewa, Malakand, Warsak in the south and Hunza, Yasin, Chitral in the north through the valleys of Dir and Swat has been broadly described. Petrography and Modal compositions of the principal petrologic units are presented. Chemistry of some of these rocks has also been discussed. Petrotectonic significance of the principal rocks units in the area is assessed. A number of linear petrotectonic belts have been established running approximately east west between Shewa in the south and Yasin in the north. It is suggested that the mass of rocks enclosed in the Kohistan area between the Indian and Asian plates is not a single island arc sequence but comprises on the other hand at least two and possibly three island arcs and associated trenches. The extensive amphibolite, and complex is separate and does not represent the lower part of a single Kohistan island arc sequence as suggested in the past but comprise at least three distinctive belts two belts of obducted melanges with a central belt consisting of a possibly trapped portion of the Tethy's oceanic crust. Finally a southward subduction of the Tethyan lithosphere is postulated under the Indo-Pak plate in contrast to north directed subduction of the Indian plate as suggested in the past. A sequence of different subduction zones is suggested.

The Agglomeratic Slate in Kaghan Valley is a lithologically heterogeneous unit. It is composed of graphitic schist, micaceous quartzite, feldspathic quartzite, pelitic schist, feldspathic chlorite calcite schist, marble and metaconglomerate. The graphitic schist and feldspathic quartzites contain volcanogenic material. In Kashmir it contains well defined volcanic horizons. The unit was deposited under varying environmental conditions, continental, lagoonal and marine in a deepening cratonic rift, and represents continuation and, at places a replacement of Tanawals of Kashmir.

C/116. Chaudhry, M.N., Ghazanfar, M., Hussain, S.S. & Dawood, H., 1995. Problems of petrotectonic modelling of suture zones in northern Pakistan. Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, 12-15.

The southern suture in northern Pakistan, popularly known as the Main Mantle Thrust (Tahirkheli, 1979) is as a whole composed predominantly of partially to completely dismembered ophiolitic suite. This suture zone is the true equivalent of the Indus- Tsangpo suture zone. Suturing of the Kohistan Island Arc to Indo- Pak Plate along this zone occurred at around 65 ma (Spencer, 1993; Smith et al., 1994; Chaudhry et al., 1994) to 35 ma (Treloar et al., 1995). The lithologies exposed are harzburgite tectonites derived from depleted mantle, dunites, peridotites and wherlites derived from upper mantle cumulates, layered and isotropic gabbros, sheeted dykes, pillow lavas, ribbon cherts, pelagic clays as well as flyschoid sediments. Because of extensive dismemberment it is rare to find all these lithologies in a single section. This has led to divergent petroTECTONIC interpretations based heavily on geochemical consideration without regard to structural or geological constraints. The sections composed of plutonic ultramafic and mafic rocks have generally been interpreted as arc related and emplaced at the base of amphibolites. One or another part of a particular section on the basis of major or trace elements alone has been assumed are related without considering the entire section and structural relations of the internal units.

C/118. Chaudhry, M.N. Ghazanfar, M., Meier, A., Ramsay, J.G., Spencer, D. & Wahrenberger, C., 1991. New stratigraphic and fossil finds in the Higher Himalayas of the upper Kaghan valley, NE Pakistan. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Auris, France, 29.

A collaborative project between the EHT and Punjab University during the summer of 1990 has led to important new discoveries bearing on the stratigraphic and structural relationships of the various rock groups marking up the Higher Himalaya Unit of NE Pakistan.

A coherent three unit stratigraphic subdivision appears to hold over most of the region. A basement consists of granitic gneiss which is overlain by a group of meta-pelitic to semipelitic sediments of original greywacke aspect which, although strongly recrystallized and locally granitized, still show traces of graded bedding with consistent younging directions away from the granitic basement. Although the relationships between these units is clear, suggesting that the granitic gneisses were metamorphic basement to a regionally overlapping group of sediments, no clear angular discordance has yet been discovered on outcrop scale.

The two basement groups are overlain by a thick series of calcareous pelites lithologically similar to the "schists lustrés" of the European Alps, and interpreted as a sedimentary cover. These rocks locally contain good sedimentational "way up" structures, synsedimentary extension faults and fossils (stromatolites, trace fossils). Considering the amphibolites metamorphic grade of these rocks, the preservation of fossil is remarkable. The base of the cover succession is marked by extensive thick sheets of amphibolite locally showing deformed amygdalites

suggesting that they were initially basaltic lavas, and thinner sheets of amphibolite of similar petrographic aspect are found throughout the succession.

As yet no firm ages have been placed on these stratigraphic units. However, lithological correlations with rocks of Swat, the Srinagar Basin and Ladakh suggest that the granitic gneisses are probably of Pre-Cambrian age. The metapelites are of Lower Paleozoic age and the calc-schists and associated basaltic lavas may be correlated with various basic volcanic rocks of Paleozoic and younger age (perhaps some being equivalent to the Panjal Trap). The overall distribution of these three units is suggestive of the presence of large scale recumbent fold nappes, but this pattern is complicated by the intensive development of later superposed fold phases and the formation of regional tectonic dome and basin structures.

This paper presents for the first time mineral assemblages, textures, structures, index mineral zones, metamorphic facies and metamorphic grades of the rocks lying between Paras and Babusar Pass, Kaghan valley. The metamorphic rocks are regionally metamorphosed and belong to a medium pressure type metamorphic series. The rocks range from unmetamorphosed units to high-grade metamorphic units e.g. from greenschist facies to high amphibolite facies. In terms of index minerals, they range from biotite to sillimanite zones and in terms of metamorphic grades the rocks range from very low grade to high grade metamorphism.

Detailed geological mapping of the valleys of Neelum, Kaghan, Indus, Swat and Dir has afforded numerous excellent sections across the Northwest Himalaya. It has now become possible to characterize the tectonostratigraphy in these areas and define the major thrusts bounding the main tectonic units. The location of the Main Central Thrust (MCT) near Naran in the Kaghan Valley and its extension into the Neelum (to the east) and Swat valley (to the west) as finally formalized the correlation and extension of the transverse subdivision of the

Himalayas from India and Kashmir into Pakistan. This paper presents a systematic account of the stratigraphy, metamorphism and tectonics of the Himalayan subdivisions in Pakistan. The four major zones of the Himalayas, the Tethyan or Tibetan Himalaya, the Higher Himalaya, the Lesser Himalayas and the Sub-Himalaya have now been followed from the Neelum Valley, Azad Kashmir, through the valleys of Kaghan and Swat into Dir. The presence and nature of the northernmost belt of the Tethyan Himalaya is also established. The separation of the various tectonic zones of the Himalaya paves the way for synthesis and correlation of local stratigraphic, metamorphic and structural studies along various sections and their correlation with researches in Kashmir, Kumaun, Nepal and further east.

Keywords: Plate tectonics, tectonostratigraphy, structure, Kaghan, Indus, Swat, Dir, Himalaya.

C/124. Chaudhry, M.N., Ghazanfar, M. & Spencer, D.A., 1996a. Main Central Thrust in northwest Himalaya, Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 31-32.

The transverse subdivision of the Himalayas, established in Eastern and Central Himalaya in India and Nepal, could not be fully extended to Kashmir and adjoining Pakistan since these areas have remained unmapped until very recently. In addition, these areas constitute the Western Himalayan Syntaxial Region characterized by sharp bends in strike with extensive imbrication and strike slip faulting that results in the attenuation or even elimination of some units. This, coupled with lack of mapping until very recently, made it difficult to extend geologic or tectonic trends from India and Eastern Kashmir into Western Kashmir and Pakistan, which resulted in various workers trying to connect the MCT trend from India into Kashmir with Panjal Thrust (PT) or MBT (Gansser 1964; Sinha 1989). This view was generally accepted for over two decades. Acceptance of such a view would lead to combining together in one block of terranes, which have entirely different tectonostratigraphic, tectonometamorphic, tectonomagmatic and structural characteristics.

Yeats and Lawrence (1984) regarded the Raikot Fault on the western margin of the Nanga Parbat Haramosh Massif as a terminal tear fault of the Main Central Thrust. Tahirkheli (1992) demarcated a NE-SW Trending Shon argali Thrust as the "MCT" between Astor and Ratta. In our opinion Raikot and Shon argali faults run entirely within the HHC block (see Spencer, 1995 for full review problems of locating the MCT in Pakistan).

Heim and Gansser (1939), while working in Garhwal and Kumaun, defined a major thrust between the sedimentary formations and moderately metamorphosed rocks. This thrust was subsequently formalized as the Main Central Thrust (MCT). They also described the inverse metamorphism from these areas. However, they did not recognize tectonic break between Mesozonal and Katazonal rocks. Sinha (1989) has followed Gansser (1964) in defining the Main Central Thrust (MCT) in the Central Himalayas. Valdiya (1984) based on an abrupt break in the grade of metamorphism and on the change in petrological composition of the rocks of the central crystalline, defined a thrust plane (MCT) at an even higher stratigraphic level (at the base of kyanite-sillimanite bearing rocks) than the one defined by earlier workers. He named this thrust as the Vaikrita Thrust.

A large number of Himalayan workers now believe that the MCT is an intracontinental thrust which demarcates the boundary between the Lesser and Higher Himalayas that resulted in the considerably thickening of the continental crust. It is a north dipping generally 5 to 20 km thick low to high angle shear zone associated with mylonitisation, a strong stretching lineation and strong foliation. It is also marked by the inverse metamorphism and a sudden jump in metamorphic grade from greenschist to upper amphibolite facies with a differing tectonic style on either side of the shear zone (Brunel, 1986; Valdiya 1984; Ghazanfar and Chaudhry et al. 1994).

The Main Central Thrust first located in the Kaghan and Neelum Valleys (Ghazanfar and Chaudhry, 1986) now extended across the entire NW Himalayas of Pakistan is a 500k to 5km thick zone of ductile deformation with the development of a strong schistosity is oblique but is being rotated into the shear zone. The ductile shear zone develops in the turbidites of Kaghan, as well as in the Malakand area. In zones of strong deformation within the turbiditic sequence, bedding is replaced by a strong mylonitic fabric. Therefore S₀ and S₁ have both been rotated into parallelism with the shear zone deformation. The thicker arenaceous beds are by contrast more folded and boundinaged. The mineral stretching lineation is strong and parallels the shear zone. Sheath folds are also present with eye-like structures developed due to fold hinges, which are curved and rotated towards parallelism with the shear zones. All kinematic indicators suggest a top to the south sense of shear.

There is a significant PT break on either side of ductile deformation. Rocks to the south of MCT in the Malakand and Swat fall in lower greenschist facies while rocks in Kaghan and Western Kashmir fall in middle greenschist facies. The rocks lying to the north of the proposed MCT in Western Kashmir and Pakistan fall in upper amphibolite facies (kyanite-sillimanite grades) and local eclogite facies. The structure style on either side of MCT is also very

different. The rocks to the north (HHC) occur as elongated structural basins and domes with fold interference pattern (Types 1 and 3) with major axis trending from NNE to the east of Besham Syntaxis and NNW to the West of Besham Syntaxis. The deformation is ductile with hardly any apparent fault. The rocks to the south of MCT generally trend EW. The deformation is brittle and is comprised of tight folds and abundant thrust comprising a schuppen structure.

Based on this work, both the Lesser and Higher Himalaya are now therefore recognizable in the NW Himalaya and are continuations of the better known LH, MCT and HH last seen in India.

C/125. Chaudhry, M.N., Ghazanfar, M. & Spencer, D.A., 1996b. Evidence for Pre-Mesozoic affinity of the Karakoram Himalaya to the Indian Plate, Northern Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 33-34.

The Karakoram Himalaya form a distinctive topographic and mountainous range in Central Asia. Geologically, they are classified as part of the Eurasian Plate, a collage of terranes into which the Indian Plate collided to form the Himalayan mountain range at times estimated from 65 to 45 Ma.

Recent mapping and traverses of the Karakoram Himalaya lead us to suggest that there is distinctive stratigraphical correlation between the units of the Karakoram Himalaya (Eurasian Plate) and the Himalaya (Indian Plate). In fact, we suggest that these similarities are so strong that the likelihood should be considered that the Karakoram Himalaya and the Indian Plate were until the early Mesozoic, attached as part of the same block or plate. With the closure of Paleo-Tethys and the opening of Neo-Tethys, a rifted piece of the Indian Plate (Karakoram Himalaya) subsequently broke away from Gondwanaland (and the juvenile Indian Plate) and was subjected to a passive collision, with eventual suturing, to Eurasia. The fact that the pre-collisional history of the Karakoram Himalaya is known to be comparable to the Lhasa block of Southern Tibet in the east (Searle, 1991) and the Helmand Block of eastern Afghanistan to the west (Blaise et al., 1977; Stocklin, 1977; Wolfart and Wittekindt, 1980), suggests that a distinctive belt with a similar pre-Mesozoic stratigraphy can be traced, north of the Indus Suture, from west to east of the Karakoram Himalaya. Here we provide evidence of a north to south correlation with the Indian Plate. For discussion purposes, we also suggest a new terminology for the Karakoram Himalaya with the implications that this has for its tectonic history. The classification that we have used is based on that of the Himalayan subdivisions (i.e., Higher Himalaya and Lesser Himalaya). We suggest that in the Karakoram the distinctive units of the Higher Karakoram and Lesser Karakoram can be found and, more importantly, be correlated to their Indian Plate equivalent (Table 1 and 2).

C/126. Chaudhry, M.N., Ghazanfar, M., Spencer, D.A, Hussain, S.S. & Dawood, H., 1995a. Higher Himalaya of Pakistan- A tectonic stratigraphic review. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, Switzerland.

Mapping of extensive areas in Neelum, Kaghan, Besham, Lower Swat, Malakand and Dir has made it possible to delineate the Main Central Thrust, MCT, and define the area of the Higher Himalaya Crystalline, HHC, slab in Pakistan and Azad Kashmir. This paper presents a first time integrated account of the stratigraphy, metamorphism and deformation of this major division and hinterland area of the Northwest Himalaya. Between Indus Suture, or the MMT, to the north and MCT in the south the HHC slab, extends from Bajaur on the Pak-Afghan border in the west to across the Neelum Valley of Kashmir in the east. The slab has a variable width. It is widest in the area of Nanga Parbat Syntaxis and is attenuated in the area of Hazara Kashmir Syntaxis.

Stratigraphically the Higher Himalaya in Kaghan, Besham and Swat comprises the oldest exposed rocks of Pakistan. The basement is composed of a lower autochthonous to parautochthonous granitoid-migmatite complex with metasedimentary enclaves and abundant pegmatites, a middle pelite-psammite sequence with paragneiss horizons of garnetiferous quartzofeldspathic rocks, abundant pegmatites, intrusive bodies of granite and contact migmatites and an upper pelite-psammite package in kyanite-sillimanite grades with subordinate pegmatites and granites. Marble, amphibolite and graphitic pelite are minor lithologies. It is overlain by two unfossiliferous cover sequences. The First cover comprises a thick calcpelite, marble sequence with an overlying pelites unit in Upper Kaghan and an underlying turbidite unit with interbedded amphibolites in Lower Swat. The basic volcanics show a stratigraphic upward jump into the lowermost part of the overlying calcpelites in the area of Upper Kaghan. We suggest that the basement and the First Cover are Proterozoic in age although the age of the cover in Kaghan is debated and has also been suggested as late as Triassic. The Second Cover comprises low-grade graphitic pelites, calc pelites and marbles, which mainly crop out below the Indus Suture. On the basis of dates on cross cutting granite veins the Second Cover may also be Late Proterozoic or it may be Palaeozoic and are here interpreted as the Tibetan Tethyan sediments elsewhere lying unmetamorphosed to the north of the HHC. However, both the age and affinity of these Second Cover rocks is debated. The basement granitoids and the overlying First Cover rocks together form the crystalline HHC slab, and are both characterised by metamorphism in the upper amphibolite facies. The metamorphism shows

sudden downward jumps to greenschist facies both in the north across an extensional detachment (Trans-Himadri Fault, THF, or the Zaskar Shear Zone) into the Tethyan cover and in the south across MCT into the Lesser Himalaya. Eclogites have been reported from the Besal area of Upper Kaghan which indicate $T=650^{\circ}\text{C} \pm 50$ and $P=15$ to 16 Kbars corresponding to a depth of 55 to 60 km. Elsewhere although the temperature was about the same the indicated depth ranged between 35 to 45 km. Whereas the whole of the HHC slab is metamorphosed in the upper amphibolite facies the conditions tend to become more intense structurally downward and the cores of major domes such as Besal, Besham and Kolangi may exhibit ultrametamorphism with profuse migmatization and generation of anatectic granites. The common model based on cooling ages considers the dominant metamorphism Himalayan in age and explains the PT conditions by burial of the Indian Plate under Kohistan consequent upon collision between India and Kohistan ($\text{Ca } 50 \text{ Ma}$) and its subsequent imbrication. Extensive mapping in the field has however not revealed evidence of thrust imbrication in the terrain of Higher Himalaya. The model as it stands also fails to explain such features as greenschist facies metamorphism of Indus Suture mélange and of the underlying low grade Tethyan cover as well as preservation and age of blue schist and the short time interval between collision and exhumation. Numerous evidences have been cited to suggest that the Higher Himalaya slab suffered at least one pre-Himalayan metamorphism, here suggested to be upto the amphibolite facies upon which a variable Himalayan metamorphism has been imprinted. Deformation in the HHC slab is characterised by the north-south trending kilometric scale domes and basins and a ductile regime. These structures are unique to the Higher Himalaya being truncated by the MMT and MCT in north and south. The Kohistan area and the Lesser Himalaya (except for the HKS) in the south both show east-west trends and a schuppen structure under conditions of increasing brittle deformation.

C/127. Chaudhry, M.N., Ghazanfar, M., Spencer, D.A., Hussain, S.S. & Dawood, H., 1995b. The division between Lesser and Higher Himalaya in Pakistan. Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, 24-26.

Lack of mapping on the ground, presence of an island arc in this section, the presence of Nanga Parbat and Hazara Kashmir Syntaxis and the continuing Kashmir dispute had complicated the task of tectonic correlation between the Pakistani northwest Himalaya with the Himalaya to the east. With the mapping of Neelum, Kaghan and Swat areas the stage was set for the delineation of the MCT for the subdivision of the Lesser and Higher Himalaya in Pakistan and correlate it across Kashmir to Kumaun and Nepal Himalaya. The MCT has now been defined from Luat in Neelum Valley and Kashmir across Batal in Kaghan through Malakand and Swat to Dir and Bajaur in the extreme west of Pakistan the HHC and the Lesser Himalaya stand differentiated.

The MCT is Characterized by a kilometric zone of milonites in the greenschist facies with a general top to the south sense of thrusting, The Major Boundary Thrust (MBT) is distinguished by major difference in lithostratigraphic packages on both sides, a sudden jump in metamorphic grade and a marked difference in tectonic style.

The HHC slab extend from Neelum Valley to Bajaur is characterized by a turbiditic basement sequence extensively migmatized in the lower part and a calc-pelitic cover sequence. A second low grade sequence appears in synclinal inliers on the high rocks of HHC. It appears the same low grade rocks appear between the suture zones and the Indian Plate in upper Kaghan as well as Banna area of Allai.

C/129. Chaudhry, M.N., Ghazanfar, M., Spencer, D.A., Hussain, S.S. & Dawood, H., 1997. The higher Himalaya in Pakistan-A tectonicstratigraphic synopsis. Geological Bulletin, Punjab University 31 & 32, 21-41.

Following the demarcation of the Main Central Thrust (MCT), the mapping and tectonostratigraphic characterisation of the Higher Himalaya across northern Pakistan and Azad Kashmir has been made for the first time. This slab has a variable width. It is widest in the area of the Nanga Parbat Syntaxis and is attenuated in the region of the Hazara-Kashmir Syntaxis. This paper presents an integrated account of the stratigraphy; deformation and metamorphism of this major tectonic division and hinterland area of the Northwest Himalaya. The Higher Himalaya is comprised of a lower basement and an upper cover unit. The basement is constituted predominantly of granitoids, migmatites, pelite schists and micaceous quartzites with minor calc-pelite gneisses, marbles and discordant amphibolites. The cover consists predominantly of calc-pelite gneisses, with subordinate marbles and pelite schists and extensive amphibolites at its base. The Higher Himalaya is characterised by the development of kilometric scale elongated structural basins and domes with a fold interference pattern (types I & 3) that trend either northeast-southwest (Kaghan), north-south (Besham) and north northwest-south southeast (Swat). These fold trends are truncated at a high angle to the south across the Main Central Thrust in the Lesser Himalaya and to the north by the Tethys and Indus Suture Zone rocks. The nature of deformation in the Higher Himalaya is ductile. The rocks of the Higher Himalaya have been metamorphosed to upper amphibolite facies or kyanite-sillimanite grade. However around Besal in Upper Kaghan and at places in Upper Neelum valley the rocks have suffered eclogite facies metamorphism. The Pressure-temperature estimates by various workers give generally upper amphibolite facies metamorphism which range from 600° to 700° C at 7-11 Kbars. However, the basement and cover lithologies of the Besal area in Upper Kaghan valley have undergone eclogite facies metamorphism at T=65±5°C and P=15-17 Kbars, corresponding to depths of 55 to 65 kilometers. To the south of the Higher Himalaya across the Main Central Thrust, the Lesser Himalayan rocks take a marked downward jump in metamorphic grade to greenschist facies. Similar observations also were found to the north in the Tethyan lithologies which overlie the HHC slab or occur as fault slivers close to the suture.

C/130. Chaudhry, M.N., Ghazanfar, M. & Walsh, J.N., 1993. The Panjal sea, Kashmir Hazara microcontinent and Hercynide geology of Northwest Himalaya. Abstract Volume, 8th Himalaya-Karakoram- Tibet Workshop, Vienna, 13.

This paper discusses the tectonic significance of the Permian Panjal Volcanics Kaghan Valley on the basis of an overview of geology, field relations and associated rocks. It is proposed that more than 400-km long rift related, generally terrestrial Panjal suite developed into an incipient ocean, the Panjal Sea with continental to oceanic transitional to oceanic crust in Kaghan area. Major element, trace element and R.E.E. characteristics appear to corroborate this conclusion.

North of this incipient ocean lay the Kashmir Hazara micro-continent. The Permian Panjal Sea which developed during rifting of Gondwanaland closed during Triassic when the overlying Malakand limestone was deposited and Neo Tethys started opening to the north of the Kashmir-Hazara microcontinent.

River Indus, the life line of Pakistan, is the single most important and major potential source of water and power in the country. Most of the future high dams, barrages, thermal and nuclear plants and bridges will be located on Indus river. This will require billions of cubic meters of concrete. The value of aggregate alone will run in billions of rupees. Aggregate may limit the strength of concrete, its durability and structural performance. Aggregate has generally been considered as inert material. In actual place, aggregate is far from inert in its characteristics and exerts a profound influence on the performance and durability of concrete. Indus gravel have shown excellent physical characteristics and are designated as most suitable for concrete. However, in service behaviour and mortar bar tests over extended periods have shown the development of significant distress. The causes of distress have been identified as alkali silica and alkali silicate reaction (A.S.R, A.St.R) between meta wackes, metagreywackes, micro-fractured quartzite and meta volcanics and the high alkali cement. Notwithstanding such evidence the controversy still rages as to the actual and relative causes of deterioration between physical and environmental factors and reactivity of aggregate.

This paper is an outcome of researches to resolve this controversy and to present a proper evaluation of various geotechnical, petrographic, mineralogical and chemical characteristics of the Indus aggregate. In the opinion of the authors, the ILS.R. and A3t.R. potential of these aggregate is a significant factor to be considered for future projects and it is proposed that this aggregate may be used either with low alkali cement (total alkalis less than 0.5%) or with the addition of appropriate quantity of pozzolanous additive or slag cement.

C/136. Chaudhry, M.N., Hussain, S.S. & Dawood, H., 1992b. The Lithostratigraphic framework of North West Himalaya, south of the Main Mantel Thrust along Mingora-Daggar section, Swat, Pakistan. Pakistan Journal of Geology 1, 29-41.

The Mingora-Daggar section constitutes the northern edge of the Indo-Pak plate west of Besham syntaxis. The rocks exposed in the area range in age from Precambrian to Eocene. Manglaur group is the oldest rock unit of the area and is divided into lower Pacha formation and an upper Ilam granite gneiss formation. Pacha formation is Precambrian in age, falls in upper amphibolite facies and is composed predominantly of psammite and pelite with smaller proportion of marble, calc-silicate marble, graphitic schist, amphibolite, migmatites and old basement non porphyritic garnet tourmaline granite gneisses outside the area. Ilam porphyroblastic granite gneiss intrudes Pacha Formation and is probably Precambrian in age. Other granitic rocks are syn to post tectonic and Tertiary in age. One of these syntectonic bodies mapped is Tertiary Amlukdarra tourmaline garnet microgranite gneiss. Alpurai group of Precambrian age overlies the porphyroblastic Ilam granite gneiss and is divided into lower Salampur formation composed of pelite psammite interbedded with abundant amphibolites and an upper Tilgram formation comprised basically of banded garnetiferous calc-pelite and marble with subordinate graphitic garnetiferous schist and

garnetiferous amphibolites. Dagar formation is comprised predominantly of low grade graphitic schist and phyllite with subordinate phyllitic pelite, marble, calc schist and green schist. Kazmi et al (1984) named this unit as Saidu schist and regarded its age as lying between Palaeozoic and Mesozoic. This formation is regarded here as Precambrian in age. Bampokha group is Lower to Middle Palaeozoic in age falls in greenschist facies of regional metamorphism and is divided into Girarai formation and Tursak formation. The Girarai formation is composed mainly of calc-pelites, light gray to gray marble and subordinate graphitic schist. The Tursak formation is composed dominantly of white and bicoloured white and gray marble with subordinate calc-pelites, pelites and graphitic schist/phyllite. The Cretaceous-Tertiary Mingora ophiolitic mélange comprises tectonic blocks of greenschist, greenstone, talc-carbonate, amphibolite, gabbro, serpentinite, peridotite, harzburgite, siliceous and graphitic metasediments and a few Assilina and Nummulite bearing (Eocene) carbonate slices.

C/137. Chaudhry, M.N., Hussain, S.S. & Dawood, H., 1992c. Position of the Main Central Thrust and sub-division of Himalaya in Swat. *Pakistan Journal of Geology* 1, 59-65.

Geological investigations and large scale mapping in Swat area of Western Himalaya has now made it possible to precisely locate the position of the Main Central Thrust (MCT). There is a clear and well-marked contrast in the tectonic style and degree of metamorphism and gross stratigraphy to the north and south of this line. The delineation of the Main Central Thrust in the area under study now makes it possible to extend the tectonic zones of Himalaya in Neelum and Kaghan to the West of Indus River. See also the following one.

Keywords: Tectonics, MCT, Himalaya.

C/138. Chaudhry, M.N., Hussain, S.S. & Dawood, H., 1994. Position of the Main Central Thrust and subdivision of Himalayas in Swat, Pakistan. In: Ahmed, R. & Sheikh, A.M. (Eds.), *Geology in South Asia--I. Proceedings of the First South Asia Geological Congress, Islamabad, 1992*. Hydrocarbon Development Institute of Pakistan, Islamabad, 208-211.

Detailed fieldwork recently carried out in southern Swat and Malakand has made it possible to locate the position of the Main Central Thrust (MCT). Across this very important line there is a marked contrast in tectonic style, stratigraphy as well as metamorphism.

Between the Main Central Thrust (MMT) to the north and MCT to the south lies the Higher Himalayan crystalline block. This deep-seated block was rapidly uplifted between these two major thrusts due to collision between Indo-Pak plate and Asian plate thus exposing some of the deepest rocks of the Northwest Himalaya in Pakistan. On the basis of delineation of these major structural lines, the Himalaya in Swat has been subdivided into Kohistan Himalaya, Tethyan Himalaya, Higher Himalaya and Lesser Himalaya.

C/139. Chaudhry, M.N., Hussain, S.S. & Dawood, H., 1997. Massive sulphide and porphyry mineralization associated with Gawachi back arc basin, Chitral, Ishkuman, Chatorkhand, Gakuch, Yasin, Gilgit and lower Hunza valleys. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 3p.

Geology, petrology and mineralization of the MKTZ ophiolites. Rakaposhi volcanics and associated rocks of the Yasin Group have been studied in Shishi Gol. Drosh and Mirkhani areas of Chitral and Ishkuman. Chatorkhand-Gakuch. Yasin, Gilgit river valley and lower Hunza river valley. On the basis of tectonostratigraphic elements and tectonomagmatic characterisation of the mafic and ultramafic rocks and associated sediments, a back arc basin named here as the "Gawachi back arc basin", has been defined by us. This basin has previously been considered by many workers as simply top of the Kohistan island arc. The Gawachi back arc basin, is composed of Rakaposhi volcanic complex and Yasin Group of middle Jurassic to Cretaceous age. These rocks have been intruded by plutons of the Kohistan arc. These plutons are sodic deformed plutons, potassic deformed plutons and potassic undeformed plutons (Treloar et al. 1989. Bard 1983).

The Rakaposhi volcanics have been classified on the basis of field characteristics, petrography and geochemistry. Most of the rocks are either basalts or basaltic andesites. Hardly any proper rhyolite could be found. Subordinate

lithologies defined on the above basis are andesites and dacites. These finds are contrary to the general implicit belief expressed in many reports and publications that these greenstones are predominantly composed of andesites, dacites and rhyolites. Tectonomagmatic discrimination diagrams were used to characterise the tectonic setting. Bonanitic characteristics are shown by certain volcanic sections. Other sections show an arc type, ocean floor and even MORB characters. Tectonomagmatic signatures as well as the contents of immobile elements coupled with tectonostratigraphic set up strongly indicate a back arc basin environment. But of course, arc input in this zone is also recognised. The Yasin Group is composed of siliciclastic as well as calciturbidites flyschoid sediments and pelagic limestones topped by platform carbonate and siliciclastic sediments. The final fill of this back arc basin is comprised of molassic fill of Reshun Formation. However this paper deals mainly with the massive sulphide mineralization and also touches upon porphyry type mineral shows. Petrology and tectonostratigraphy of the region will be dealt with in a separate publication. Mineral models were worked out for extensive Cu-Pb-Zn-Ag mineralization in Kaldam Gol-Purgar Got area. This volcano-sediment hosted deposit occurs in the Chitral part of the Gawachi back arc basin and holds promise for Ag and Au anomalous zones as well.

Values of 1.0% Cu and Zn and upto 905 ppm Ag and 8.5 ppm Au have been found in samples of mineralized zone from Purgar Gol in Shishi area of Chitral. This zone is an extension of Kaldam Gol massive sulphide mineralization. Cu-Pb-Zn-Ag mineralization from Kaldam Gol and adjoining areas of Drosh in Chitral has been studied in detail for metal values, extent of mineralization and host rock alteration. Substantial anomalies of Au values are also being reported. This mineralization occurs in a sedimentary-volcanic zone associated with the back arc basin. It has all the characteristics of massive sulphide deposits. The genesis of this mineralization has been discussed. Our studies and modelling show that this area holds potential for Au and Ag mineralization as well. This mineralization is likely to be much more extensive than realised so far. These mineral shows have anomalous values of Cu and merit further exploration. Porphyry type Cu mineralization from Kaldam Gol and adjoining areas has also been reported by some workers. A volcano-sedimentary zone in the Reshun formation of Darn area, Shishi valley, Chitral, hosts Cu mineralization. Only a few exposures of this mineralization have been observed so far.

The mineralization in lower Hunza valley and Singal is associated with the Rakaposhi volcanics and the associated metasediments. The peak metamorphism occurred at about 80 ma. This metamorphism is associated with the closure of the back arc basin between Asian plate and the Kohistan island arc. The metallic sulphide mineralized zones have been deformed and metamorphosed during this event. Due to this metamorphism and subsequent alteration, the primary zones of alteration associated with mineralization are difficult to delineate properly. The Normal mineralized zone (Leghari et al. 1986) is again associated with Rakaposhi volcanics and shows anomalous values of Cu, Zn, Pb, Mo and Mn. This is a composite mineralized zone. Here massive sulphide mineralization has been superposed by porphyry type overprint.

The Garesh mineralized zone is pyrite rich and occurs intimately associated with Rakaposhi volcanics. Although this mineralization is of pyrite type yet it shows somewhat anomalous values of Cu, Pb, Zn and Au. The Jutial mineralized zone is in the nature of "massive pyrite deposit" and is associated with neoturbidites of flyschoid origin. The mineralization in the Singal area (Khan et al. 1987) is also intimately associated with the Rakaposhi volcanic complex. The metallic contents are somewhat anomalous with respect to Cu, Zn, Co, Mo, and Fe.

A substantial volcano-sedimentary sulphide mineralized zone of Gawachi back arc basin (1 50m x 300m) is being reported from Mayoona Nala, Ishkuman valley. The extension of this zone is covered by scree and talus. The actual zone of this massive sulphide deposit may be much bigger than the exposed area. The metal values of this zone are being studied. In Drosh area amphibolites of the mélange zone contain disseminated Cu mineralization. These are strongly metamorphosed massive sulphide deposits.

Sulphide mineralization associated with Rakaposhi volcanics as well as associated metasediments has been studied in detail. The modified and reconstituted sulphide alteration zones have been studied and reinterpreted in some detail. On the basis of these studies working mineral models for sulphide mineralization have been established. These mineral models can now be applied for the search and study of other comparable areas. Disseminated copper mineralization "shows" associated with Kohistan arc diorites and associated porphyries have been studied and interpreted in Ashret and Mirkhani areas of Chitral. Mineral models for these deposits have been worked out. The Ashret and Mirkhani mineralization is related to porphyry type mineralization.

C/140. Chaudhry, M.N., Hussain, S.S., Qamar, N.A., Islam, Z., Akhtar, J. & Rehman, S., 1987. Geology and petrology of Barawal-Dir-Bibior area (toposheet No. 38 M/16), Dir District, N.W.F.P., Pakistan. Geological Bulletin, Punjab University 22, 143-153.

A consolidated map of about 250 sq. miles of Dir-Barawal-Bibior area is presented on a scale of 1"=1 mile. Out of this 100 sq. miles has been mapped by the authors for the first time, Geology, petrology and genesis of the igneous, metamorphic and sedimentary rocks of the area has been described. The amphibolites of the area represent an obducted subduction mélange which is a metamorphosed sequence originally composed of a variable admixture of submarine Lavas and an assortment of sediments of calcareous and siliceous marly nature and arc-derived detritus. Quartzites and calcareous schists have been derived mainly from the arc zone.

The quartzites are overlain by slightly metamorphosed marls, calcareous shales and limestone beds and bonds. The calcareous rocks contain Eocene foraminifera. Volcanic horizons containing flows as well as pyroclasts occur interbedded with metasediments. The arc-related acid to intermediate intrusives occur intruding the metamorphic sequence.

Keywords: Mapping, petrography, igneous-sedimentary-metamorphic rocks, Barawal, Dir.

C/141. Chaudhry, M.N., Iqbal, M.A. & Ahsan, N., 1994. Petrology of Lumshiwal Formation from Gulgaah Nala near Chinali Bridge, Abbottabad-Nathiagali Road, Hazara with special reference to Nandpur Gasfield, Punjab Platform. *Pakistan Journal of Hydrocarbon Research* 6, 41-52.

A detailed study of petrology of Lumshiwal Formation of Early Cretaceous age from Gulgaah has been carried out for the first time. The objective was to study the petrography, provenance, environment of deposition and diagenesis of the Formation and to compare it broadly with Nandpur gasfield section of Punjab Platform where it is a gas reservoir.

The section of Lumshiwal Formation from Gulgaah Nala near Chinall Bridge is medium to thick bedded glauconite sandstone with intercalations of shale. This is petrographically divisible into 8 internal units. The unit overlying Chichali Formation is clay and quartz cemented arenite. The other units are mainly quartz, glauconite and carbonate cemented, moderately well to well sorted, sub-mature to mature quartz arenites and shale. The maximum development of glauconite is in the central part. Since glauconite appears to have originated from clay, the glauconite rich arenites might have originally been wackes. Some horizons are selectively cemented with flint. However, intraclasts of quartz grains cemented with flint are also observed towards the top of the Formation.

Accessory tourmaline, zircon, epidote and sphene which may occur either as discrete grains or as inclusions within quartz grains suggest an ultimate derivation from sialic igneous metamorphic basement with minor contribution from basic source. Granitoids were mainly S-type. However, overall mineralogy and texture suggest recycling.

The Lumshiwal Formation indicates low energy conditions in the sub-tidal zone. The formation of glauconite itself reveals slow rates of sedimentation and mildly reducing conditions. diagenetic history indicates the formation of glauconite, secondary quartz, feldspar and flint earlier and ferroan calcite and dolomite at a later stage. Development of stylolites in the carbonate parts and suturing of quartz grains occurred during deep burial. The last stage involves the formation of ferroan dolomite during final uplift with part converting into dedolomite.

Keywords: Sedimentology, Cretaceous, Lumshiwal Formation, Abbottabad.

C/142. Chaudhry, M.N., Jafferri, S.A. & Saleemi B.A., 1974. Geology and petrology of the Malakand granite and its environs. *Geological Bulletin, Punjab University* 10, 43-58.

A detailed geological map on the scale of 3.8" to a mile of about 50 square miles of the area around the Malakand Pass is presented on a reduced scale. Detailed petrology and geology of the Malakand granite and the associated argillaceous, calcareous and arenaceous metamorphic rocks are being presented here for the first time. Five chemical analysis of the Malakand granite, one analysis of the pegmatite vein and one analysis of the Malakand granite gneiss along with their mode and norm are given. The metamorphics range in grade from biotite to garnet grade of the regional metamorphism. Malakand granite has been derived from the Malakand Granite gneiss but has undergone reconstitution and silicification.

Keywords: Petrography, petrology, granite, Malakand.

C/143. Chaudhry, M.N., Kasuri, R.A. & Ahsan, N., 1997. Facies, microfacies, diagenesis and environment of deposition of Lumshiwal Formation at Thub near Ayubia, District Abbottabad. *Pakistan Journal of Hydrocarbon Research* 9, 57-56.

A detailed study facies, microfacies, diagenesis and environment of deposition of Lumshiwal Formation of Early Cretaceous age from Thub Top near Ayubia has been carried out for the first time. The objective was to study the facies, microfacies, provenance, environment of deposition and diagenesis of the formation in the northwestern part of the oil and gas producing Indus Basin. The formation is producing gas at Nandpur and Panjpir located near Sargodha high in the northern part of Punjab platform. This section of Lumshiwal Formation is divisible into 5 facies and 20 microfacies. Compositionally all the sandstone horizons are mature. Texturally only one microfacies is immature and one microfacies is super mature, rest of the microfacies are mature to sub-mature. The sandstone is predominantly fine to very fine grained, only one microfacies is medium grained, and two microfacies are coarse grained.

Quartz and glauconite are the common cements while iron oxides, clay and flint occurs as subordinate cements.

Accessory to trace amounts of tourmaline, zircon, epidote and sphene which may occurs either as discrete grains or as inclusions within quartz grains suggest an ultimate derivation from sialic metamorphic-igneous basement with minor contribution from basic sources. The source granitoids were mainly S-type. However, overall mineralogy and texture strongly suggest recycling.

The Lumshiwal Formation was deposited in low energy conditions in the subtidal zone. The formation of glauconite itself suggests slow rates of sedimentation and mildly reducing conditions. Diagenetic history indicates the formation of glauconite followed by flint and kaolinite. This was followed by ferroan calcite and dolomite at a later stage. Suture of quartz grains occurred during deep burial. Fracturing of quartz grains occurred during tectonic deformation in brittle regime. Microcrystalline quartz developed along fracture cleavage. The last stage involved the formation of ferroan dolomite during final uplift with parts converting into dedolomite.

Key words: Facies, microfacies, diagenesis, Lumshiwal Formation, Abbottabad.

C/144. Chaudhry, M.N., Kausar, A.B. & Lodhi, S.A.K., 1974. Geology of Timurgara-Lal Qila area, Dir District, NWFP, Pakistan. Geological Bulletin, Punjab University 11, 53-73.

One hundred and twenty square miles of the Timurgara-Lal Qila area, a part of Hindu Kush Range, and situated in the middle of Dir Distt. N. W. F. P. was mapped on 4" = 1 mile scale. A map on the reduced scale is presented. The oldest rock of the area is an amphibolite. This has been intruded by a diorite intrusion followed by a noritic intrusion. The amphibolites have formed as a result of the regional metamorphism of basic igneous rocks. The diorite body is composed of diorite, quartz diorite and tonalite. It has formed by the crystallization of a diorite magma of pyroxene andesitic composition. The latter basaltic magma of strong tholeiitic affinities formed the norite intrusion. Differential crystallization of this magma gave rise to peridotites, pyroxenites, norite and gabbro. Petrogenesis of the area is discussed at length and sixty modal analyses of the various types have been presented.

Key words: Maps, amphibolites, petrography, Dir.

C/145. Chaudhry, M.N., Mahmood, A. & Chaudhry, A.G., 1974. The ortho- amphibolites and the para-amphibolites of the Dir District, NWFP, Pakistan. Geological Bulletin, Punjab University 11, 89-96.

Extensive field and laboratory studies have been carried out on the amphibolites of the Dir District. As a result, the Dir amphibolites have been divided into southern Dir amphibolite belt and northern Dir amphibolite belt. As a result of field and laboratory studies and on the basis of textural, mineralogical and field characteristics, the northern Dir amphibolites have been called para-amphibolites, while southern Dir amphibolites have been called ortho-amphibolites.

Key words: Amphibolites, metamorphism, Dir.

C/146. Chaudhry, M.N., Mahmood, A. & Shafiq, M., 1974. Geology of Sahibabad-Bibior area, Dir District, NWFP Geological Bulletin, Punjab University 10, 73-89.

Fifty square miles of Bibior-Sahibabad area, a part of Hindukush Range and situated ten miles south of the town of Dir, was mapped on 3" = 1 miles scale. A map on the reduced scale is presented.

The area is composed of igneous and metamorphic rocks. Igneous rocks include granodiorite and some minor granite intrusions. The metamorphic sequence is represented by calcareous schists and amphibolites. Calcareous schists are the oldest rocks of the area. Study of fossils recovered from a marl band show Eocene age. Amphibolites are formed as a result of regional metamorphism of calcareous pelitic rocks.

Granodiorite is intrusive into amphibolite. It is a massive granitoid of igneous origin. A mixed zone ranging from 100 to 250 yards in width is formed due to interaction of the granitic magma and the amphibolite.

Seventy-two thin sections of various units were studied. Sixteen modal analysis of leuco-amphibolite, twenty-three of the mela-amphibolites, nine of the mixed zone, six of the granodiorite, four of the calcareous schists and two of the minor veins and bodies are presented.

Key words: Maps, granitoids, amphibolites, calcareous schists, Dir.

C/147. Chaudhry, M.N., Mahmood, T., Ahmed, R. & Ghazanfar, M., 1992. A reconnaissance microfacies study of Kawagarh Formation near Giah, Abbottabad-Nathiagali Road, Hazara, Pakistan. *Pakistan Journal of Hydrocarbon Research* 4, 19-32.

The Kawagarh Formation of Upper Cretaceous age from near Giah, Abbottabad-Nathiagali Road, Hazara, has been studied in detail for internal units, microfacies and diagenetic fabrics. A total of eighteen microfacies and five internal units have been defined. The eighteen microfacies is based on depositional textures cum composition from bottom to top are Wackestone (Biomicrite)-Dolomitic limestone, Dolomitic limestone, Wackestone (Biomicrite), Dolospar, Wackestone (Biomicrite)-Dolomitic limestone, Dolospar, Wackestone (Biomicrite)-Dolomitic limestone, Calcitic Dolomite, Wackestone (Biomicrite), Sandy Wackestone (Biomicrite), Sandy Dolomitic limestone and Sandy Dolospar. A total of five facies units have been established which (internal units) from bottom to top are mixed dolomitic limestone and dolospar Unit, Biomicrite Unit, Sandy Biomicrite Unit, Sandy Dolomitic limestone Unit and Sandy Dolospar Unit. The lower three units contain predominantly Late Cretaceous planktonic foraminifer species of Globotruncana and deeper water Algae (Oligosteginids) and are considered to have been deposited in deep water low energy environments (outer shelf close to the edge) while the upper two units which contain rare planktonic foraminifera and are sandy in nature are interpreted to have been deposited in shallower waters (Littoral to inner shelf) with ingress of detrital material. There is evidence to suggest that the dolomitization in the lower two units took place mainly during the deep burial diagenesis which dolomitization in the upper two units owes its origin to ground water mixing during early diagenesis. A study of diagenetic fabrics show that mechanical compaction is unimportant while chemical compaction is wide spread.

C/150. Chaudhry, M.N., Sattar, A. & Mateen, A., 2001. Muscovite bearing peraluminous granites from upper Kaghan valley, NW Himalaya, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 61-62.

Upper Kaghan Valley in NWFP provides a cross-section through the Higher Himalayas of Pakistan. The Higher Himalayas are composed of a lower basement and an upper cover unit. The basement is comprised of granitoids,

turbidites, migmatites with minor marble and pelite-psammities horizon and discordant amphibolites. The cover consists predominantly of garnetiferous calc-pelites, marbles and pelites with extensive amphibolites at the base.

A spectacular feature of the lithologies of Higher Himalayan slab in the Upper Kaghan Valley is the occurrence of granitoids. These granitoids are peraluminous and mainly syenogranites and monzogranites, containing muscovite + biotite + garnet ± apatite + tourmaline and rare opaques.

The peraluminous granitoids are generally subdivided into two main groups; the muscovite bearing peraluminous granitoids (MPGs) and the cordierite bearing peraluminous granitoids (CPGs), which are both anatectic but can be distinguished on the basis of mineral content, texture, rock associations and mode of emplacement. A generalized petrogenetic model for peraluminous granitoids assigns that cordierite bearing peraluminous granites are generated where mantle derived magmas are injected into or have underplated crustal rocks. While muscovite bearing peraluminous granites are produced mainly in orogenic zones affected by major crustal shears or overthrust structures through wet anatexis of crustal rocks and crystal fractionation of the magma.

The granitoids from Higher Himalayas of Upper Kaghan Valley have composition close to the granitic minimum melt. They are mainly leucogranites i.e. felsic granites rich in K-feldspar and sodic plagioclase and little mafic minerals and primary muscovite, so they are categorized as muscovite bearing peraluminous granites.

Key words: Peraluminous granites, petrography, Kaghan valley, Himalaya.

C/152. Chaudhry, M.N. & Shams, F.A., 1983. Petrology of the Shewa porphyries of the Peshawar Plain Alkaline Igneous Province, NW Himalayas, Pakistan. In: Shams, F.A. (Ed.), *Granites of Himalaya, Karakoram and Hindu Kush*. Institute of Geology, Punjab University, Lahore, 171-181.

Chemical analyses and petrography are presented of acid black porphyries and acid grey porphyries, riebeckite porphyrics and riebeckite gneisses belonging to Peshawar Plain alkaline igneous province, north-west Pakistan.

Study shows that the intrusive rocks have developed from an anatectic melt generated at deep crustal level and emplaced along roughly en-echelon weak planes of a zone which suffered intermittent and alternate periods of variable tension and compression. The alkaline rocks had developed during the period of tension whereas acidic rocks had developed during the period of non-tension to compression. This zone was a complimentary centre to the regional belt of strong but variable compression along margin of the Indo-Pak plate in the North. Implications of this study are commented upon for regional application.

Key words: Petrology, Shewa alkaline porphyries, Peshawar Plain Alkaline Igneous Province, Himalaya.

C/153. Chaudhry, M.N. & Shams, F.A., 1984a. The triple amphibolite belt of northwest Himalayas, Karakorum and Hindu Kush, northern Pakistan. Abstracts, First Pakistan Geological Congress, Lahore, p.22.

Three amphibolite belts have been distinguished for the first time from NW Himalayas, Karakoram and Hindu Kush west of the Nanga Parbat-Haramosh loop. They have been named as 'Southern Amphibolite Belt', "Middle Amphibolite Belt" and "Northern Amphibolite Belt" Their structures, textures and mineral compositions are summed up, compared and contrasted. Their geotectonic disposition is also discussed.

It is proposed that the three belts represent obducted blocks of a subduction mélange. The "Southern Amphibolite Belt" represents the obducted mass of the subducted and transformed Tethyan tholeiites formed at the mid-oceanic rises with small amounts of marine sediments. The "Middle Amphibolite Belt" also represents subduction mélange of submarine tholeiites formed at oceanic rise with substantial amounts of marine and arc-derived sediments. This belt is dispositioned south of the outer arc. The "Northern Amphibolite Belt", again is a part of the subduction mélange formed south of the main inner arc This belt represents fairly pure transformed marine tholeiites. All the three amphibolite belts contain mantle derived d exotic blocks of peridotite, harzburgite and eclogite.

Key words: Amphibolite belts, oceanic tholeiites, Himalaya, Karakoram, Hindukush.

C/154. Chaudhry, M.N. & Shams, F.A., 1984b. Geology of northern Indus Kohistan and parts of Chilas District, northern Pakistan. Abstracts, First Pakistan Geological Congress, Lahore, 69-70.

For the first time, a geological map of 600km² of the Northern Indus Kohistan and parts of Chilas District, Northern Areas, is being presented on a scale of 1" = 4 miles.

The rock units mapped and studied from South to North are:-

North Yasin Granite

Amphibolitic Diorite, Diorites and amphibolites

Norite, Noritic Gabbro

Amphibolitic Diorites

The Southern Amphibolite Belt

Volcano-sedimentary zone

South Salkhala

The above units have been studied petrographically as well as chemically. The petrography and chemistry are described and discussed in the light of field relations and petrotectonic dispositions.

The Salkhalas represent elements of the Indo-Pak shield edge. The sedimentary - volcanic zone may represent a remnant arc, the amphibolites and norite represent oceanic lithosphere, the diorites and amphibolitic diorites represent subduction related partial melting products of oceanic crust at intermediate depth and under hydrous conditions. The Yasin granite is a typical anatectic rock containing xenolithic elements of greenstone. This is very young and postdates subduction and obduction episodes as of independent origin.

A number of workers have proposed different positions for the Main Central Thrust in the northwest Himalaya of Pakistan. These positions have varied from considering the Panjal Thrust, the Oghi Shear Zone and even the Raikot Fault, as well as many other intervening locations in the area between the Main Mantle Thrust in the north and the Main Boundary Thrust in the south, as the Main Central Thrust. All these positions are enumerated and critically appraised in their context of the geology of the area. They are subsequently evaluated to see whether, they follow the tectonic requirements of the Main Central Thrust as a Boundary Thrust that marks the contact between the Higher and Lesser Himalaya. It is subsequently argued that, except for the Batal Fault near Naran (in Upper Kaghan Valley) Luat Fault (in Neelum Valley) and the tectonic lineament near Malakand (in Lower Swat), no other position fulfils the required criteria specified for the definition of Main Central Thrust. These most likely positions of the Main Central Thrust, according to this review, were only located after extensive geological mapping of the terranes in Neelum and Kaghan Valleys and in the area of Besham and lower Swat.

This paper discussed the tectonic significance of the Permian Panjal Volcanics of Kaghan Valley on the basis of an over view of geology, field characteristics, associated rocks and plots of major and trace elements. On the basis of these studies it is proposed that the 400 km long Panjal rift developed into an ensialic marine basin with a thinned continental crust which in Kaghan further developed into an incipient ocean in Permian. This ocean closed in Late Permian followed by the deposition of unmetamorphosed oolitic Malkandi limestone of Triassic age.

Key words: Tectonics, continental rifting, geochemistry, Panjal volcanics.

C/158. Chaudhry, M.N., Walsh, J.N., Khan, M.S. & Ghazanfar, M., 1995. Petrology and geochemistry of the Panjal volcanics of the Northwest Himalaya in Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

Geological and geochemical (major, minor and trace elements including rare earth elements) data for the Panjal volcanics of the NW Himalaya are presented. These data show that the Panjal volcanics are mainly tholeiitic basalts. The rocks are moderately enriched in trace elements and the light REE elements relative to N-type MORB. These basalts are characterized by Zr/Y 1.7 to 3.92, Zr/Nb 2.6 to 33, Ti/Y 266 to 400 ratios and LREE enrichment [(La/Yb)_N = 3.29 to 11.16, (La/Sm)_N = 1.96 to 4.09, (Sm/Yb)_N = 1.68 to 3]. These characteristics suggest derivation of magma from an enriched mantle source, probably a mantle plume. The lavas exhibit from within plate to P-type mid ocean ridge trace element characteristics with minor crustal contamination.

Trace elements and REE element data indicate that the lavas were derived by partial melting of garnet lherzolite followed by fractionation of olivine and pyroxene. The geological and geochemical data suggest that the Panjal volcanics in the Kaghan area developed in a progressively evolving rift initially within an ensiatic environment and finally reaching the stage of a PMORB type crust.

C/159. Chaudhry, M.N. & Zaka, K.J., 1994. Terbela Dam: A discussion on the discrepancy between the laboratory testing and inservice behaviour of Indus aggregate in cement concrete. Dam Engineering 5, 63-80.

This paper discusses the problem of alkali aggregate reaction (AAR) developed in the Tarbela Dam, which was built in 1976 on River Indus in North-West Frontier Province of Pakistan. In Tarbela Dam natural sand and gravels from the riverbed were used after proper testing by petrographic, chemical and mortar bar methods (TAMS report, WAPDA 1965). After testing, aggregates were considered non-deleterious and were used with ordinary Portland cement having alkali level ranging from 0.9% to 1.03% (Table IX). These aggregates contain large amounts of slightly metamorphosed acid to intermediate volcanics, argillites and greywacks.

Although these aggregates contain large quantities of potentially deleterious rock types yet they were presumably regarded safe either because their parent rocks had undergone metamorphism or on the grounds that they had large quantities of mildly reactive rock type and therefore, would not develop deleterious reaction. The inference drawn from petrographic studies was further strengthened by the quick chemical tests carried out in accordance with ASTM C289 and mortar bar tests carried out in accordance with ASTM C227 which did not predict AAR potential of Indus aggregates at Tarbela.

Three years after the completion of Tarbela Dam only one incidence of AAR was reported. However, it was only after twelve years of completion that AAR was confirmed at a number of places. Therefore the need for alternative or modified chemical mortar bar test is stressed. Petrographic examination can however, prove most useful for quickly predicting AAR in Indus River aggregates like the ones used in Tarbela and similar aggregates which contain deleterious metamorphosed rocks like greywacks, acid to intermediate mesocrystalline volcanics and argillites.

Key words: Tarbela dam, Indus aggregates.

C/160. Chaudhry, M.N. & Zaka, K.J., 1998. Petrographic evaluation of alkali aggregate reaction concrete structures of Warsak Dam, NWFP Pakistan-A case study. 8th International IAEG Congress Vancouver/ Canada, 2841-2846.

This paper presents a case study of Alkali Aggregate Reaction (AAR) in concrete structures of Warsak Dam. The dam has suffered deterioration due to AAR and had undergone extensive repairs during 1985-86. The fractures in the concrete structures are of two types. The first type of fractures is random and may not be directly related to deleterious reaction. The second type of fractures shows distinct pattern resembling map cracks. AAR and gel formation were positively identified and confirmed. This paper is based on Petrographic, chemical and X Ray Diffraction (XRD) studies of cores and sample of AAR affected parts of the dam carried out since the confirmation of AAR. Microfractured and strained quartzite, phyllite/slate, metagreywacke partially reconstituted microcrystalline acid to intermediate meta-volcanics and jasper/cherts are directly affected by deleterious reaction.

C/163. Chaudhry, R.S., 1987. Petrogenesis of Cenozoic sediments of Northwestern Himalayas. *Geological Magazine*, 108, 43-48.

Cenozoic rocks of north-western Himalayas (excluding the sub-Recent, Recent and Karewa deposits) are represented by the Subathu, Dagshai, Kasauli and Siwalik rocks, which together have a thickness of over 10,000 m and range in age from Upper Palaeocene to Middle Pleistocene. From field and laboratory investigations it is propounded that these sediments, except the Middle and Upper Siwalik, have been derived from low and medium grade metamorphic rocks, acid plutonics and sedimentary rocks of the nearby Himalayan terrains. For the Middle and Upper Siwalik rocks, detritus was supplied by sedimentary and trap rocks as well as by the underlying medium and high grade metamorphic and plutonic rocks. A major part of these sediments has been derived from the rising Himalayas rather than from the Peninsular Shield as believed hitherto. The Subathu rocks were deposited in shallow to moderately deep marine environments; the Dagshai rocks under shallow freshwater conditions; and the Kasauli and Siwalik rocks in a shallow fast-sinking basin. All these sediments accumulated under conditions of rapid erosion, short transportation and rapid deposition.

C/165. Cheema, A.Q., 1999-2000. Structure, stratigraphy, petrography, micropaleontology and petroleum geology of Kotli-Tattapani area, District Kotli, Azad Jammu and Kashmir (Pakistan). M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 217p.

The Himalayan mountain belt is the result of Tertiary collision between the Indian and Eurasian plates. The kotli-Tattapani area of the Kashmir foreland fold-and-thrust belt is the part of the Sub-Himalaya of Pakistan. A sequence of Cambrian to Cenozoic rocks is folded and imbricated along the northeastern margin of the Indian plate.

In Cambrian time, the calcareous to arenaceous facies of Muzaffarabad formation are deposited under shelf to outer shelf environment. The Muzaffarabad formation is unconformably overlain by the Paleocene Hangu Formation. The Hangu Formation is deposited under tropical to subtropical environments. The absence of Ordovician to Cretaceous rocks in the area is the result of non-deposition due to pre-Eocene Himalayan uplift. Subsequently, after the deposition of the Hangu Formation, the Early Eocene Tattapani Formation is deposited under shallow marine environment. This marks the Early Eocene transgression of the Neotethys ocean.

In Middle to Late Eocene the variegated shales of the Kuldana Formation are deposited in open marine, lagoonal and fluvial environments. The Kuldana Formation marks the transition from marine to continental environment. This shows the closing of the Neotethys ocean and the initiation of deposition of the Himalayan molasses in the Kashmir foreland basin.

In Oligocene to Miocene, the hinterland in the northeast was uplifted and the low to medium grade basement and cover rocks were exposed to the weathering and erosion. The detritus derived from the orogen was deposited as molasse of the Murree and Nagri Formations in the Kashmir foreland basin.

The Cambrian to Cenozoic rocks show at least three phases of deformation. These deformational phases are D1, D2 and D3. D1 deformational phase is the major event in the area and can be divided into D1a and D1b. The D1a is marked by the F1 southwest-vergent folds and northwest-directed thrusts. The F1 folds and D1a thrusts are northwest-southeast trending. The D1b is marked by northeast-directed backthrust and backsteepening of axial planes of F1 folds. The D2 deformation is related to the F2 cross-folding of northwest-southeast trending outcrops and fold axes of F1 folds. The F2 cross-folds are the result of counter clockwise rotation of Indian plate. F2 folds are associated with the development of the Hazara-Kashmir syntaxis. The D3 deformation is related to the northeast-southwest late Himalayan extension. This deformational phase caused the north-northwest trending normal faults, horst and graben structures.

C/166. Cheema, I.U., 1990. Late Astaracian small mammals of the Chinji Formation of Ghok Thalian, Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, p. 41.

A small mammal assemblage of a middle Chinji Formation locality PMNH 8608 contains at least fourteen species of ten rodent and insectivore families including a single specimen of chirpotera. Cricetids are represented by three species, which resemble those from the Banda Daud Shah assemblage. *Antemus chinjiensis* is the only murid recognised but included in them are the three molars of relatively larger dimensions having extra cusps (styles) which have not been noted earlier as yet. *Prokanisamys benjavuni* and *Kanismys indicus* constitute the typical middle Miocene rhycomyid site in the Siwalik sequence. Comparison with other Chinji Formation fauna indicate that this high species diversity is normal and presents a stable species composition during most of the Middle Miocene. Murid species appear to have the shortest life-span and hence their chronological successive species are used for precise faunal dating. The PMNH 8608 locality is assigned a late Astaracian age and closely resembles the Daud Khel local fauna assemblage.

C/170. Cheema, M.R., 1968b. Biostratigraphy of Changla Gali area, District Hazara, West Pakistan. M.Sc. Thesis, Punjab University, Lahore.

Biostratigraphical study of the Khanaspur Mandri area has been done. A geological map on the scale 8" -1 mile is prepared. A new time -rock unit, the Nummulitic Shales representing the youngest lithostratigraphic unit is identified and mapped. The lithologies and environments of deposition of each formation are discussed. Their ages are reviewed in the light of new faunal evidences, if any, and regional correlations are suggested.

A systematic and detailed sampling of U. Cretaceous to Middle Eocene strata was done to investigate foraminiferal assemblages of different stratigraphic units, fauna species and many genera are identified. All the species are described but only very few genera are dealt with. Three species, *Assilina mukshpuriensis* nov., *Assilina depressa* nov., and *Lokhartia smouti* nov., and a variety *Lokhartia altispira* var *conica* nov. are erected new.

Cretaceous -Tertiary boundary and Palaeocene -Eocene, boundary is placed on faunal evidence. Palaeoecologic conditions are inferred for Cretaceous and Lower Tertiary times as depicted by the faunal assemblages.

C/171. Cheema, M.R., 1970. Sedimentology of Miranjani algal limestone member, Nathiagali. *Geological Bulletin*, University of Peshawar 5, 57-61.

Microscopic sedimentological study of the Miranjani Algal Limestone Member of the Hazara Formation (Hazara Slates) of Nathiagali area, District Hazara, is made, following the petrographic classification of limestones of Folk (1959).

Varied association of all three basic constituents of limestones allochems, microcrystalline calcite and sparry calcite is met with indication a diversity of physiochemical conditions. Mega and microscopic sedimentary structures and composition are used to inter environment of deposition for every thin section and for the unit, as a whole. Systematic of algal material is not dealt with except for identifying it as "Green Stomatolytic Algae". Ostracodes were met within a thin section which, however, could not be identified.

C/172. Cheema, M.R. & Alam, G.S., 1990. Pyrite deposits of Naz Bar area, Yasin valley, Gilgit District, Northern Area, Pakistan. *Geological Survey of Pakistan, Information Release* 333.

Pyrite deposits are located in the Yalter Bar Multan Bulang Bar area of Naz Bar at a distance of about 23 miles from Yasin village, Gilgit Agency. The deposits are in the form of 3 lenses and 12 pockets, exposed at 5 locations at high elevation ranging from 13,500 feet to 16,000 feet A.S.L.

The pyrite is hydrothermal in origin and is developed within the quartzites and phyllites of the Permo-Carboniferous Darkot group. Geological reserves are estimated at 1.7 lakh tons. Out of these, 1.54 lakh tons are present in one lense (Location A) with average sulphur and iron content of 30 and 45 percent, respectively. Pyrite also contains copper from 0.476 to 0.834% and cobalt from 0.061 to 0.976 per cent .

Key words: Pyrite, Yasin valley, Gilgit.

C/176. Chilasi, E.U., 1999-2000. Geological mapping of Muzaffarabad-Chattar Kalas area with special emphasis on slope instability analysis and hazards evolution of Abhal area, Muzaffarabad (A.K.). M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 117p.

About 100 sq. Km area including the landslided parts was mapped to find out the possible solution of this hazard. The study was carried out to understand the landslide problems in the area. The Abhal landslide was studied in detail based on its large size and proximity to foot-tracks, residential buildings and land property. Presence of MBT, heavy rain fall, toe-cutting by river Jhelum, steep slopes and water seepages contribute to landsliding in the area. The principal types of failure in the area have been recognized as slumps, earth flows, rock fall or combination of these three types. Soil samples were collected from the slided areas to evaluate the engineering properties of soil that contribute the failure. It includes Atterberg limits, natural water content, specific gravity, plasticity character, compaction and swelling. To establish the causes of landslides all the information and field data were collected. The results suggested that the failure occur due to high swelling potential of soils, steep slopes and presence of active fault (MBT).

C/177. Chishti, H.M. & Ahmad, N., 2000. Characterization of pyrolysis derived hydrotreated shale oil from a Pakistani oil shale. Abstracts, Third South Asia Geological Congress, Lahore, p.124

Hydrotreatment has received increasing attention in upgrading shale oil. The aim of this work was to elucidate the compositional changes after hydrotreatment of Salt Range shale oil. Pyrolysis derived raw shale oil from Salt Range oil shale was hydrotreated in stirred reactor with a cobaltmolybdenum (CD-Mo) catalyst at 395 °C and 15 Mpa of hydrogen pressure for 12 hours. The pyrolysis and hydrotreated oils were analysed for elemental analysis, liquid chromatography fractionation, size exclusion chromatography and gas liquid chromatography/mass spectrometry. Distribution of nitrogen and sulphur compounds in raw pyrolysis and hydrotreated upgraded oils was determined. Hydrodenitrogenation of nitrogen containing compounds occurred concurrently with the hydrogenation of non-nitrogen containing aromatic hydrocarbons. In particular the pyrolysis and catalysis oils were analysed for polycyclic aromatic hydrocarbon (PAH) compounds and for nitrogen containing PAH (PANH) and Sulphur containing PAH (PASH). Analysis of the product oils showed that three and four ring higher molecular weight compounds decreased in concentration. Removal of nitrogen and sulphur proceeded successively with time which resulted in corresponding reduction in the concentration of nitrogen and sulphur containing PAR.

Key words: Pyrolysis, oil shale, hydrocarbon.

C/178. Chishti, H.M., Ahmad, N. & Rashid, S., 2000. Influence of final pyrolysis temperature on pyrolysis of Kark oil shale from Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, 124-125.

The final pyrolysis temperature has received special interest in the fixed bed pyrolysis of oil shale. Kark oil shale from Pakistan was retorted in a bench scale static bed reactor at various pyrolysis temperatures. The pyrolysis oils were collected in a series of cold traps. Gases evolved were analysed off-line by packed colour gas chromatography. The composition of oils and gases were determined in relation to the various final pyrolysis temperatures. Oils were analysed by a number of techniques for determining composition including liquid chromatography, gas chromatography/mass spectrometry size exclusion chromatography, chemical class fractionation and elemental analysis. Products of pyrolysis were liquid condensate, non-condensable gases and solid residue (spent shale). The yield of oil was maximised at 520°C. Both the hydrocarbon and non-hydrocarbon gases increased with increase in final pyrolysis temperature. A consistent decrease in spent shale was observed with increase in pyrolysis temperature. Hydrogen to carbon ratio (H/C) and the aromatic content the product oils was found to respectively decrease and increase with increase in final pyrolysis temperature.

Key words: Pyrolysis, oil shale, Kark.

C/179. Chishti, M.N.A., 1977-79. Lithostructural Mapping and Geology of Baragali-Bagnoter Area, Abbottabad District, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 169p.

Approximately 20 miles² of Baragali-Bagnoter area in the form of a strip on both sides of Nathiagali-Abbottabad road has been mapped at the scale 1:10,000. It is a mountainous humid region with fairly high relief. The stratigraphic sequence ranges from Precambrian Hazara slates to the Kuldana Formation of Middle Eocene. The structure of the area is in the form of a major synclinorium, which is interrupted and deformed by high angle thrust faults dipping southeast near the surface. Over 50 thin sections were studied under the microscope and a detailed petrography and petrogenesis are included.

Key words: Stratigraphy, structure, lithology, petrography, Abbottabad.

C/181. Chroston, P.N. & Simmons, G., 1989. Seismic velocities from Kohistan volcanic arc, Northern Pakistan. Journal of the Geological Society, London 146, 971-979.

The rocks bounded by the Main Mantle Thrust and the Northern Suture in northern Pakistan constitute an exhumed section through a Cretaceous volcanic arc. Samples have been collected from all the principal lithological groups of the arc, and P and S-wave seismic velocities have been measured in the laboratory with the prime objective of comparing the velocities with those determined by seismic refraction experiments on modern volcanic arcs. Velocities were measured at up to 0.7 GPa and consideration has been given to the effect of confining pressure, pore pressure and temperature and to the deformation and metamorphism involved in the Himalayan collision.

The reconstructed velocity section through the arc shows a distinct 'upper crust' comprising granitic-dioritic intrusions, metasediments and volcanics with a P-wave velocity of 6.2–6.4 km S⁻¹ depending on the parameters used. Beneath, the 'lower crust' of amphibolites and pyroxene granulite has a velocity mainly about 6.4–6.7 km s⁻¹, though the garnet granulites extend to 7.8 km S⁻¹. The more mature arc with a higher proportion of granitic rocks would show a slightly lower upper crustal velocity than the younger arc. Velocity inversions might be expected with a thermal gradient of as little as 10–15 °C km⁻¹, depending on the pore pressure. In general, the proposed velocity structure is comparable with that of volcanic arcs and with many other sections of the continental crust.

C/182. Chuhan, F.A., Chaudhry, M.N. & Ghazanfar, M., 1992. Microfacies, diagenesis and environment of deposition of Datta Formation from Jaster Gali, District Abbottabad, Hazara, Pakistan. *Geological Bulletin, Punjab University* 27, 47-62.

Datta Formation shows marked vertical variation in the environment of deposition from continental, subtidal, intertidal to supratidal. However, in the Galiat area this formation is predominantly marine as opposed to dominantly continental facies of Salt Range. The petrographical/sedimentological study of this formation shows the following lithologic units. Fine grained quartz and clay cemented ferruginous sublithic arenite with streaks and layers of grit; alternating bands of medium grained intraclast bearing oolitic-pelletoidal limestone intercalated with nodular marl; fine grained quartz cemented quartz arenite intercalated with shale; fine to medium grained quartz cemented quartz arenite ; nodular marl ; limestone (sparse biomicrite, - wackestone); coarse to medium grained oolitic, carbonate cemented quartz arenite with streaks and layers of grit. Recycled clastic component is dominant. Tourmaline, zircon, epidote and sphene indicate an ultimate derivation from an igneous, metamorphic sialic basement with _subordinate basic/metabasic component, the granitic component was predominantly S-type. The diagenetic events show that kaolinite cement is early as well as formed at final stage. The early "diagenetic kaolinite cement was partially transformed to illite at a depth of at least 3500-4000m whereas quartz and non-ferroan carbonate cements were formed after the early diagenetic kaolinite. The non-ferman carbonate cement was transformed to ferroan carbonate cement. A part of ferroan dolomite, so formed, was probably dedolomitized at the final stage.

The Kuldana Formation is a sand-poor redbed complex that prograded into the Persian Gulf-like Kohat depositional basin of northern Pakistan at the end of an early Eocene marine regression. It was formed by a poorly developed system of small, episodic, briefly active, shallowly incised and readily abandoned streams that wandered into a very flat, aggrading, semi-arid basin. Their deposits are about 95% red mud and 5% predominantly trough-bedded and fining-upward channel sand. The streams did not meander, however, because avulsion was too frequent. During low flow they became braided but their bedforms underwent little alteration. Partly because of the basin's flatness, the only available coarse clastics in eastern areas were calcareous soil nodules and, locally, fish and mammal bone fragments. The primary determinants of this stream system seem to have been a below-grade basin floor and a semi-arid climate.

C/195. Contin, G., Lombardo, B., Petrini, R., Rolfo, F., Antonini, P., Vison, D. & Le Fort, P., 1998. Geochemistry of metabasaltic and metadoleritic garnet granulites from the NE Nanga Parbat-Haramosh Massif, Northern Pakistan. Preliminary results. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop. Abstract Volume, 45-47.

In the NE Nanga Parbat-Haramosh Massif (NPHM) of the NW Himalayan syntaxis (Stak and upper Turmik valleys, Susrut Nala) metabasaltic and metadoleritic dykes of garnet granulite intrude garnet-kyanite-biotite-muscovite para- and orthogneisses of the Higher Himalayan basement complex. Compositionally the garnet granulites are tholeiitic to mildly alkaline basalts and (rarely) picritic basalt and picrite. In a Ti-Zr-Y diagram most of the samples plot in the field of within-plate basalts as defined by whereas the metapicrites and a few metabasalts lie in the compositional field of ocean floor basalts because of their higher contents of Y.

Significant variations of major and trace element contents occur between the metapicrites (mg# 0.75-0.67) and the most evolved metabasalt, an alkali metabasalt from the Subsar area of the Indus valley (mg# 0.27), which still has the pristine igneous plagioclase and titaniferous ferroaugite. Harker diagrams show a good agreement in trends of major and trace elements plotted against an index of magma evolution such as MgO and the less mobile element Zr. A positive correlation exists between Zr and P₂O₅, K₂O, TiO₂, Ba and Rb whereas Ni and Cr are negatively correlated with Zr. SiO₂, Na₂O, Al₂O₃, Y and Sr show more scattered trends relative to Zr. Such trends, particularly the enrichment in incompatible elements, and major elements variations are explained by polybaric fractional crystallization of olivine, clinopyroxene and plagioclase at low pressures and low amounts of water.

MORB-normalized spidergrams show subparallel trends of enrichment up to 100x MORB values and variable depletion of Ni and Cr from the metapicrite to the alkali metabasalt. The observed enrichment is consistent with the effects of the fractional crystallization mentioned above. A negative Sr anomaly is observed for all samples with the exception of the metapicrites. The Sr anomaly is larger for the alkaline metabasalt and it might be explained as the effect of plagioclase fractionation. REE data for one metapicrite and three metabasalts indicate a positive Eu anomaly (Eu/Eu* = 3D1.15) and LREE enrichment for the metapicrite, whereas the metabasalts appear more REE-enriched with higher LREE/HREE ratios. The positive Eu anomaly decreases with the increase of the REE content. These features may result from fractional crystallization after removal of mafic phases in an earlier magmatic stage or by presence of inherited cumulus plagioclase previously equilibrated with a magma in conditions of very low oxygen fugacity. However, the range observed in contents of REE and other trace elements (for example Rb and Nb) cannot be completely accounted for by a simple mechanism of fractional crystallization starting from a parental magma of composition similar to the less evolved metabasalts. Open-system magmatic fractionation or element mobility during metamorphism is therefore invoked for these cases. Further isotopic studies could better identify the dominant mechanism of differentiation and the possible role of crustal contamination. The NPHM metabasic dykes are geochemically similar to the Lower Carboniferous Baralacha La Dyke Swarm of SE Zaskar, Upper Lahul and NW Spiti [5] and to the amphibolite-facies metabasaltic dykes of the Higher Himalayan basement of the Western Syntaxis area [6]. On the other hand, different trends of Ba, Rb and Y during fractionation and the different contents of TiO₂ and P₂O₅ suggest a different magmatic evolution of the NPHM metabasic dykes relative to the Middle Permian Panjal Traps basalts of SE Zaskar, Upper Lahul and NW Spiti studied by.

C/197. Cornwell, K., 1998. Quaternary break-out flood sediments in the Peshawar basin of northern Pakistan. Geomorphology 25, 225-248.

The presence of horizontally bedded, fining upward sequences of sands, silts, and clays throughout the Peshawar basin of northern Pakistan has previously been ascribed to Pleistocene lakes within the basin. Close inspection of these sediments, however, show sedimentological properties that suggest these stacked sequences are more characteristic of deposits of periodic break-out flood deposits and not lacustrine deposits. Exposures near the villages of Piran, Nowshera, Jehingira, Jalala and along the Kabul River show evidence of subaerial exposure (mudcracks and bioturbation zones), lateral continuity and fracture sets. At least three distinct cycles of deposition are apparent in the basin, each exhibiting slightly different structural and sedimentological properties. The groupings and dimensions of the rhythmite sequences indicate that within each cycle multiple episodes of flooding occurred. The absence of significant erosional and depositional features, as well as the preservation of mud rip-up clasts and bioturbation zones further suggests that the periods between episodes of flooding were probably on the order of 101 to 102 years. Evidence of ice-dams and lakes in the Indus drainage system is abundant. Cross-valley moraines and lacustrine deposits that stretch many kilometers upstream are visible in the middle Indus valley between the villages of Sazin and Shatial and Skardu. Calculated ratios of sediment to water suggest that an upstream reservoir at least 32 km³ and perhaps as large as 128 km³ would have been required to produce the extent of rhythmites observed in the Peshawar basin. Generating a reservoir of this size in the Indus drainage system was accomplished near the villages of Sazin–Shatial where large cross-valley moraines and upstream lacustrine sediments indicate large ice-dams as do the moraines and lacustrine sediments near Gilgit and Skardu. The origin of the graded sediments in the Peshawar basin, however, has not been correlated to the failure of a specific ice-dam. The temporal relationship of the graded sediments is unclear. Limited thermoluminescence (TL) analysis of the youngest set of graded sediments (referred to as 'lake beds' by previous investigators) in the Peshawar basin suggest an age of at least 130,000 years BP. This time correlates to the Yunz stage of glaciation along the middle Indus valley which spans from the mid to late Pleistocene to about 130,000 years BP.

C/198. Cornwell, K. & Hamidullah, S., 1992. Geomorphic evidence of catastrophic flooding along the middle Indus valley. *Geological Bulletin University of Peshawar* 25, 113-121.

Catastrophic floods have inundated the middle Indus River valley throughout the late Quaternary. These floods have produced very distinct geomorphic signatures within the valley such as boulder beds, plunge pools, and chutes. These features have been mapped and measured to develop estimates of flood hydraulic parameters. The bedrock nature of the Indus valley along this stretch constrains floodwater from lateral migration or significant down cutting within the channel. This constraint results in increased flow velocity and greater flood power.

Keywords: Floods, geomorphology, Quaternary, Indus valley.

C/201. Cotter, G, de P., 1929. The erratics of the Punjab. *Records, Geological Survey of India*, 61 (4), 327-336.

Cotter gave a list of the blocks near Campbellpur, Jand and Pindi Gheb, resting on alluvium deposits (sand, silt, clay with beds of coarse gravel), or directly on Siwaliks or Mesozoic limestone. He described near Jassian a deposit of "morainic kind" formed by blocks of various lithology that emerge from a "mixture of sand and gravel". The author thought that the erratics were deposited due to some catastrophic event (glacial outburst of water or of mud-

avalanche). In proof he mentions the events of December 1840 and January 1841, when a natural dam formed by landslide near Gor, south of Bunji, collapsed, causing exceptional flooding of the Indus and the river was described as “an absolute wall of mud”.

C/209. Coulson, A.L., 1937b. Pleistocene glaciation in North Western India, with special reference to the erratics of the Punjab. North West Frontier Province. Geological Survey of India, Record 72, part 4, 422-439.

This is an account of the extent of Pleistocene glaciation in NW India, and in particular of the erratic rock blocks in the sandy plain of Punjab. He does not agree with the explanation given by Cotter (1929) for the origin of the erratics. He argues that owing to the aerial distribution of the erratics the alleged catastrophic flood should have advanced not along the present course of the Indus through the gorge of Attock, but along the Indobrahm, the paleoriver considered responsible for the sedimentation of the local succession of Siwaliks. He says that this ancient river followed the course of the present Soan, south of the Kala Chitta Range. However Coulson tends to consider the possibility of the erratics being moved by icebergs breaking off the snout of glaciers and then carried by water flowing into a large lake before the last tectonic events created the present fluvial system.

C/213. Coward, M.P., 1985. A section through the Nanga Parbat syntaxis, Indus valley, Kohistan. Geological Bulletin, University of Peshawar 18, 147-152.

The Nanga Parbat gneisses show polyphase Himalayan age deformation, the last major phase being the development of large upright folds which form the syntaxial structure. These folds are related to a different kinematic system to the main thrust systems of Pakistan and probably formed due to localized high strain near the pinning point of the Himalayan thrusts at the western end of the Himalayan arc.

Key Words: Deformation, structure, Nanga Parbat, Himalaya.

C/214. Coward, M.P., 1985. Aspects of Kohistan tectonics. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

The Himalayas are generally considered in terms of India/Asia (or Tibet) collision, the thrusts developing in a piggy bank sequence on to the foreland. The structure of Kohistan shows that this is only a small part of the story. Much of the deformation in the Kohistan arc relates to early (80-100 my) compression and southward directed overthrusting, post-dating Cretaceous collision of the arc with "Asia" and occurring while India lay some several thousand kilometers to the south. Following the collision with India there was considerable further deformation, rethrusting

the Asia Plate back over Kohistan, imbricating late to post-Cretaceous sediments and accounting for some of the necessary shortening of the Asia-Tibet plate, north of the suture. This shortening must have occurred in a break-back position relative to the main Himalayan thrusting.

Key Words: Tectonics, collision, India-Asia, Kohistan, Himalaya.

C/215. Coward, M.P., 1987. The evolution of mountain belts: structure of the Himalayas and Tibet. *Science Progress*, Oxford. 71. 249-273.

Mountain belts form by isostatic uplift, related to a decrease in density of the local lithospheric column. This may develop from (a) localized heating of the mantle, (b) by the addition of new low density material within or below the crust, but (c) more generally it develops from crustal thickening related to continental collision. Early views on mountain belts assumed homogeneous thickening processes, but we now know that horizontal or low-angle displacements play a larger part. Collision involves the subduction of oceanic crust and the eventual underthrusting of one crustal segment beneath that of another plate. The structures developed depend on the strength of the underplating crust, that is, on the original geothermal gradient, rock type and time since underthrusting commenced. For a thrust to have a large displacement, it needs to overcome the resistance to shearing. It builds up a thrust wedge, whose critical taper depends on the basal shear strength. As erosion removes material, the wedge shape is modified by thickening, or by the accretion of new material from beneath and many of the small to medium scale structures in mountain belts are related to this process. The most dramatic mountain belt is that of the Alps-Himalayas, formed as India collided with Asia at about 55 my ago, this time being fairly accurately constrained by the syn-tectonic sediments as well as the history of the Indian ocean. Structural sections through the faulted sedimentary cover to the Indian plate indicate a minimum of 470 km displacement. Thrust rates can be measured by dating syn- to post-tectonic sediments from the front of the thrust wedge, giving about 1 cm/year. From a study of the Indian ocean floor, however, we know that India has moved into Asia some 2500 km, at a rate of about 5 cm/year for the past 50 my. Some of this extra displacement may be taken up by major crustal thickening in Tibet, where the crust doubled in thickness between about 50 and 20 my ago. The remainder must be taken up further north, in central Asia, or by the lateral expulsion of parts of Tibet and adjacent China, along major faults, such as that marking the Kun Lun mountains in northern Tibet. To solve the deep structure of mountains such as the Himalayas, or high plateau such as Tibet, we need new techniques, such as the deep seismic reflection profiling. Such work will be expensive, but it is only when we understand the deep structure and its relationship to what we see at the surface, that we will be able to fully model the kinematics and mechanics of crustal movements.

Keywords: Orogeny, tectonics, Himalaya.

C/216. Coward, M.P. & Butler, R.W.H., 1985. Thrust tectonics and the deep structure of the Pakistan Himalaya. *Geology* 13(6), 417-420.

The systematic restoration of thrust systems provides a powerful constraint on the deep structure of orogenic belts. A balanced cross section, through the imbricated upper crust of the Indian plate in the footwall to the Main Mantle thrust of the western Himalaya, restores to a minimum width of 730 km, the implicit shortening being in excess of 470 km. This requires the Himalaya and southern Tibetan region to be underlain by a wedge of Indian crust. However, a full appraisal of gross crustal structure awaits deep seismic control.

C/217. Coward, M.P., Butler, R.W.H., Chambers, A.F., Graham, R.H., Izatt, C.N., Khan, M.A., Knipe, R.J., Prior, D.J., Treloar, P.J., Williams, M.P. & Barnicoat, A., 1988. Folding and imbrication of the Indian crust during Himalayan collision. *Philosophical Transactions of the Royal Society of London A326*, 89-116.

India collided with a northern Kohistan--Asian Plate at about 50 Ma ago, the time of ocean closure being fairly accurately defined from syntectonic sediments as well as the effect on magnetic stripes on the Indian Ocean floor. Since collision, Asia has over-ridden India, developing a wide range of thrust scrapings at the top of the Indian Plate. Sections through the imbricated sedimentary cover suggest a minimum displacement of over 500 km during Eocene to recent plate convergence. This requires the Kohistan region to the north to be underlain by underthrust

middle to lower Indian crust, deformed by ductile shears and recumbent folds. These structures are well seen in the gneisses immediately south of the suture, where they are uplifted in the Indus and Nanga Parbat syntaxes. Here there are several phases of thrust-related small-scale folding and the development of a large folded thrust stack involving basement rocks, the imbrication of metamorphic zones and the local development of large backfolds. Some of the important local structures: the large late backfolds, the Salt Ranges and the Peshawar Basin, can all be related to the necessary changes in thrust wedge shape as it climbs through the crust and the three dimensional nature of the thrust movements associated with interference between the Kohistan and western Himalayan trends.

C/218. Coward, M.P., Butler, R.W.H., Khan, M.A. & Knipe, R.J., 1987. The tectonic history of Kohistan and its implications for Himalayan structure. *Journal of the Geological Society, London* 144, 377-391.

The tectonic history of Kohistan, northern Pakistan, involves two collisional events. Cleavage and folding developed at 90-100 Ma along the northern suture between the Kohistan island arc and the Asian plate. At the same time there was major folding and shearing of the lower part of the Kohistan arc, approximately 100 km south of the suture. This deformation was followed by ocean subduction south of the Kohistan arc, generating the Kohistan calc-alkaline batholith, with subsequent ocean closure during the Eocene and obduction of the Kohistan arc, together with the adjacent part of the Asian plate, over the Indian continental crust. The construction of balanced cross-sections through the imbricated upper part of the Indian continental crust, in the footwall to this southern suture indicates a minimum displacement of 470 km, requiring the western Himalayan hinterland to be underlain by a large wedge of Indian middle to lower crust. There is some shortening of the overriding Kohistan and Asian plates by thrusts and shear zones, but it is insufficient to satisfy the palaeomagnetic data; there must be major crustal shortening, involving thrusts, in the Hindu Kush and Pamirs north of Kohistan.

The post-Eocene thrust direction, which for most of Pakistan is towards 160°, is almost perpendicular to that immediately to the east in the Himalayan belt, generating complex refolded thrust patterns in the Hazara syntaxis and large scale folding and rapid uplift with associated brittle faulting and seismic activity adjacent to the Nanga Parbat syntaxis. These different thrust trends indicate that major thrust movement as well as the folds and deformation fabrics, cannot always be related to plate movement vectors, but are modified by, or develop from, complex rotations during plate collision or from the gravitational spreading of a thickened crust. A regional approach is required to recognize and correctly attribute the various components in thrust displacements.

C/219. Coward, M.P., Izatt, C., Ries, A.C. & Williams, M.P., 1992. Passive margin subsidence and inversion along the western margin of the Indian Plate. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 15-16.

Palaeogeographical plate reconstructions, restoration of cross sections and analysis of present day outcrop data have been used to put forward a model for the development of the north-western margin of the Indian Plate (Katawaz basin, Kirthar and Sulaiman Ranges).

The margin was affected by Permo-Triassic Karroo rifting event in an approximately E-W extensional field, continuing in the early Jurassic as India and Madagascar broke away from Africa. The early Cretaceous saw a change in the orientation of the extensional stress field (N-S) as India began to break away and move north along its current path. The Cretaceous is characterized by volcanism, mainly clastic sedimentation, transtension and transpression, and end Cretaceous ophiolite obduction.

The end Cretaceous is also marked by a regional phase of uplift, and volcanic extrusion of the Raj Mahal and Deccan Traps. Rapid subsidence occurs throughout the Tertiary, marine carbonate shelves and shale rich offshore basins in the Palaeocene-Eocene, shallowing to marine-continental basins in the late Tertiary.

During the Palaeozoic NW India lay on the eastern flank of intra-continental basins whilst still part of Gondwanaland. An early basement fabric may have been acquired at this stage. The NW margin of Pakistan/India has been subjected to various phases of uplift and shortening, the most prominent being during the end-Cretaceous/Paleocene and during the Pliocene. Major tectonic inversion of the Katawaz and Sulaiman Ranges occurred during the Pliocene/Pleistocene. Previous thin-skinned models call for geometrically unreasonable amounts of shortening. Our models call for approximately 23-25 km shortening, reactivating Mesozoic faults at depth.

The western margin of the Indian plate was a passive margin, and remains connected by transitional crust to oceanic crust of the Arabian Sea until the Mio/Pleistocene. The Chaman Fault marks the eastern edge of the overriding Afghan plate expelled laterally from N. Pakistan during the Pliocene. The western edge of Pakistan then collided with this expelled block.

The inversion model has implications for the overall structure and shortening in NW Pakistan. Many of the thrust uplifts may not be thin-skinned; for example, earthquake data suggest the reactivation of faults at depth beneath the Kohat region. The thin-skinned overthrusts sheet of the Himalayas is therefore uplifted by faults reactivating basement structures. This revised model has exciting hydrocarbon potential for Pakistan.

The above history has implications for total Himalayan shortening. It suggests that the edge of the Asian plate was much farther north than previously suggested and hence if collision occurred at 55 to 40 mm, Greater India might have been much larger than previously supposed. Much of the shortening in the Himalayas/Tibet probably occurred in the Indian Plate rather than the Asian Plate.

In the Karakorum Range there is a structurally complicated Cretaceous arc comprising the Kohistan sequence. On its northern side the Northern Suture consists of a mega-mélange and is bounded to the S by tightly folded pillow-bearing volcanics and sediments. To the S the Kohistan Plutonic Belt consists of (southwards): (a) early foliated and late post-tectonic tonalites and diorites, (b) aplites and pegmatites (up to 30% of rock volume), (c) basic dykes up to 10 m thick, (d) the Chilas Complex, a stratiform cumulate body over 300 km long and 8 km thick (chromite-layered dunites, gabbros and norites) with a low pressure granulite-facies mineral fabric of tectonic origin, (e) an amphibolite belt with a complex mixture of other rocks, and (f) the Jijal Complex, a 200 km² tectonic wedge of high pressure granulites and chromite-layered dunites. Cumulate graded units in the Chilas Complex show that it is folded by an isoclinal anticline (F_1). The mid-upper crust of the arc is folded by a 50 km half-wavelength F_2 syncline. The whole Kohistan sequence with its two phases of isoclinal folds was tilted during Himalayan collision so that the structures are now subvertical. The Southern Suture (Main Mantle Thrust) has a wedge of glaucophane schists. The Indian plate contains a basement of psammites and schists intruded by Cambrian granites and overlain by isoclinally folded and metamorphosed carbonates and shales.

The Indus suture in northern Pakistan splits into two branches that bring rocks of diverse nature in contact. The northern suture consists of a mega-mélange passing northwards into pelitic and calcareous rocks, which show a rapid increase in grade of metamorphism away from the suture. These rocks are intruded by the calc-alkaline Karakoram batholith. Sedimentary rocks to the north of the batholith are mostly Paleozoic in age and are dominated by slates and shale with some calcareous and arenaceous rocks, and extend up to the Chinese border. The southern suture, with associated ultramafics and a wedge of blueschists, is bordered on the south by the rocks of the Indian plate consisting of a basement of psammites and schists intruded by Cambrian granites and overlain isoclinically folded and low grade metamorphosed cover of carbonates and shales.

Between the two sutures occur rocks of the Kohistan sequence represented by, from north to south, tightly folded pillow-bearing volcanics and sediments; early foliated and late post-tectonic tonalities and diorites with small but abundant intrusions of aplites and pegmatites and basic to intermediate dykes; the Chilas complex, a stratiform cumulate body over 300-km long and 8-km thick; an amphibolite belt with a complex mixture of other rocks; and the Jijal complex, a 200-km² tectonic wedge of high-pressure mafic granulites and chromite-layered ultramafics. The Chilas complex is folded by an F1 isoclinal anticline and the upper part of the Kohistan plutonic belt by a major F2 syncline. The whole of the Kohistan sequence with its two phases of isoclinal folds was tilted during the Himalayan collision so that the structures are now sub vertical.

West Himalayan tectonics involve the collision of microplates between the Indian and Asian Plates. The Kohistan Complex consists largely of tightly folded basic volcanics and sediments generated as Late Jurassic to Late Cretaceous island arcs. These were intruded by post-folding Mid-Cretaceous — Eocene plutonics produced from continued subduction of the Indian Plate after closure of a suture between Kohistan and the Karakoram. The Himalayan structures show major thrust sheets and the Kohistan Arc is essentially a crustal 'pop-up' with southward-upright and northward-verging structures developed above a thick ductile decoupling zone (the Indus Suture), which can be traced for >100 km beneath Kohistan on large reentrants. This pop-up formed by a two stage process, closure of the Northern Suture followed by closure of the southern Indus Suture. Granitic rocks of the Kohistan-Ladakh Batholith (dated at $\cong$ 100-40 Ma) post-date most of the structures related to the Northern Suture but were deformed and carried southwards on shear structures related to the Indus Suture. Post-collisional deformation carried this Kohistan Complex on deep decoupling zones over the Indian Plate on a series of imbricated gneiss sheets, the thrusts climbing up section in the movement direction so that in the far S some override their own molasse debris. Folds above these deep decoupling zones deformed their overlying thrust sheets into large antiforms - i.e. the Nanga Parbat and Hazara Syntaxes. The Nanga Parbat Syntaxis probably formed due to a shear couple near

a branch line where one of the main Himalayan thrusts joined the Indus Suture beneath Kohistan. Crustal delamination, to produce the imbricated gneiss sheets, could not account for all the displacement of India into Asia, suggested by palaeomagnetic data. There must also have been lateral displacement as demonstrated by the large oblique-slip shear zone in the Hunza Valley, N of Kohistan.

Natural dry steam zones (vapour only) are relatively rare; most geothermal systems contain both liquid and vapour and typically follow a boiling point-depth (BPD) relationship. The Nanga Parbat uplift-driven conductive thermal anomaly results in a geothermal system which follows a BPD relationship at shallow levels, but below about 3 km fluid inclusions show that the hydrothermal fluid is dry steam with fluid densities from 0.36 to as low as 0.07 g/cm³. This dry steam zone may persist down to the brittle-ductile transition. The dry steam has salinities up to 5 wt.% dissolved salts, and up to 22 mole% dissolved CO₂. The dry steam originated as meteoric water high on the slopes of Nanga Parbat, with $\delta^{18}\text{O}$ as low as - 16‰. Oxygen isotopic exchange with the host rock was facilitated by high temperatures (340° to 450°C) and low fluid densities so that the fluid meteoric isotopic signature was completely obliterated. Hence, quartz veins formed by the migrating dry steam have $\delta^{18}\text{O}$ between +9 and + 15‰, a range which is indistinguishable from quartz in the host rocks.

Quartz vein precipitation from dry steam requires 3 to 5 orders of magnitude greater volume of fluid than typical hydrothermal fluids. The dry steam zone at Nanga Parbat has formed due to near-isothermal depressurization of very hot fluid during rapid tectonic uplift at rates > 3-6 mm/year.

C/232. Craw, D., Koons, K.O., Winslow, D., Chamberlain, C.P. & Zeitler, P.K., 1994. Boiling fluids in a region of rapid uplift, Nanga Parbat Massif, Pakistan. *Earth and Planetary Science Letters* 128, 169-182.

The Nanga Parbat massif of northern Pakistan is currently undergoing rapid uplift ($\sim 5\text{--}10\text{ mm a}^{-1}$), resulting in near-surface elevated temperatures. Numerous quartz veins cut geologically young structures ($< 2\text{ Ma}$), attesting to widespread young fluid flow. Fluid inclusions in quartz veins are predominantly low density water vapour (down to 0.05 mg m^{-3}), with some low density carbon dioxide vapour, and the fluid is predominantly meteoric in origin. Fluid inclusions provide evidence for boiling near to the critical points for water and for 5 wt% NaCl solution (up to 410°C). Head-driven meteoric water was convecting in fracture permeability under hydrostatic pressures which followed the boiling point-depth curve and near-boiling springs emanate from the surface. Hydrostatic pressures persisted to depths of about 6 km below the topographic surface, or near to sea level, where the brittle-ductile transition is inferred to lie. Numerical modelling of conductive heat flow in an area of high relief during rapid uplift indicates that the shape of the near-surface conductive geotherm is significantly influenced by topographic relief. Reasonable approximations for topography at Nanga Parbat produce a conductive geotherm which implies high, near-surface geothermal gradients ($> 100^\circ\text{C km}^{-1}$), and the isotherms describe a giant pillar of heat. Above about 4 km, fluid temperature is greater than conductive rock temperature in permeable zones which carry convecting boiling meteoric fluid.

C/233. Crawford, A.R., 1974. The Salt Range, the Kashmir syntaxis and the Pamir arc. *Earth and Planetary Science Letters* 22, 371-379.

The enigmatic Salt Range of Pakistan is suggested to have been rotated about 75° counter-clockwise from an original position in line with the main Himalayan front, about a pole near the eastern end of the Range. Rotation was a consequence of the creation of the Pamir Arc by major block movements in Central Asia which also produced the Kashmir Syntaxis. Although direct palaeomagnetic testing of the hypothesis is not possible, Cambrian pole positions obtained from the Purple Sandstone and Salt Pseudomorph Beds of the Salt Range lie anomalously on the Precambrian part of the apparent polar wander curve for Gondwanaland. These revert to positions in correct chronological sequence on that curve if rotation is allowed for.

C/235. Crawford, A.R., 1974. The Indus suture line, the Himalaya, Tibet and Gondwanaland. *Geological Magazine* 111, 369-383.

Misunderstanding exists about the origin of the Himalaya, Indo-Tibetan relationships and the extent and history of Gondwanaland. The Indus Suture Line is a relic of fracture to the mantle but for a period only represented by the faunas of the 'exotic blocks' of the Tibetan Himalaya, i.e. Permian—Late Jurassic. Tibet appears originally to have been part of a plate including India, but submerged while India remained continental. Associated with the fracture extending to the mantle represented now by the Indus Suture Line, shallower subparallel fractures developed within which the Gondwana sediments of the Himalaya were preserved. These, together with the salt at the base of the Tethyan marine sequence, facilitated intra-continental orogeny when, much later, India was affected by vigorous sea-floor spreading and plate movement in the NW Indian ocean after it had become attached to Asia.

The northern plate boundary was beyond Tibet, on the N side of the Tarim Basin Block, and along the Tien Shan. The Tien Shan present peculiar features, particularly very deep long intramontane depressions such as Issyk Kul in USSR and Turfan-Hami in China, and their stratigraphy shows persistent mobility. The Tarim Basin Block has moved sinistrally relative to Tibet and in Gondwanaland lay near northern Western Australia. The suggested extent of Gondwanaland explains the present lack of continental crust W of Western Australia, now in Tibet, and the

intracontinental origin of the Himalaya is consistent with the absence of recent volcanism in an area of considerable seismicity. The association of Tibet with India in Gondwanaland destroys the effectiveness of arguments against continental drift based upon the extension of Indian stratigraphic sequences across the Himalaya. The hypothesis of an enlarged Gondwanaland is given support by recent Chinese discoveries of terrestrial vertebrate fossils of Gondwanic type near the Tien Shan.

C/240. Crawford, M., 1985. Field relationships of the Karakoram Batholith and metamorphic rocks of the Hunza valley, North Pakistan. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

The W-E striking Karakoram batholith in the Hunza Valley is very heterogeneous on both small and large scales but is dominantly calc-alkaline in composition. The main mineralogy is quartz, plagioclase and biotite with hornblende also often occurring in the more mafic areas. There are no mafic dykes but making up 40% of the batholith volume in places are two suites of leucogranitic dykes, one suite being concordant with the foliation and the other later and discordant. These dykes contain quartz, alkali feldspar, garnet, biotite and muscovite and probably represent the residual magma. A little tourmaline indicates late boron-rich fluid phase.

To the north the foliation dips south and low-grade metamorphic chistolite slates of the contact aureole have a south dipping contact with the batholith. A migmatitic belt forms the southern part of the batholith and this is truncated against metamorphic rocks to the south by a north dipping thrust plane.

South of the batholith the foliation dips north and there is a sharp change in the direction of foliation dip near the center of the batholith. Thrust planes and lithological contacts are parallel to the foliation suggesting the folding and thrusting episodes were synchronous and there may be related to the emplacement of the batholith. The metamorphic rocks show a Barrovian-type sequence of facies and include metapelites, calc-silicates and pure carbonate bands. With increasing grade from greenschist to amphibolite facies a series of index minerals

representing isoreaction-grade change through chloritoid to staurolite to kyanite to sillimanite with gneissic melting next to the batholith. The isogrades dip north and the metamorphism increases to the north so the sequence is therefore inverted.

C/241. Crawford, M.B., 1988. Leucogranites of the NW Himalaya: mantle-crust interaction beneath the Karakoram and the magmatic evolution of collisional belts, Ph.D. Thesis, University of Leicester.

The Karakoram Axial Batholith in N. Pakistan records the magmatic development of the Eurasian continental margin since the late Jurassic. Magmatism prior to the collision of India with Eurasia at c.45Ma is represented by subduction-related, calc-alkaline granodiorite plutonism. The chemical variation within these plutons is caused by high-level fractionation processes. However, heterogeneous isotope data suggest that the source of these magmas was the mantle wedge, enriched by a subducted slab component, with the melts being contaminated by a Sr-rich crustal component.

There are two types of post-collisional leucogranites. The Sumayar pluton is related to restricted partial melting of sillimanite-grade metapelites triggered by fluxing of fluids from the underthrust Indian crust. This water-saturated, minimum melt is considered to be an analogue of the High Himalayan leucogranites.

The other Karakoram leucogranites are related by fractionation to a more basic monzogranitic parent, whose geochemistry indicates a lower crustal source. However, melting of typical crust cannot explain the anomalously high large ion lithophile element (LILE) content of the monzogranites. Associated with the granites are ultra-potassic, LILE-enriched lamprophyres. This LILE-enrichment is attributed to alteration of the mantle wedge by fluids and /or siliceous melts from the slab. Amphibole in the resulting metasomatic assemblage acts as a sink for the otherwise incompatible LILE. As a result of heating and thermal relaxation beneath the thickened continental crust, enriched amphibole, stable in the pre-collisional after collision to give the lamprophyres. Fluid precursors to this melting contaminated the source region of the granites selectively enriching it in LILE and triggering/promoting melting. The identification of the above magma-types, which have different generative processes and magmatic triggers, in other collisional environments, will lead to information about the evolution of similar orogenic belts.

Keywords: Leucogranites, Karakoram batholith, Himalaya.

C/242. Crawford, M.B. & Searle, M.P., 1992a. Crustal structure and collision-related granitoid magmatism of the Hunza Karakoram, north Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 17.

The Karakoram batholith in the Hunza segment of the Karakoram Range, north Pakistan, is dominated by a pre-50 Ma collision, calc-alkaline, quartz diorite-granodiorite batholith which separates a dominantly sedimentary terrain to the north from a regional metamorphic terrain to the south. The southern part of the batholith and the metamorphic rocks to the south are affected by strong south-vergent thrusting related to the collision, which has brought deeper level, hotter rocks over higher level, cooler rocks, creating an apparent inverted metamorphic profile. Isograds have been disrupted by large-scale, post-metamorphic thrusts. Stretching lineations are dominantly north-dipping throughout. The northern part of the batholith is relatively undeformed and shows an intrusive contact with the sediments to the north and an andalusite-bearing contact metamorphic aureole.

A massive dyke complex, the Hunza dykes, intrude the early phase of the batholith as well as the high-grade sillimanite gneisses to the south. The Hunza dykes consist of a co-genetic suite of monzogranites, granodiorites and leucogranites, which are related by feldspar-biotite fractionation. They are volatile-depleted non-minimum melts with unevolved Sr isotope ratios and LILE-enriched signatures similar to the Baltoro pluton further east. The Sumayar pluton intrudes the kyanite and staurolite-grade metamorphic rocks south of the batholith and is a homogeneous, water-saturated, minimum-melt leucogranite, with a major element composition similar to that of the Manaslu leucogranite of central Nepal. Abundant tourmaline and high Sr isotope ratios (>0.8) together with REE modeling indicate a metapelitic source for the Sumayar leucogranite.

The massive post-collisional Baltoro monzogranite-leucogranite pluton is not continuous across to the Hunza region. The Hunza dykes are, however, almost certainly related to the Baltoro pluton, and represent lower crustal magmas derived by dehydration melting of metasediment following the India-Kohistan-Asia collision events. Consideration

of the petrogenesis of the Hunza dykes and the Sumayar pluton allow inferences to be made concerning the deep crustal structure of the Hunza Karakoram.

C/243. Crawford, M.B. & Searle, M.P., 1992b. Field relationships and geochemistry of pre-collisional (India-Asia) granitoid magmatism in the central Karakoram, northern Pakistan. *Tectonophysics* 206(1-2), 171-192.

In the central Karakoram Range, northern Pakistan, seven major granitic units which were emplaced prior to the Eocene (ca. 50 Ma) India-Asia collision have been mapped and analysed geochemically. The mid-Cretaceous Hunza plutonic complex dominates the Karakoram batholith in the west and is composed of quartz diorite-granodiorite plutons which have been deformed in the south by later collision-related thrusting. The Sost and Khunjerab plutons intrude the Palaeozoic-early Mesozoic sediments north of the batholith. In the east pre-collision magmatic units occur both north of (K2 gneiss, Broad Peak quartz diorite, Muztagh Tower unit) and south of (Hushe gneiss) the batholith which is dominated by a Miocene monzogranite-leucogranite pluton (Baltoro unit). The plutonic units to the north of the batholith are mid- to late Cretaceous with an age range of ca. 115-80 Ma whereas the Hushe gneiss to the south is dominantly Jurassic spanning the age range 200-145 Ma.

All the pre-collision magmatic units display similar chemical and isotopic characteristics. Major, trace and REE variations in the Hunza plutonic complex are controlled by high-level fractionation of clinopyroxene, hornblende, plagioclase, biotite, ilmenite and allanite. High LILE/HFSE and LREE/HREE ratios, together with negative Nb, P and Ti anomalies suggest an ultimate source in the mantle wedge above the subducting slab. $^{87}\text{Sr}/^{86}\text{Sr}$ initial ratios (0.7055-0.7157) in the Hunza plutonic complex can best be explained by contamination of a mantle-derived magma by a crustal component with highly radiogenic Sr.

All the units except the Hushe gneiss are probably related to subduction during closure of a back-arc basin between the Karakoram to the north and the Kohistan-Dras arc to the south during the mid- to late Cretaceous, and correlate with widespread plutonism from the same period in Kohistan, Ladakh and southern Tibet along the southern margin of Asia. The Hushe gneiss is probably related to an earlier northward-directed subduction phase during the Jurassic.

C/245. Crawford, M.B. & Windley, B.F., 1990. Leucogranites of the Himalaya/Karakoram: implications for magmatic evolution within collisional belts and the study of collision-related leucogranite petrogenesis. *Journal of Volcanology and Geothermal Research*, 44, 1-19.

Two types of leucogranite have been identified in a collisional setting in the Himalaya. Type-a (e.g., Manaslu, High Himalaya) are syn-tectonic crustal melts related to "hot over cold" thrusting and subsequent fluid fluxing. Type-b (e.g., Baltoro, Karakoram) is related to lower crustal melting during/following crustal thickening and thermal re-equilibration, followed by crystal fractionation. For type-b, melting is triggered/promoted in the lower crust by input of heat and material from the sub-continental lithospheric mantle which is contemporaneously melting due to removal of the slab input and downward displacement.

Both these granite types can be explained in terms of recent thermal models for continental collision, and so might be expected to be found in other orogenic terranes. These models also show that extension and thinning will occur as a result of the crust becoming gravitationally unstable, due to thickening, sometime after collision. Thinning will lead to upwelling and melting of asthenosphere which could then intrude the base of the crust and promote further melting. This could explain the common occurrence of A-type granitoids as final plutonic events in orogenic terranes following intrusion of the collision-related type-a and type-b granites.

Existing genetic classification schemes only classify granites in terms of source-type or broad environmental affinity (e.g., collisional). To further subdivide such broad environmental fields it is considered that processes and a general

evolutionary model must be used. Source-type is not suitable due to the number of source components that are often involved and the overlap of these components from one environment to another. One or two selected features of a granite are not, however, sufficiently exclusive to identify different petrogenetic histories. We propose that an evaluation of field style, mineralogy, isotope and elemental geochemistry should be used to subdivide the collisional granite field into type-a and type-b (or Manaslu and Baltoro-types) respectively.

The valley of the Tochi River is an outlying corner of the British Empire in India forming a portion of Waziristan, the boundary of which was delineated in 1894-5 by an Anglo-Afghan Commission from the Afghan provinces of Khost on the north and Birmul on the west. Mr. F. H. Smith, of the Geological Survey of India, accompanied this Commission as geologist, and his observations "On the Geology of the Tochi Valley" were published in 1895 in the "Records of the Geological Survey of India" (vol. xxxviii, pt. 3, pp. 106-110, pl. iii). On p. 109 he says:—"The range of hills between Idak and Mirán Shah is formed by an anticlinal ridge which approximately strikes north and south, and which is composed of these lower Eocene beds. In the core of the anticlinal a considerable thickness of massive dark grey limestone is exposed, in which I could find no fossil remains; the age of this limestone is therefore doubtful, and there is no evidence of any kind to show whether it belongs to the lowest tertiary or upper Mesozoic age."

C/249. Critelli, S. & Garzanti, E., 1991. Petrology of remnant ocean sandstones derived from the Himalayan suture belt. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Auris, France, 31-32.

After the Indian-Eurasia collision, which determined the final closure of the Neothetys Ocean in the early Eocene, "recycled orogenic" arenites began to be deposited in remnant oceanic basins at both sides of the Indian Peninsula. These sediments, of late Oligocene to early Pliocene age, were progressively incorporated in accretionary prisms formed at subduction zones both to the east (Andaman-Mentawi islands: Moore 1979) and west (Makran: Critelli et al. 1990) of the collision zone. Detritus derived from the elevated Himalayan chain is still being accumulated today in the two greatest turbiditic cones of the world, floored by remnant oceanic crust (Bengal and Indus Fans: Ingersoll and Suczek, 1979; Suczek and Ingersoll 1985).

Detrital modes of these "recycled orogen" clastic wedges are all comparable, and testify to a predominant contribution from the Himalayas. They thus represent the distal "flysch" equivalent of ancient and recent "molasses" (Siwaliks: Prakash et al; 1980, Indo-Gangetic Plain, Potter, 1978), deposited in subaerial foreland basins floored by Indian continental crust.

A major difference in detrital modes among these deposits is represented by the significant volcanic contribution from active magmatic arcs to the subduction complex sandstones (Nias and Makran). Both the Indus and Bengal

turbiditic cones and the ancient and recent foredeep deposits were instead entirely derived from the uplifted Himalayan Chain. While volcanic detritus is absent in the Siwaliks and Ganges sands, recycled volcanoclastics derived from the Transhimalayan arc and Indus-Tsangpo suture zone are transported by the Indus and Brahmaputra rivers up to the turbiditic cones of the Indian Ocean.

C/250. Critelli, S. & Garzanti, E., 1994. Provenance of the lower Tertiary Murree redbeds (Hazara-Kashmir Syntaxis, Pakistan) and initial rising of the Himalayas. *Sedimentary Geology*, 89(3-4), 265-284.

The Murree Supergroup of northern Pakistan is represented by an over 6 km thick succession of deltaic redbeds and intercalated impure foraminiferal limestones of latest Paleocene to Middle Eocene (Ieridian to Lutetian) age, cropping out in the northern part of the Hazara Syntaxis, and by redbeds of younger age (early Middle Eocene to Early Miocene) cropping out in the southern part of the Syntaxis (Rawalpindi area). The quartzolithic composition of the Murree redbeds testifies to a “collision orogen” provenance. Detritus was derived from a suture belt including thrust sheets of metasedimentary and subordinately sedimentary rocks, volcanic or volcanoclastic rocks, and ophiolites. Phyllite rock fragments are most common in the Ieridian sandstones, whereas volcanic and carbonate rock fragments are more abundant in the Lutetian sandstones. Minor quantities of chert and serpentine schist, indicating contribution from uplifted subduction complex sources, as well as siltstone, shale and limestone grains, are invariably present. Detrital modes of sandstones and southwestward progradation of Tertiary clastic wedges both testify to provenance from the proto-Himalayan chain located to the north, and uplifted since the very first stages of the India/Asia continental collision at the end of the Paleocene. The coeval Chulung La redbeds of the Tethys Himalaya instead, consisting of volcanic and subordinate ophiolitic detritus, testify to exclusive provenance from the obducting Trans-Himalayan arc-trench system. This major petrographic difference may be accounted for by the different structural setting of the Chulung La “piggy-back” and Murree foreland basins. These two distinct collisional basins have been separated probably since the onset of collision by a fold-thrust belt, beginning to rise in the position occupied today by the High and Lesser Himalayan structural domains. Throughout the Murree Supergroup, main petrographic parameters do not vary greatly, and volcanic, sedimentary, low-grade metasedimentary and ophiolitic detritus persisted until the Early Miocene, indicating slow progressive growth of the chain. Only during the Middle Miocene, when the highly metamorphosed rocks of the High Himalaya were carried southward along the Main Central Thrust (MCT), the mountain range began to rise to dramatic heights, and huge amounts of detritus started to feed the Siwalik foreland basin sandstones and the remnant ocean turbidites of the Indus and Bengal Fans.

C/251. Crompton, T.O., 1984a. The Pakistan to Russia triangulation connexion: past and project error analyses. In Miller, K.J., *The International Karakoram Project, Volume 1*. Cambridge University Press.

Using those data available, an error analysis of the triangulation connexion from Gilgit to the Russian border, which was observed by Kenneth Mason's 1913 expedition, is performed. This analysis is compared with an error analysis of the projected re-observation of this connexion. The latter analysis may be treated, in part, as an optimization process enabling crucial measurements for the control of scale, to be identified, based on a priori estimates of measuring accuracies.

The paper continues with some comments on how the calculation of the observations should proceed with a view to abstracting tectonic movements by comparison of the two epochs of measurement. The difficulties of obtaining such results and their statistical significance are described. Finally, looking to the future, the relevance of the 1980 observations is discussed in the context of possible repeat measurements within, say, the next ten years.

C/252. Crompton, T.O., 1984b. The calculation of crustal displacement and strain from classical survey measurements. In: Miller, K. J. (Ed.). *The International Karakoram Project 2*. Cambridge University Press.

This paper identifies some of the problems inherent in the determination of planimetric displacement and strain in the earth's crust by repeated survey measurements. An approach which avoids the use of co-ordinates is developed. The technique should be familiar to the surveyor and, at the same time, useful to the geophysicist. After some discussion of the relative accuracies of 1913 and 1980 measurements, the paper concludes with a simple application using data acquired during the International Karakoram Project.

C/254. Cronin, V.S., 1989. Structural settings of the Skardu intermontane basin, Karakoram Himalaya, Pakistan. Geological Society of America, Special Paper 232, 183-202.

Skardu Basin is a northwest-trending intermontane basin along the Indus River in the Karakoram Himalaya Mountains of Pakistan. Seismotectonic domain boundaries in the Karakoram Himalaya commonly cross lithologic and some older structural boundaries. Four major structural-seismotectonic domains exist in the Skardu area: the Himalayan seismic zone, characterized by thrust tectonics; the complex Hindu Kush-Pamir seismic zone; the Skardu quiet zone, characterized by strike-slip, extensional, and rotational tectonics with relatively little seismicity; and the southern edge of Eurasian lithosphere (Tarim-Kun Lun-Tibet) northeast of the Karakoram fault. The Skardu quiet zone is interpreted to be within the Himalayan thrust prism, above an aseismic detachment along which stable sliding or ductile faulting accommodates displacement. Stresses transmitted into the Skardu quiet zone laterally from the Himalayan seismic zone toward Eurasia and perhaps upward from the inferred basal detachment result in gross clockwise rotation, translation to the north-northwest, and a right-lateral sense of shear in the Skardu region.

Landsat lineaments defined by major drainages suggest an array of fractures and faults in the Skardu quiet zone. Field data suggest that the lineaments generally reflect distributed shear along myriad small faults rather than displacement exclusively localized on major, discrete fault surfaces. Extensive glacial and fluvial erosion have accentuated trends characterized by relatively dense fracturing and faulting. At its confluence with the Indus at Skardu, the Shigar River flows through a breach that may have originated as a pull-apart structure similar to the pull-apart basin along the upper Sutlej River.

The preserved vestiges of the upper Cenozoic Bunthang sedimentary sequence reflect Skardu's early basin phase. Uplift along the Nanga Parbat-Haramosh syntaxis and along the northeastern margin of the Himalayan seismic zone

may have contributed to the ponding of the Indus River in the Skardu Basin during Bunthang time. These axes of uplift may be related to movement of the Himalayan thrust wedge from a region of easy basal slip (Skardu quiet zone) to a region of increased resistance to basal slip (Himalayan seismic zone, or, in the case of the NP-H syntaxis, the Hindu Kush-Pamir seismic areas). Regional uplift within the Skardu quiet zone may reflect thickening of the thrust prism in response to variations in shear resistance along the detachment. Quaternary glacial lake beds located on the floor of Skardu Basin are generally on deformed in the western half of the basin. Local deformation within the lake beds in the eastern half of the basin is probably due to interaction with glaciers.

C/256. Cronin, V.S., Johnson, P.W., Johnson, N.M. & Johnson, G.D., 1989. Chronostratigraphy of the upper Cenozoic Bunthang sequence and possible mechanisms controlling base level in Skardu intermontane basin, Karakoram Himalaya, Pakistan. *Geological Society of America, Special Paper 232*, 295-305.

A 1.3-km-thick section of basin-fill sediments within the Skardu intermontane basin of the Karakoram Himalaya, termed the Bunthang sequence, is predominantly reversely magnetized. Glacial deposits and landforms are closely associated with the Bunthang sequence. This implies that basin filling took place between glacial advances and prior to the present Brunhes normal chron, i.e., between 3.2 and 0.73 Ma. Four major facies interfinger within the Bunthang sequence: glacial facies; lacustrine facies, indicative of periods during which the Indus River was ponded within the basin; aggradational fluvial facies that represent periods during which the gradient of the Indus River was controlled by rising base level downstream; and alluvial conglomerates that prograde transversely from the basin margin into the basin at different stratigraphic levels. The last facies represents periods of decreased sedimentation by the Indus River relative to alluvial sedimentation from the basin margin.

Downstream from the Skardu Basin, the Indus River crosses the Nanga Parbat-Haramosh syntaxis; this is an area of rapid late Cenozoic uplift (as much as 1 cm/yr). Differential uplift of the Nanga Parbat-Haramosh syntaxis relative to its surrounding terrain led to local variations in Indus River gradient. Temporary ponding of the Indus River is inferred to have occurred when the uplift rate of the Nanga Parbat-Haramosh syntaxis exceeded the rate of downcutting by the Indus River. Temporary blockage of the Indus River Gorge through the Nanga Parbat-Haramosh syntaxis by glaciers or by major landslides may also have led to variations in base level. Temporal variations in the gradient and base level of the Indus River downstream from the Skardu Basin, are reflected in the different facies that interfinger within the Bunthang sequence at Skardu.

C/257. Cronin, V.S., Schurter, G.J. & Sverdrup, K.A., 1992. Landsat image analysis of drainage lineaments to locate possible faults and structural discontinuities along the Nanga Parbat-Haramosh Massif, northwest Himalaya. *Abstract Volume, 7th Himalaya-Karakoram Workshop*, Department of Earth Sciences, Oxford University, England, 18-19.

The Nanga Parbat-Haramosh Massif (NPHM) of northern Pakistan is a prominent salient of allochthonous Indian continental crust that is exposed within the Kohistan-Ladakh magmatic arc. Nanga Parbat (8126 m) has the greatest local relief and one of the most rapid rates of uplift yet observed in continental crust. The northerly trend of the NPHM is nearly perpendicular to the active thrust faults of the Himalayan foreland. The reasons for the rapid uplift and anomalous trend of the NPHM are not yet fully understood.

A better understanding of the NPHM awaits collection of a more complete suite of primary structural, seismic, and lithologic data throughout this area. Published structural geologic mapping in this area is inconsistent and very incomplete, particularly in areas that are not close to the roads that follow the Indus, Gilgit, Hunza and Astor Rivers. In this study, satellite imagery was analyzed to supply a family of hypotheses regarding the structures exposed at the

surface that may be active in accommodating the uplift of the NPHM. The development of these hypotheses will enhance both the focus and economy of future structural reconnaissance mapping along the NPHM.

The study area is located between latitudes 35°15'N and 36°15'N and longitudes 74°15'E and 75°15'E. A collection of photographic prints of Landsat 2 MSS band 7 imagery was analyzed to identify lineaments defined by stream drainages that may have developed along structural discontinuities. Discontinuity types relevant at this scale include faults, joints, contacts, spatially persistent foliation, and lithologic variations that result in differential weathering. Virtually all of the ~2500 drainages that are clearly observable on the imagery were manually digitized using a 1200 lpi digitizer. Each drainage was recorded as a polyline of short, linear drainage segments. The azimuth of each drainage segment was determined, and the ~12,000 segments were sorted by azimuth into 36 overlapping sets. A given set contains the endpoint coordinates of each segment whose trend lies within a specified 10° wide azimuthal class. Each set of drainage segments was then automatically re-plotted on a separate map to indicate more clearly the location of linear arrays of drainage segments.

Drainage lineaments are defined as essentially collinear arrays of drainage segments that are traceable across at least one drainage divide. Assisted by the maps of drainage segments, a set of ~200 lineaments was identified by direct inspection of the Landsat imagery. Multiple images of the same Landsat frame were used to identify lineaments, taking advantage of differing sun angles and snow conditions. Most of the lineaments extend for many kilometers, and cross several drainage divides.

The drainage lineaments identified in this study include the traces of the few known active faults in the NPHM area; the Stak, Baroluma, and Raikot Faults. It is reasonable to hypothesize that structural activity is being accommodated on more than the few active faults that have been mapped in this area, given that the NPHM is in one of the most structurally active areas on Earth. Many of the lineaments that do not correlate with known faults or lithologic contacts are located in areas that have not yet been mapped adequately, or at all. We suggest that at least some of the drainage lineaments correspond to previously unmapped active faults. Evaluation of the various hypotheses concerning the origin and significance of these lineaments requires fieldwork.

C/258. Cronin, V.S., Schurter, G.J. & Sverdrup, K.A., 1993. Preliminary Landsat lineament analysis of the northern Nanga Parbat-Haramosh massif, northwest Pakistan. In: Searle, M.P. & Treloar, P.J. (Eds.), *Himalayan Tectonics*. Geological Society of London, Special Publication 74, 193-206.

Analyses of mosaic of Landsat2 MSS band 7 images covering the northern Nanga Parbat-Haramosh Massif (NPHM) has yielded approximately 540 lineaments defined by sets of collinear drainage segments and aligned linear greytone boundaries. Segments of the few well-mapped faults along the NPHM as lineaments are identified. The paucity of field data concerning faults, joints, lithological fabric and contacts prevent from interpreting most of the lineaments. However, some of the poignant lineament trends probably mark the trace of previously unmapped active faults that accommodate the recent uplift of the NPHM. The origins of these lineaments must be established through structural geological field work.

Dainelli made contribution on the glaciers of the region during the expedition. Although he did not have the opportunity of visiting the erratics of Punjab, he also addressed their problem. He summarized the views of Theobald (1874, 1877, 1880) and Wynne (1877, 1878, 1881) and explained their occurrence according to his opinion. He thought that the blocks were deposited on the bottom of a lake extending over the area where the blocks were found. The glacier snout of the Indus faced this lake. This event is thought to have taken place during the second of the four glacial expansions he considers likely to have occurred, as the lake formed between the first and the second of his suggested glacial expansions due to the marginal lifting of the Himalayan range.

This is a description of the Siachen Glacier. It is considered as the major glacier on earth.

Key words: Glaciers, Siachin, Karakoram.

D/15. Dainelli, G., 1932. A journey to the glaciers of the eastern Karakoram. Geographical Journal 79, 257-274.

This paper was read at the Evening Meeting of the Society on 11 January 1932. Following is the first page of the paper.

It may perhaps seem superfluous that I should say why I undertook this journey into Eastern Karakoram. But for its story's sake I may mention that I had the great fortune of being a member, as Geographer and Naturalist, of the memorable expedition organized by Dr. Filippo De Filippi and led by himself in 1913-14. During that time I asked and obtained from the leader the widest freedom of action and movement. And thus for a whole year and a half, nearly always alone with my very light personal caravan, I was in continual movement, because I knew it was necessary, for my own experience of the region and for the contribution I could bring to its knowledge, that I should see as many valleys and glaciers, as many plateaux and villages or shepherds' camping grounds as I possibly could. And thus at the end of the expedition I could say to myself I knew all Baltistan and all Ladakh and the first Tibetan plateaux as far as Pankong lake and the Aksai Chin. One blank, however, had remained: the Nubra valley from its mouth in the Shyok valley to its origin in the Siachen glacier. The Nubra valley in its lower half is frequented by caravans which cross the Karakoram Pass during the summer, and it has been followed by various travellers; however not much was known about it, and I had special ideas regarding its population, from an anthropological point of view. The upper half of the valley had been climbed by very few travellers indeed, of the old ones Moorecraft in 1821, Vigne in 1835, Thomson and Henry Strachey in 1848, and some years later by Drew. Then we come to quite modern times, with Longstaff in 1909 and the Vissers in 1929; but its geological conditions were practically unknown. At the head of the Nubra valley is the Siachen glacier, which is said to be the largest glacier on Earth outside Polar regions. Longstaff had discovered and been on it in 1909, the Workmans followed in 1911 and 1912, and also the Vissers climbed it in 1929, but only for a few miles from the front upwards. Of the geological

conditions of its immense basin nothing was known. And this represented the chief blank in my personal knowledge and in connection with the attempt that I have been preparing for years, of reconstructing the geological history of the entire region, which is the last part, and perhaps not the least important, of the scientific results of the De Filippi Expedition.

D/25. Daniel, C., 1972-73. Detailed gravity survey of Gilgit Valley, northern areas of Pakistan. M.Sc. Thesis, Punjab University, Lahore, 142p.

A detailed gravity survey comprising of 256 observation covering an area of 15 miles² was conducted for delineation of subsurface geology. The spacing of stations along profiles was kept 1 furlong. Total number of profiles spread was 18 and was spaced 3 furlong apart from each other. The scale was 1:15840. The contour interval kept for Bouguer anomaly map was 0.5 mgals.

In order to get gravity values of all the stations the Master Worden Gravimeter Model 111 No. 955 with scale constant 0.0902/S.D.* was used to conduct geodetic survey, a Russian Transit Theodolite T.T.S. was used. The main gate Marcopolo Inn (Gilgit) was selected the base station, and all the profiles were connected to the base station. Since the regional gravity anomaly map should have regional effects, therefore Bouguer anomaly map was not taken into account. The residual anomaly was considered to be the most suitable. The anomalies developed in residual anomaly map were described very carefully.

Residual anomaly map was prepared after Griffin's and second derivative map was prepared after Elkin's. The various graphical curves obtained from anomalies along different cross-sections were compared with standard curves given in 'The Theory Applied Geophysics by Grant and West'.

The Makarwal area of the Trans-Indus Salt Range (Surghar Range) presents an excellent section of thick, fossiliferous sedimentary rocks. The lower part comprises Upper Jurassic (barosh) Limestone, followed upward by Lower Cretaceous sandstone Belemnite-bearing rocks, sandstones (Lamshiwal). These rocks are followed upward unconformably by Lower Eocene Ranikot Limestone with coal seams and Patala shales, and Upper Eocene marl and Laki Limestone. These are overlain unconformably by Miocene conglomerates and sandstones of the Siwaliks. The paper gives details of stratigraphy, lithology and structure of the area, together with the iron ore in the Lower Cretaceous belemnite-bearing beds and Lower Eocene coal.

D/30. Danilchik, W. & Tahirkheli, R.A.K., 1959. An investigation of alluvial sands for uranium and minerals of economic importance in Indus, Gilgit, Nagar and Hunza Rivers, Gilgit Agency, West Pakistan. Geological Survey of Pakistan, Information Release 11, 12p.

Uniformly low uranium content of 18 samples from widely distributed sample locations on the Indus, Gilgit and Hunza Rivers suggests that economically significant concentrations of uranium are not likely to be found in the alluvium of the upper Indus watercourses. Sands collected from boulder and cobble gravels in terraces and river beds contain 0.001 percent uranium or less. Wind- and water-deposited mantle sands contain 0.001 to 0.006 percent uranium. Spectrographic analyses of sand and heavy mineral concentrates show no unusual or economically-significant concentration of rare or valuable elements.

D/33. Danishwar, S., Majid, M., Shah, M.T. & Haq, N., 1994a. Fluoride abundance in drinking water and related health hazards: A case study from Kheshki area, Nowshera district, NWFP, Pakistan. Geological Bulletin, University of Peshawar 27, 113-116.

Fluorides in food or drinking water have drastic effects on human health. High concentrations of fluorine in drinking water causes a disease called fluorosis. Geochemical study of groundwater and soil samples from the Kheshki area in Nowshera District, NWFP. (where from frequent cases of fluorosis are related) was carried out in February to June 1994. The results show high concentration of fluorides (0.00 to 41.2 ppm) in the groundwater samples from the studied area, which confirms fluoride toxicity. Necessary measures are required to be adopted to minimize the effect of this environmental deterioration.

Key words: Fluoride, water, health hazard, Nowshera.

D/35. Danishwar, S., Majid, M. & Shah, M.T., 1995. Mineralogy and Geochemistry of lacustrine deposits of the Kheshki area N.W.F.P. Pakistan. Journal of Science and Technology, University of Peshawar, 19, 33-38.

Kheshki area is a part of the Peshawar basin in N.W.F.P. and is covered by lacustrine deposits. A stratigraphic section north east of Kheshki, is studied in detail. These deposits predominantly contain minerals like quartz, calcite,

albite, orthoclase along with subordinate amount of chlorite, illite, tourmaline, fluorite, hornblende and vermiculite. Chemical analyses of the studied samples are compared with the average analyses of residual clay deposits of various rocks. This study suggests that source rocks of lacustrine deposits of the Khashki area are the acidic plutonic rocks of Warsak and Ambela granitic complex with influx of residual clay from the Nowshera Formation.

D/36. Danishwar, S. & Shah, M.T., 1997. Geochemistry of ground water and the source of contamination of fluoride in the drinking water of the Naranji area, District Swabi, NWFP, Pakistan. *Pakistan Journal of Scientific and Industrial Research* 40, 5-12, 83-00.

Inhabitants of the Naranji village are known for their yellow coloration of teeth throughout the Mardan Division. A general survey of the area shows prevalence of dental and skeletal fluorosis of varied degree in the village. A detailed geochemical analysis of ground water of the village indicates fluoride concentration of 13.5 mg/L which is about 9 times more than WHO's maximum contaminant level. The source of high fluoride in drinking water is considered to be the alkaline rocks of Koga Complex. Tube well water should be supplied to the area in order to avoid the fluoride contamination.

Key words: Geochemistry, groundwater, fluorine, drinking water, Swabi.

D/37. Danishwar, S., Shah, M.T. & Majid, M., 1995. Abundance of fluoride and its source in drinking water of Khashki and surrounding area, district Nowshera, NWFP, Pakistan. *Geological Bulletin, University of Peshawar* 28, 31-37.

Fluoride, if present in minute amount in human body, is beneficial for the growth of bones and teeth. Its excess is, however, very harmful and usually causes skeletal fluorosis. Few cases of skeletal fluorosis are reported in Khashki and surrounding areas in NWFP. The drinking water of study areas has been, therefore, analyzed for the fluoride contents. It is noticed that this water has high concentration of fluoride. The source of fluoride enhancement in the drinking water of the area needs to be unraveled. For this purpose the water of Kabul river, rocks of Nowshera Formation and the lacustrine and soil samples of the area have been analyzed for fluoride. These media show elevated amounts of fluoride. The study suggests that in the lacustrine and soil deposits of the Khashki and surrounding area the detrital minerals, which accommodate fluoride in their structure, are the main contributors of fluoride to be the drinking water.

D/43. Davidson, D.F., 1975. The geology and mineral resources of Kakul and Lagarband phosphate deposits, Hazara District, Pakistan. US Geological Survey/Geological Survey of Pakistan Information Release PK-63.

Based on field examinations and study of all available information concerning the phosphate deposits of the Kakul-Mirpur area, Pakistan, there is believed to be approximately 700,000 tons of minable phosphate rock of a grade of 30 percent or more P₂O₅ in the area. A similar study of available information of the Lagarband deposit suggests that there may be approximately 1,000,000 tons of minable phosphate rock containing 30 percent or more p₂O₅; in addition, approximately 1,500,000 tons of rock containing 20 percent to 30 percent p₂O₅ appear to be minable,

The total resource so far identified thus appear to be just over 3,000,000 tons of rock which may or may not be usable because of its chemical and mineralogical characteristics, but which can be mined. It must be pointed out that the figures given are based on very limited physical exploration, and equally limited analytical data. Further studies in the two areas are as likely to lessen as to increase them.

D/54. Davies, L.M., 1932. The genera *Dictyoconoides* Nuttall, *Lockhartia* nov., and *Rotalia* Lamarck: their type species, generic differences, and fundamental distinction from the *Dictyoconus* group of forms. Royal society of Edinburgh, Transactions, 57, 397-428.

The author recalls the facts regarding the rediscovery, in recent years, of Carter's genus *Conulites* (= *Dictyoconoides* Nuttall). He shows how, of seven species which have been referred to this genus, three always have numerous intercalary whorls in their spires, and four never have any such whorls. The association of these two groups together within a single genus has, so far as he himself is concerned, been due to the uncertainty hitherto existing regarding the type species *cooki*, whose spire was stated by Carter sometimes to show an intercalary whorl, but generally to be "single throughout." Carter's original specimens, which had long been mislaid, have recently been found, however, and they all prove to belong to now familiar types, which invariably contain numerous

intercalary whorls in their spires. The author therefore separates the four species which do not possess such whorls into a new genus, *Lockhartia*.

The author next discusses the supposed identity of *Dictyoconoides* with *Rotalia*, and shows that the *Rotalia* must be judged by their type species *R. trochidiformis*. He shows that this species, among other characteristic features, invariably displays the structures called “astral lobes” by Carpenter and Brady, and is distinguished by the same from both *Dictyoconoides* and *Lockhartia*; while it is further distinguished from *Dictyoconoides* by the absence of intercalary whorls in its spire.

The author then compares the development of Rotalid forms, like the above, with that of piano-spiral ones like *Nummulites* and *Assilines*; and he finally shows the fundamental difference in structure between all these spirally wound types and those with an “end-on” development, like the *Dictyoconus* group of forms, with which some of them have been confused in the past.

D/62. Davies, L.M., 1943. Tertiary Echinoidea of the Kohat-Potwar basin (India). *Quarterly Journal of the Geological Society, London* 99, 63-77.

The author describes the results, to date, of work on the Tertiary echinoids of the Kohat district and northern Punjab. He recalls facts published in previous papers, and deals with collections more recently made. He outlines the stratigraphy of the northern basin, and shows how its echinoids help to correlate its elements with the early Tertiary deposits of Baluchistan and Sind.

A Number of Tertiary echinoids from the Kohat-Potwar basin have already been dealt with (Davies 1925, 1926A, 1927, 1937), but many more were collected during my last visit to India. An attempt is here made to summarize existing information on the subject.

By the expression "Kohat-Potwar basin" (cf. Davies 1940B, p. 489; 1940C, p. 209), is meant an area approximately covered by the Kohat district and the Potwar plateau. This region formed a fairly well-marked basin during late Cretaceous and early Tertiary times, when an arm of the Tethyan sea crossed the north-western corner of the Indian horst on its way to what is now southern Tibet (Davies 1940B). In the final phases of its marine history this basin showed increased individuality, owing to earth movements which severed its trans-Himalayan extension to the east and restricted its communications with Sind to the south.

D/68. Davies, R.G., 1963. Some preliminary observation on the geological structure of the Hazara Slate Formation in the area of the Lora-Maqsood road. *Geological Bulletin, Punjab University* 3, 32-35.

The Hazara Slate Formation, according to Marks and Muhammad Ali (1961, p. 451, is composed of a thick succession of arenaceous and argillaceous rocks, largely fissile and well-bedded, but with true slates largely absent. The common alternations of sub-greywacke sandstones with silty and argillaceous rocks were likened by them to the Alpine Flysch; they drew attention to the graded bedding in the sandstones and to their smooth tops, flowcasts on the undersides, and worm tracks, and commented on the absence of ripple marks and current bedding. Muhammad Ali (1962, p. 32) suggested that the formation was in excess of 10,000 feet thick.

Key words: Structure, slates, Hazara.

D/69. Davies, R.G., 1964a. Some anomalous formations lying within the Attock Slates in the area immediately south of Attock, Peshawar Division, West Pakistan. *Geological Bulletin, Punjab University* 4, 101-102.

As a result of a photogeological examination of the country south of Attock, it was decided to carry out a ground check on the nature of certain bands of rock, apparently lying within the Attock Slates and giving rise to lighter tones than do the slates themselves. In August, 1964, a preliminary examination was made along the road which leads southwards from the western end of the Attock bridge and which cuts through the rock bands concerned. After passing through the slates themselves for about one thousand yards, the first band was found to form a narrow NW-SE trending ridge of a dark- coloured limestone which thickened to the south east. An exactly similar limestone occurred about half a mile to the south as a narrower band crossing the road with a W N W trend. Typical Attock slates or shales made up the area between the two limestones and also occurred again to the south of the southernmost band for about half a mile; they were followed, to the south by :

1. A band of white quartzite with some quartz veins.
2. Alternations of thinly bedded, purplish and greenish siltstones, rather fissile.
3. A white, fine-grained, compact limestone with a porcellanous appearance.

The total horizontal thickness of these (last mentioned) sedimentary rocks is about 2,000 feet; the dips are quite steep, but variable, and usually towards the south. Unit number 3 (above) is followed to the south by appreciable thicknesses of Quaternary superficial deposits belonging to the Upper Pleistocene and including silts, sands, gravels etc. The situation of these outcrops is given in Fig. I. An examination of the aerial photographs and a rapid scrutiny of the ground showed that the formations are present, not only on the west side of the Indus, but also on the east side, in the area shown by Cotter (1930), in his map, as Attock slate.

The formations extend far to the west, in the westerly trending ridges of Khattak and also to the east, in the hills north and west of Dakhner. It is seen that the structure is a rather tightly folded one with a mainly E-W trend and southerly dips; a number of very narrow folds are present which appear to be overturned towards the north. Small faults, often with N-S to NE-SW trends are present. A microscopic examination of thin sections of the more important lithologies present has led, in the case of the more northerly of the two limestone bands, to some rather unexpected results. The band concerned, which is narrow and enclosed by typical Attock slate, appears to have been plastically deformed and fractured and was found to be speckled with small Foraminifera. Among these, have been identified, by Mr. Riaz Ahmad, the following genera: *Miscellanea*, *Nummulites* and *Assilina*; fragments of gasteropods are also present, including *Turritella*. It is evident that this rock is of Palaeogene (probably Paleocene-Lr. Eocene, age). The rocks of the other, more southerly, outcrops do appear to be in a much better state of preservation than are the adjacent slates, and give the impression of being much younger, despite the overall complex structure. They seem to bear certain similarities to some of the rocks of the Abbottabad Formation of Marks and Ali (1962, p. 56).

It is thought that these outcrops represent in- folded and, perhaps, unfaulted representatives of two formations of different ages, both of which are younger than the Attock slates. Careful mapping is required, both to the west, in the Khattak hills, and to the east towards Dakhner. This may be undertaken by this department when time permits.

D/70. Davies, R.G., 1964b. The orthoconic nautiloids of the Kala Limestone-A correlation. *Geological Bulletin, Punjab University* 4, p.105.

The specimens extracted from the Kala limestone and described in the last issue of the bulletin (1963, p. 1-5), were re-examined by Dr. C. Teichert. He confirms the identification of *Michelinoceras* and feels that the specimen

compared with *Harrisoceras* may be correctly identified, although further information, about the annulosiphonate deposits and of the presence of an endosiphuncular tube, is needed. The identification of *Arthophyllum* is, however, regarded as incorrect, although the specimen is clearly one of the *Michelinoceratidae*. What appear to be the radial lamellar structures in the camera1 deposits are, in all likelihood, due to portions of crinoids having been introduced into the specimen during deposition. This identification has, therefore, to be withdrawn. The stratigraphic significance is, however, little changed and it is still true to say that a Middle Palaeozoic age is indicated. Should, however, it be possible (by further collecting) to confirm the presence of *Harrisoceras*, the upper portion of the Lower Palaeozoic (Silurian) would probably be a more precise date.

Key words: Stratigraphy, palaeontology, Kala limestone.

D/71. Davies, R.G., 1965. The nature of the Upper Swat Hornblendic Group of Martin et al. 1962. *Geological Bulletin, Punjab University* 5, 51-52.

The Upper Swat hornblendic group crops out in a northeast-trending band in northern West Pakistan. Widely varied rock types ranging from granite to gabbro are cut by narrow, very coarse-grained pegmatoid veins and dikes. In thin section the rocks are seen to be mainly plutonic, although some metamorphic rocks are included, especially in the southern part of the outcrop area. Unpublished data from a gravity survey confirm that the zone under study is an overthrust.

Key words: Hornblendic group, pegmatoids, petrography, Swat.

D/72. Davies, R.G. & Ahmad, R., 1963a. The orthoconic Nautiloids of the Kala Limestone and the probable age of the Swabi Formation. *Geological Bulletin, Punjab University* 3, 1-5.

Some orthoconic Nautiloids from the Kala Limestone of the Swabi Formations are described, figured and discussed. It is considered that they indicate a Siluro-Devonian age for these formations which, prior to 1969, have usually been regarded as Pre-Cambrian. The broader stratigraphic implications are also discussed. This is the first time that definite Middle Paleozoic fossils have been recorded from West Pakistan.

Key words: Stratigraphy, orthonautiloids, palaeontology, limestone.

D/73. Davies, R.G. & Ahmad, R., 1963b. Fossils from Hazara Slate Formation at Bara Gali, Hazara, West Pakistan. *Geological Bulletin, Punjab University* 3, 29-30.

This is a preliminary report of some fossils from Hazara slates near Baragali. The samples were collected during a visit to the area in year 1962. The authors discussed these samples with other paleontologists and were of the view that further studies need to be carried out in the area to find any fossils which may help in deciphering the stratigraphy of the area. The authors have suggested that the Hazara slates are Lower Paleozoic rather than Pre Cambrian.

Key words: Fossils, Hazara slates, Baragali, Hazara.

D/80. Dawney, R. & Clavariono, J., 1994. Gold exploration and mineral analysis project (GEMAP) northern Pakistan. Abstracts, Second SEGMITE International Conference on the Export Oriented Development of Mineral Resources and Mineral Based Industries, 9-10.

The GEMAP project was designed to assist the Government of Pakistan develop its metalliferous mining sector through strengthening its mineral exploration and geochemical analysis capabilities.

The project is built around four components: Gold exploration in Northern Pakistan, centred on the Eurasian Plate and the Kohistan Arc complex and with associated field training of geologists from PMDC and SDA (A small component of the project with GSP is centred on the Makran of Balochistan).

Training of personnel in Pakistan and Australia in exploration philosophy, methodology and techniques, exploration management, analytical chemistry, mineralogy, cartography, mineral law formulation and administration. Provision of equipment for both field and laboratory activities. Provision of specialised analytical equipment and training of personnel to support exploration for lead/zinc. Integrated, early-stage exploration, including interpretation of satellite images and aerial photographs and systematic drainage sampling, is in progress to systematically cover the project area on a regional basis for the first time. Fast-track investigation of identified mineral occurrences is also being undertaken.

Exploration is primarily directed towards rapid identification of commercially viable deposits. Preliminary results to-date indicate a number of area requiring follow-up investigations.

In addition, the project is developing reliable data base (of world class standard) sufficient to demonstrate the mineral potential of Northern Pakistan and attract foreign and local, private sector investment in the mineral exploration and mining industry.

D/86. Debon F., 1992. Geological setting of Eocene “Batura Granites” (Western Karakorum axial batholith, Northern Pakistan). Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, p.108.

In the Karakorum, contrary to the Trans Himalaya, the existence of an Eocene plutonic episode remains poorly documented. Such an episode corresponds to the Batura plutonic unit (BAPU) of Debon et al. (1987) that only relies on a petrographic, geochemical and isotopic study of boulders from the terminal moraines of the Batura, Pasu and Ghulkin glaciers (draining the northern part of the Western Karakorum axial batholith, on the west of the Upper Hunza valley). The BAPU is dominantly made up of light-coloured and unfoliated biotite $\pm$ amphibole granites s.l. Based on the Rb-Sr whole-rock isotope analysis of five samples from the Batura moraine, it is Eocene in age [45 ± 7 Ma (5 samples) or 43 ± 3 Ma (4 samples), with an initial $^{87}\text{Sr}/^{86}\text{Sr}$ isotope ratio of 0.7055 ± 3 or 0.7056 ± 3 and a MSWD of 3.3 or 0.7 respectively]. It does not outcrop along the Hunza valley and differs in texture, composition and age from all the rock types [mainly foliated dark-coloured (meta) granodiorites] that compose the huge Mid-Cretaceous (95 ± 41 -6 Ma by U-Pb on zircons; Le Fort et al., 1983) Hunza plutonic unit of the Karakorum axial batholith, as also from the Upper Cenozoic dense network of peraluminous leucocratic dykes cutting through this unit.

The field trip I carried out in September 1991, in the framework of a joint EEC project, was mainly devoted to the BAPU, along the northern margin of the Western Karakorum axial batholith [Kuk-i Jerab (and Yashkuk) glaciers, south of the Chapursan valley; Batura glacier]. Among the observed features, the following ones seem of particular interest:

- The BAPU corresponds, but in part only, to the aplite-granite etc. group previously described and roughly mapped by Schneider (1957), Desio (1964), and Desio & Martina (1972).

- The BAPU displays sharp contacts and typically intrusive relationships with its Upper Palaeozoic (?) metasedimentary surroundings (e.g. Kuk-i Jerab glacier) as well as with the Cretaceous Hunza plutonic unit (Pup-i Shikorga, north of the Middle Batura glacier).

- The BAPU is composite. It comprises several (~ 2) individual plutons, up to more than 20 km in size. Texture and composition are rather homogeneous within a given pluton but vary significantly from pluton to pluton. Microgranular porphyritic textures are not rare.

-The BAPU may be associated with large coeval(?) gabbroic stock(s?) (Western branch of the Upper Kuk-i Jerab glacier).

In order to better constrain and understand the magmatic and geodynamic evolution of the Karakorum, complementary field and laboratory studies devoted to the BAPU are needed. In particular:

The possible extension of the BAPU on the east of the Upper Hunza valley (e.g. Distaghil Sar-Pumori Chhish area) has to be checked up

The emplacement age (s?) of the BAPU must be refined.

A comparison between the BAPU and the still very poorly-known Giraf syenite pluton, some 40 km north of the Karakoram axial batholith and maybe also Eocene in age (53 Ma according to a biotite Rb-Sr date of Desio et al., 1964), could be fruitful.

Key words: Geochemistry, geochronology, granite plutons, Batura, Karakoram.

D/87. Debon, F., 1995. Incipient India-Eurasia collision and plutonism: the Lower Cenozoic Batura granites (Hunza Karakoram, North Pakistan). *Journal of the Geological Society, London* 152, 785-795.

Plutonism of the Karakorum, north of the India-Eurasia suture zone, comprises two major intrusive stages: the oldest, mid-Cretaceous, predates the collision; the youngest, Miocene, is post-suturing. In between, Lower Cenozoic plutonism, roughly syn-suturing and represented by the Batura complex, is made up of a few small and usually undeformed plutons. The complex has a subalkaline (i.e. intermediate between alkaline and calc-alkaline) and feriferous association, dominated by light-coloured metaluminous and slightly peraluminous granites and adamellites with biotite $\pm$ amphibole $\pm$ titanite. Whole rock Rb-Sr isochron ages of 63 Ma (this study) and 43 Ma (Debon et al. 1987b) have been obtained for two plutons, with rather low initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (0.7050, 0.7056). A comparison with granitoids of similar age from Kohistan suggests that the complex relates to the subduction of the Tethys ocean, and originates from a mantle source with but small crustal contribution, through a two-stage melting process. The apparently limited extent of Lower Cenozoic plutonism in the Karakorum contrasts with its wider development in the Transhimalaya and Kohistan. This contrast could be partly accounted for by changes in tectonic and magmatic subduction-related processes after the initial contact between India and Eurasia was established, in the NW Himalaya.

Key words: Tectonics, plutonism, Batura granites, Karakoram.

D/88. Debon, F. & Khan, N.A., 1993. Field Study of the Western Karakoram axial batholith along the Karambar valley (Northern Pakistan). Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 15.

The detailed study of the Karakoram axial batholith undertaken by different teams for the last ten years has shown its composite character. Different plutonic units, dominantly ranging in age from Cretaceous to Miocene, have been recognized. However, their inventory is far from being over, and their extent and relationships remain often ill-defined.

Our 1992 field trip in the Karakoram Range was mainly devoted to the Karambar valley (N. Pakistan), the choice of which was based on several grounds; - the Karambar valley offers a complete and easily accessible N-S section of the western axial batholith, perpendicular to its elongation; this section, hitherto poorly known (review in Casnedi, 1984), cross-cuts a cartographic plutonic "blank", about 120-km long, separating two already investigated N-S sections of the batholith, namely the Yasin-Darkot and the Hunza-Batura sections. The study concerns a section around 40-km long, 28 of them for the batholith itself.

Along the Karambar valley, surrounding rocks of the batholith are essentially made up of metapelitic formations, usually trending WNW-ESE. Metamorphism is dominantly developed south of the batholith, where biotite-garnet metapelites are crosscut by a conspicuous swarm of diversified leucocratic dykes that could be hold responsible for their transformation into migmatites of the injection type. This migmatitic zone is about 4-km wide. More to the south, around 6-km far from the batholith, dykes almost completely disappear and metamorphism decreases abruptly (phyllites, slates).

At its northern and southern margins, the batholith intrudes metapelites along sharp, normal and steep contacts, roughly concordant at map scale. Metasedimentary xenoliths, a metre up to several decametres in thickness, are frequent close to either margins, particularly along the southern one where they occur within a zone some 700 m

wide. Metasedimentary rocks seem to be completely lacking in the internal part of the batholith. The huge screen, which, more to the west, divides the batholith into two branches, does not reach the Karambar valley.

Three major types of plutonic rocks can be distinguished along the section studied: (1) strongly foliated biotite amphibole granodiorite, often rich in mafic enclaves, sometimes blastomylonitic, representing the westward continuation of the well-known mid-Cretaceous calc-alkaline “Hunza Granodiorite” (HG); (2) diversified foliated amphibole-biotite granite, locally porphyritic, corresponding to the mid-Cretaceous subalkaline “Darkot Pass Granite” (DPG); (3) various and more or less foliated fine grained rocks of acidic and intermediate composition (FGR). From north to south, the arrangement of the different units is: HG + metapelitic xenoliths (~0.2-km)/DPG, often porphyritic, + FGR + HG (~0.5-km)/DPG, often porphyritic, ($\sim \leq 1.5$ -km)/DPG + FGR (+ HG) $\sim \geq 3.5$ -km)/FGR + HG (often as angular enclaves within FGR) (~ 5.5 km)/HG (~ 16-km)/HG + metapelitic xenoliths (~ 0.7-km). The different units usually display sharp and sinuous contacts. HG was emplaced before FGR, whereas FGR and DPG could be coeval.

On the whole, the section shows a very complex imbrication between the Hunza and Darkot Pass plutonic units, as also between them and the fine-grained igneous group (FGR), of uncertain affinity.

Numerous leucocratic dykes of various composition cross-cut the batholith. At least part of them were emplaced during or before the deformation(s) responsible for the foliation of their host granitoids. Their study, in relation with deformation and metamorphism, both within and out of the batholith, remains to be done and should be of particular interest.

D/89. Debon, F. & Khan, N.A., 1995. Cretaceous Alkaline Granitoids in the Karakoram axial batholith (Karambar valley, N Pakistan). Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

The Karambar valley offers a complete and easily accessible section of the western Karakoram axial batholith (Fig. 1). Following a reconnaissance study by Casnedi (1984), the section was mapped (Fig. 2), sampled, and briefly described by Debon & Au Khan (1993). Geochemical data (Table 1) allowed us to discover an alkaline complex in the northern part of the section. As in the Transhimalaya, subalkaline intrusives (i.e. intermediate between alkaline and calc-alkaline) are widespread in the Karakoram batholith (e.g. Le Fort, 1988). But it is the first time that alkaline granitoids are reported in this batholith.

The alkaline complex crops out for some five kilometres (Fig. 2). It is a heterogeneous body made up of medium-grained rocks associated with various fine-grained granitoids and mafic igneous enclaves.

Medium-grained rocks, at times deformed and foliated, are predominant and represent the most typical members of the complex. They form a widely differentiated group comprising metaluminous monzonites, quartz monzonites, granites and leucogranites (Table 1), with amphibole (ferroedenite, .4, highly ferri-ferous biotite, ilmenite, clinopyroxene, $\pm$ allanite, apatite, sphene, zircon. They are two-feldspar granitoids, with plagioclase usually of the albite-type. They define a coherent alkaline (Fig. 3) and highly ferri-ferous series (Table 1), including some slightly peralkaline members [$Al / (Na+K) < 1$]. From monzonites to leucogranites, differentiation is characterized by a rapid increase of the quartz content counterbalanced by a decrease of the mafic mineral and feldspar contents (Fig. 3). In the field, at the scale of the complex, this differentiation broadly progresses from south to north. Light-REE contents are high (LaN up to 549). REE patterns of the different rock types are comparable (Table 1; Fig. 4). They show a regular increase of the negative Eu anomaly from monzonites to leucogranites, most probably related to the decreasing abundance of feldspars. Four monzonites and two quartz monzonites have yielded a Rb-Sr isochron age of 87 ± 3 Ma (2σ), with an initial $87\text{Sr}/86\text{Sr}$ isotope ratio of 0.70439 ± 8 (2σ) and a MSWD of 1.8 (when taking for calculations errors of 2% and 0.01% on the $87\text{Rb}/86\text{Sr}$ and $87\text{Sr}/86\text{Sr}$ ratios respectively) (Table 2; Fig. 5). The three analysed granites and leucogranites scatter below the isochron.

Working hypotheses include: (1) Emplacement of the Karambar alkaline complex could relate to the early Late Cretaceous collision between the Karakoram and Kohistan island arc along the Northern suture (Fig. 1). (2) Its alkaline character suggests a relationship with extensional processes, maybe linked to an oblique collision between the two domains, with subsequent strike-slip faulting. (3) Its initial $87\text{Sr}/86\text{Sr}$ isotope ratio is low (0.7044 ± 1), and undistinguishable from that of the mid-Cretaceous (109 ± 4 Ma) Darkot Pass granitoids (0.7044 ± 1 ; Figs 1, 5). Such features are compatible with a derivation of both plutonic complexes, one alkaline and the other subalkaline, from a similar mantle source, with but small crustal contribution.

D/90. Debon, F. & Khan, N.A., 1996. Alkaline orogenic plutonism in the Karakorum batholith: The upper Cretaceous Koz Sar Complex (Karambar, N. Pakistan). *Geodinamica Acta* 9(4), 145-160.

The Karakorum is located north of the India/Kohistan-Ladakh/Eurasia sutures. Along the Karambar valley, its axial batholith comprises four plutonic complexes. (1) The largest one represents the westerly continuation of the huge mid-Cretaceous calc-alkaline Hunts plutonic unit. This unit here displays a remarkable reverse zoning that would result from a differentiation at depth followed by multipulse intrusions. (2) A stock of subalkaline (i.e. intermediate between alkaline and calc-alkaline) granitoids (Warghut porphyritic granite). (3) A composite group of fine-grained granitoids. (4) The so-called Koz Sar alkaline complex (KSAC), a unique example of this composition of plutonism so far reported in the batholith. In addition, leucogranite dykes and rare alkaline mafic ones occur. The KSAC is a heterogeneous and more or less deformed body, ca. 5 km wide and possibly 20 km long, comprising two coeval groups of rocks. (1) Medium- to coarse-grained rocks are the most representative members of the complex. They consist of metaluminous to slightly peralkaline monzonite, quartz monzonite, granite and leucogranite, with iron-rich mafic silicates and Fe-Ti oxide. These subsolvus granitoids define a strongly ferriferous alkaline series. Five monzonite and quartz monzonite samples yield an isochron Rb-Sr age of 88 ± 4 Ma ($\text{Sr-87/Sr-86(i)} = 0.70440 \pm 7$; MSWD = 1.7). (2) Fine-grained rocks (monzogabbro to quartz syenite) are compositionally comparable to the dark-coloured members of the preceding group. The KSAC was emplaced into a post-collisional environment resulting from the accretion, maybe at least since Aptian times, of the Kohistan island arc to the Karakorum. Its alkaline character testifies to the development of extensional tectonics, a process compatible with an oblique collision and/or with the decrease, at the time of collision, of the convergence velocity between the two colliding terranes. Available data suggest that this alkaline complex (1) is late-orogenic, (2) is genetically-related to the nearby subalkaline granitoids and originates from the same mantle-source with a small crustal contribution, and (3) represents the ultimate member of the mid-Cretaceous subduction-related plutonism emplaced into the Karakorum continental margin.

D/92. Debon, F., Le Fort, P., Dautel, D., Sonet, J. & Zimmermann, J.L., 1985. Plutonism in western Karakoram and northern Kohistan (Pakistan): a composite Mid-Cretaceous to Upper Cenozoic magmatism. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

The petrography, the chemical-mineralogical typology, and the ages of six plutonic units from the Karakoram axial batholith (Darkot Pass, Ghamu Bar, Batura and Hunza units) and the northern Kohistan (Gindai and Nomal plutons) are defined and compared based on field data and analyses of up to 78 samples (major elements, REE, Rb-Sr and K-Ar isotopes).

The Karakoram axial batholith is a composite body. Two major stages of intrusive emplacement occurred: by Mid-Cretaceous times (ca. 110-95 Ma) with the emplacement of subalkaline, i.e. monzonitic, (Darkot Pass) and calc-alkaline (Hunza,? Ghamu Bar) units;

during Palaeogene, at least up to 43 Ma (Batura subalkaline unit). A strong tectonometamorphic event, recorded in the gneissification of the Cretaceous intrusive, happened between these two phases; it may be of Palaeocene age. P-T estimates of the highest metamorphic grade rocks of the Hunza unit have yielded values of 580-640°C and 5 ± 0.5 kbar. Finally, a conspicuous network of aplo-pegmatitic dykes emplaced in the Hunza area, possibly from the Eocene up to the Upper Cenozoic with a maximum during the Middle Miocene (ca. 15 Ma).

These major magmatic stages are met again among the acidic intrusive and dykes of northern Kohistan: the first one as blastomylonitic tholeiitic plutons (Noma; ca. 102 Ma; Petterson & Windley, 1985), the second one as subalkaline

plutons (Gindai; ca. 58.5 Ma), and the third one as leucocratic dykes, of Oligocene age (ca. 30 Ma; Petterson & Windley, 1985).

These data may be related to the geodynamic evolution of the NW part of the India-Eurasia suture zone, this allowing to better constrain the major steps of this evolution. The partly synchronous closures, by N-dipping subduction, of the two Tethys branches assumed to have encircled the Kohistan arc in Upper Mesozoic times, may have generated both the Karakoram and the Kohistan intrusive. The northern branch very likely closed before the southern one. By the time of the second stage of intrusive emplacement (Palaeogene):

Kohistan and Karakoram had already collided, were welded and had suffered the same major tectonometamorphic event;

subduction of the southern Tethys floor beneath the welded Kohistan-Karakoram was still active;

however, collision between India and Kohistan-Karakoram may have already begun, particularly at the level of the Nanga Parbat promontory.

Key words: Plutonism, magmatism, Cretaceous, Cenozoic, Karakoram, Kohistan.

D/93. Debon, F., Le Fort, P., Dautel, D., Sonet, J. & Zimmermann, J.L., 1987. Granites of western Karakoram and northern Kohistan (Pakistan): A composite Mid-Cretaceous to Upper Cenozoic Magmatism. *Lithos* 20, 19-40.

The petrography, the chemical-mineralogical typology and the ages of six plutonic units, four from the Karakoram axial batholith (Darkot Pass, Ghamu Bar, Batura and Hunza units) and two of northern Kohistan (Gindai and Nomal plutons) are defined and compared based on field data and analyses of up to 78 samples (major elements, REE, Rb-Sr and K/Ar isotopes). The Karakoram axial batholith is a composite body. Three major intrusive stages occurred: (1) around Mid-Cretaceous times (ca. 110-95 Ma) with the emplacement of subalkaline, i.e. monzonitic (Darkot Pass) and calc-alkaline (Hunza, ?Ghamu Bar) units; (2) during Palaeogene, maybe up to 43 Ma (Batura subalkaline unit). A strong tectonometamorphic event, recorded in the gneissification of the Cretaceous intrusives, occurred between these two stages; it may be of Palaeocene age. *P-T* estimates of the highest metamorphic grade rocks of the Hunza unit have yielded values of 580–640°C and 5 ± 0.5 kbar; and (3) during Upper Miocene (ca. 9 Ma; Baltoro subalkaline unit; Debon et al., 1986c). In addition, a conspicuous network of aplo-pegmatitic dykes emplaced into the Hunza area, possibly from the Eocene up to the Upper Cenozoic with a maximum during the Middle Miocene (ca. 15 Ma). Most of these major magmatic stages are met again among the acidic intrusives and dykes of northern Kohistan: the first one as blastomylonitic tholeiitic plutons (Nomal; ca. 102 Ma; Petterson and Windley, 1985), the second one as subalkaline plutons (Gindai; ca. 59 Ma), and a third one as leucocratic dykes, of Oligocene age (ca. 30 Ma; Petterson and Windley, 1985).

These data may be related to the geodynamic evolution of the NW part of the India-Eurasia suture zone, thus allowing better constraints on the major steps of this evolution. The partly synchronous closures, by N-dipping subduction, of the two Tethys branches which are assumed to have encircled the Kohistan arc in Upper Mesozoic times, may have generated both the Karakoram and the Kohistan intrusives of Cretaceous and Palaeogene ages. The northern branch very likely closed before the southern one. At the time of the second intrusive stage (Palaeogene): (a) Kohistan and Karakoram had already collided, were welded and had suffered the same major tectonometamorphic event; (b) subduction of the southern Tethys floor beneath the welded Kohistan-Karakoram was still active; (c) however, collision between India and Kohistan-Karakoram may have already begun, particularly at the level of the Nanga Parbat promontory. Finally, it is emphasized that the intrusive processes continued in the Karakoram long after the collision (e.g., Baltoro granite).

D/110. De Filippi, F., 1932. The Italian expedition to the Himalaya, Karakorum and eastern Turkestan (1913–14). (English Transl.) Arnold, London.

The Italian Expedition 167 barren plateaux of the Karakoram were undertaken in the summer of 1914. The arrangements for "supplies and transport" needed to maintain so large an expedition, encumbered by elaborate and heavy scientific equipment, for months at a stretch on elevated ground utterly devoid of resources might well by themselves have sufficed to absorb the leader's energy and attention. All the same Dr. De Filippi managed to find time during those stays for a careful study of varied aspects of local life, customs, religious organization, architecture, etc. To this we owe inter alia the detailed description contained in chapter vi of the monastic institutions of Ladak, their structures, art, etc. Illustrated by a wealth of excellent photographs, which the skill of Colonel Antilli provided as for the rest of the book, this chapter helps the general reader perhaps better than any previous book of travel to realize the remarkable wealth of products of local industry, art, and craft to be found in that comparatively small portion of Western Tibet. Considering the very limited extent of arable ground, the

adversity of climatic conditions at those great altitudes, and the very scanty population, the Census of 1911 gave for Ladakh and adjacent tracts only some 36,511 Buddhists? The abundance of monasteries, shrines, religious monuments, and other structures, whether maintained or in ruins, must impress every visitor. By contrast with the Dard and Balti tracts, which also were once Buddhist, this wealth conveys a very instructive lesson to the antiquarian student as to the way in which peculiar cultural factors may affect the extent of structural and other remains of the past in neighbouring territories. A distinctive and very useful feature of the book is the diligent, one might almost say loving, care which Dr. De Filippi has bestowed upon notices of previous travellers' visits to those regions and of the records left of their observations and labours. All students interested in the geography and history of that fascinating borderland between India and Central Asia must feel grateful for this

D/113. DellAngelo, L.N. & Tullis, J., 1989. Fabric development in experimentally sheared quartzites. *Tectonophysics* 169, 1-21.

A fine-grained quartzite was deformed under a combination of simple shear and axial compression to varying amounts of shear strain (1.3 to 2.9). The experiments were conducted at 800 °C, 1500 MPa, and an axial strain rate of 10–6/s, in the dislocation creep regime. Shear zone boundaries were oriented at 45° or 30° to the compressor axis. The progressive development of deformation microstructures, including planar fabrics and c axis preferred orientations, was studied as a function of increasing shear strain. Elongate original grains define a foliation (S) which rotates from 45° to 0° to the shear zone boundary with increasing strain, producing a sigmoidal foliation in a single shear zone. A second foliation, invariant in orientation, is defined by elongate recrystallized grains, which lie at about 30°–40° to the shear zone boundaries. No C-surfaces, parallel to the shear zone boundaries, were observed. However, extensional crenulation cleavages (C'), defined by parallel zones of recrystallized grains as well as impurity and melt segregations, were observed even at low strain, lying at approximately 30° to the shear zone boundaries, and these could easily be mistaken for C-surfaces. C axis preferred orientations of original grains define symmetric type I crossed circle girdles at low strain ($\gamma < 2$) and asymmetric broad maxima at high strain ($\gamma > 2$), with the greater concentration of c axes in the direction of shear. These features are very similar to those observed in natural ductile shear zones.

D/114. Dell'Mour, R.W. & Rodgers, M., 1993. Deformation history and structural pattern within an exploration concession in the Eastern Potwar basin (NE Pakistan). Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 68-69.

Structural Data gained from fieldwork carried out in 1992, Satellite TM interpretation and seismic interpretation provides the basis for a Tectono-Kinematic interpretation of a small portion of the Eastern Potwar Plateau (Fig. 1).

The Potwar Basin is part of the Central Fold Belt of Pakistan, the northern portion of which forms part of the Himalayan foreland fold and thrust belt. This deformed belt is a product of the ongoing collision between the Eurasian and Indian plates which forms the northernmost element of the Indus Basin. Compressional deformation throughout the Himalayan foreland is taking place as the Indian Shield is overridden by sediments along its northern

margin. In the eastern Potwar deformation is distributed along a broader zone of northeast/southwest trending, tight to overturned anticlines separated by broader synclines.

Three phases of deformation have been observed within this compressional stress field (Fig. 2):

Phase 1: Thrusting and folding WNW/ESE

Phase 2: Strike-slip faulting (W)NW/(E)SE

Phase 3: Strike-slip faulting NE/SW

Intensity of deformation increases to the NW as expressed by the more intensely sheared and compressed Riwar anticline. The easternmost Kallar anticline shows only minor deformation of the crest owing to southeast directed thrusting which does not appear to have significantly disturbed the stratigraphic sequence.

The most extensively developed thrust zone has been observed on the eastern limb of the Buttar anticline although the poorly developed outcrop exposure prevents accurate identification on the Satellite images. Southeasterly directed thrusting over several hundreds of metres is likely and lithologic indicators in the kataclastic zone suggest probable detachment within the Kamlial or Chinji Formations.

D/118. Dennell, R.W., 1997. Palaeoanthropology of South Asia and the upper Siwaliks of Pakistan. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, 69-71.

The Upper Siwaliks of northern Pakistan provide one of the longest and most detailed fluvial sequences for the Pliocene and Lower Pleistocene outside East Africa, the source of most early hominids. Although China and Indonesia have provided younger specimens of *Homo erectus*, there is scarcely any relevant fossil or archaeological evidence between these parts of East Asia, and East Africa, over 5,000 miles to the west. Northern Pakistan is, thus, one of the key areas for linking the early East African evidence for human evolution with the later East Asian material.

Recently palaeoenvironmental reconstructions have shown that in the late Pliocene, grasslands were continuous between northern China and Western Africa (Dowsett et al. 1994). There was therefore no ecological barrier - such as the present-day Sahara- that prevented early hominoids from living outside East Africa. Other work from northern Pakistan indicates that the South Asian grasslands are substantially older than those of East Africa (Quade et al. 1989), and Upper Siwalik faunal remains also indicate the prevalence of a grassland fauna, broadly comparable to that of East Africa. Recent discoveries from Chad (Brunet et al. 1995) indicate that hominids may have colonised the grasslands of Africa on a continental scale by 3 million years ago; if grasslands extended further east into Asia, they could also have occupied these. In the last two years, hominid remains from Indonesia (Swisher et al. 1994), China (Wanpo et al. 1995) and Georgia (Gabunia and Vekua 1995) have been dated to 1.8 million years, raising

again the possibility that hominids had left Africa by 2 million years ago. Although each of these claims is highly contentious, an obvious working hypothesis that needs testing by fieldwork in northern Pakistan is that hominoids were living in South Asia by the late Pliocene/early Pleistocene (Dennell 1995).

Despite the potential palaeoanthropological importance of the Upper Siwaliks, they are still largely unexplored. As predicted as long ago as 1953 by Louis Leakey - the discoverer of *Paranthropus boisei* and *Homo habilis* at Olduvai Gorge, Tanzania - the discovery of early hominids in the Upper Siwaliks is only likely to result from several years, if not a life-time, of exploration (Leakey 1953: 214). Unlike East Africa, the Upper Siwaliks are a predominantly fluvial sequence formed by large perennial rivers. Although vertebrate fossil remains are often abundant and well-preserved, they tend to be highly dispersed, and rarely occur in the localised and repeated manner that often occurs in East Africa. Although carnivores are present, they tend to be very localised, and found mainly in association with very dense accumulations of fossils that probably represent their prey. For these reasons, fossil collecting surveys have to be conducted over a much larger area, and the discovery of fossils in one horizon rarely leads to the discovery of other material in the same place in later contexts. An additional problem is that the fossils found are overwhelmingly from animals more than 100 kg in weight - in other words, larger than most primates, including early hominids. Smaller animals are present, but found only after repeated and sustained searching.

A promising start to palaeontological and palaeoanthropological investigations of the Upper Siwaliks was made by the author, in collaboration with GSP and the Department of Archaeology, between 1985 and 1990, following on from earlier work conducted with the Department of Archaeology between 1980 and 1983 (Ashfaq and ul-Haq 1988, Dennell 1993, Jenkinson et al. 1989). The Pabbi Hills, Gujrat District, proved to be extremely promising. Over 40,000 fossil remains were collected, of which ca. 15,000 were identifiable to taxon and/or skeletal element, from horizons between 0.9 and 2.0 million years old. Preservation was often extremely good, and three exceptionally rich fossil localities were excavated. One important result of this work is that GSP now has a useful comparative collection from the Upper Siwaliks that is available for other scholars to study. The fieldwork in the Pabbi Hills has also provided much useful information of the type and spatial distribution of fossil vertebrate remains in these kinds of fluvial landscapes.

Although hominid remains have not so far been found, indirect evidence that they were present in the late Pliocene and early Pleistocene was found in the form of stone tools. The oldest are those from Rawat, Southwest of Islamabad, which were dated initially to a minimum of 1.9 million years (Dennell et al. 1988). In the light of subsequent analyses, this date has been revised to 2.4 million years, which implies that stone tool-making in Pakistan is of comparable age to that in East Africa (Rendell et al. in press). Stone tools were also found in the Pabbi Hills, in the course of collecting fossil remains from the erosional surfaces of deposits between 1 and 2 million years old (Hurcombe and Dennell 1992), and one was found in situ in a horizon 1.2 million years old (Dennell et al. 1992). It is only a matter of time before more, and better, evidence is found.

These results are now being prepared for publication by the author, for a monograph to be completed in 1997. The author very much hopes to continue palaeoanthropological investigations of the Upper Siwaliks, both in the Pabbi Hills and in other promising areas. Fieldwork need not be on a large scale, providing it is sustained over several years. At some stage, early hominid remains more than a million years old will be found in the Upper Siwaliks of either Pakistan or India; however, they are unlikely to be found unless people look, and are prepared to search for several years.

D/119. Derbyshire, E., 1984a. Sedimentological analysis of glacial and proglacial debris: a framework for the study of Karakoram glaciers. In Miller, K.J., The International Karakoram Project, Volume 1, 347-364. Cambridge University Press.

Sediments of mixed grain sizes exhibiting multimodal particle size curves (diamictos) are widely distributed. Processes producing them include glacial deposition, periglacial solifluction, debris slide and flow, mudflow, lahar flow (volcanic) and lacustrine and marine density currents (turbidities). Glaciers and ice sheets are a major source, deposits of this origin, mostly Pleistocene age, being found over about one third of the land area of the earth.

Diamictos of glacial, periglacial and mud and debris flow origin are abundant in glaciated terrain, and they have considerable significance in the study of both pure and applied geomorphology.

This paper presents a framework for the study of Karakoram glacial and proglacial debris based on knowledge of the processes involved and the properties of sediments.

Opinions on the extent and style of the Quaternary glaciations of the Karakoram and northwest Himalaya have ranged from restricted alpine-style glaciation to extensive inundation by montane ice caps, too overwhelming by sheet ice from the Qinghai-Xizang (Tibet) Plateau. The sedimentological and geomorphological evidence underpinning these contrasting opinions is used to integrate the sedimentary record with what is known about uplift and incision rates and broad-scale changes in the regional climate. By reference to the independent record of monsoon-versus westerly strength provided by the lacustrine and loess record of central and east Asia, increasing relative relief and topographical discordance are considered as influences upon glaciation style, glacier extents, and sediment budgets since the Middle Pleistocene. Ice extent may have progressively declined with increasing constraints on glaciation limits through time, but total ice volumes during glaciations may have shown less variation as valley systems enlarged in conditions of quasi-balance between uplift and incision.

D/123. Derbyshire, E., Li, J., Perrott, F.A., Xu, S. & Waters, R.S., 1984. Quaternary glacial history of the Hunza Valley, Karakoram mountains, Pakistan. In: Miller, K.J. (ed.), *The International Karakoram Project*, Volume 2, 456-495. Cambridge University Press.

The glacial landforms and glacial and paraglacial sediments, of the upper Hunza valley were mapped and resolved into a chronological sequence on the basis of morphostratigraphy, superposition, and degree of surface weathering. Sediments recognized include fluvial, gaciofluvial, debris flow and lacustrine types together with tills of predominantly meltout origin. Sediments were analysed for particle size, projection roundness, surface texture, clast and microfabric and clay mineralogy. Weathering of surface boulders, degree of subsurface weathering, point compressive strength of boulder surfaces, desert-varnish development and percentage lichen cover were used to establish a relative chronology, the desert varnish index providing results consistent with other tests.

Eight glacial phases of varying magnitude were recognized, as follows:

A widespread glaciation, leaving isolated and deeply weathered erratics on summit surfaces above 4150 m altitude. This occurred when valleys were much less incised and is considered to be the earliest Pleistocene glaciation represented in the area and termed Shanoz.

(2) and (3) A second series of valley glaciations (c. 2500m) was recognized from weathered till remnants on benches in the main Hunza valley. These are attributed to the Yunz and Borit Jhell glacial stages, the former being older than 139, 000 yr BP (TL dating of lake silts) and correlated with the penultimate Pleistocene glaciation. The Borit Jhell glaciation filled the high diffuence cols and is dated (TL) as early last Pleistocene glaciation.

A stage of 'expanded foot' and minor valley glaciation (Ghulkin I); this is younger than 47,000 yr (TL). A more limited glacial advance of several km, blocking the Hunza River, occurred in the Ghulkin II stage; considered to be a late phase of the last Pleistocene glaciation. A glacial extension of 1-2 km left larger, well defined moraines with well varnished and weathered surfaces (Batura stage; considered mid-Holocene). A minor advance restricted to tributary valleys is indicated by mildly varnished moraines (Pasu I). It is bracketed by 14C dates of 840±80 and

325±60 yr BP. Minor oscillations of 19th and 20th centuries, which left sharp, unweathered metastable moraine forms and termed the Pasu II stage.

D/127. Derbyshire, E. & Owen, L.A., 1997. Quaternary glacial history of the Karakoram Mountains and Northwest Himalayas: a review. *Quaternary International*. 38–39, 85–102.

The style and extent of glaciation in the NW Himalayas and Karakoram Mountains of Pakistan, and the Himalayas in NW India are reviewed. At least three glacial events, progressively less extensive with time, can be recognised in most regions. The timing and status of these glacial successions is poorly known. This is partially due to poor dating constraints, but also arises from a lack of adherence to strict stratigraphic procedures. Recommendations are made for a more rigorous approach to the study of Himalayan Quaternary glacial histories.

D/129. Dercount, J., Zonenshain L., Ricov, I.E., Kazmir, V.G., Le Pichon, X., Knipper, A.L., Grandjacquet, C., Sborschchikov, I.M., Geyssant, J., Lepvrier, C., Pechersky, D.H., Boulín, J., Savosin, L.A., Sorokhtin, O., Westphal, M., Bezhenov, M.L., Lauer, L.P. & Biju-Duval, B., 1986. Geological evolution of the Tethys Belt from the Atlantic to the Pamirs since the Liassic. *Tectonophysics*, 123, 241–315.

We discuss nine palinspastic geological maps (Plates 1-9) at 1/20,000,000 scale, which depict the evolution of the Tethys belt from the Pliensbachian (190 Ma) to the Tortonian (10 Ma). A Present structural map (Plate 10) is shown for comparison at the same scale with the same conventions. Our reconstructions are based on a kinematic synthesis (Savostin et al., 1986). a paleomagnetic synthesis (Westphal et al., 1986) and geological compilations and analyses concerning in particular the western domain (Ricou et al., 1986), the eastern passive margins (Kazmin et al., 1986a), the eastern active margins (Kazmin et al., 1986b) the Black Sea-Caspian Sea basins (Zonenshain and Le Pichon, 1986) and the ophiolites (Knipper et al., 1986).

A key feature of our reconstructions is that we have adopted on the basis of the paleomagnetic synthesis, a unique 30° counter-clockwise rotation of Apulia with respect to Africa between 130 and 80 Ma. Before 130 and after 80 Ma, Apulia was rigidly linked to Africa. Between 130 and 80 Ma, Apulia collided with Eurasia to the north and separated from Africa to the south. The separation of Apulia from Africa resulted in the formation of the Mesogea, which included the present Eastern Mediterranean. Concerning Iberia, the kinematic solution indicates that it moved with Africa between 110 and 54 Ma. Between 130 and 110 and between 54 and 35 Ma, Iberia moved independently of both Africa and Eurasia. Prior to 130 and after 35 Ma, Iberia belonged to Eurasia. In the Late Triassic, pieces of Gondwana collided with Laurasia and as a result the Paleo-Tethys Ocean disappeared. A Neo-Tethys ocean opened to the south within Gondwana and reached Pangea to the west where it ended in sphenochasm.

During the Mesozoic and Paleogene, most of the consumption of surface in the Tethys area was the result of subduction of oceanic or highly thinned continental crust although continental collision occurred as early as the Lower Cretaceous to the north of Apulia and the Middle Eocene to the north of Arabia. However, distension and oceanic accretion played a major role in redistributing oceanic space within the shrinking Tethys belt during the Mesozoic. A northern 3000 km long intra-continental east-west system of deep oceanic basins which we interpret as marginal basins ^{s1} extended from the Valaisan trough and Carpathian basin to the west to the South Caspian basin to the east, between the Upper Jurassic and the Upper Cretaceous; it has since been progressively destroyed. A southern oceanic belt extended from the opening Central Atlantic to the shrinking Neo-Tethys. The connection between the Neo-Tethys and the Central Atlantic occurred first through a North Apulian seaway (the Maghrebian-Ligurian Sea) formed during the Jurassic and completely destroyed at the end of the Cretaceous.

At the same time as the North Apulian seaway was almost completely destroyed the accreting Neo-Tethys plate boundary was subducted below Eurasia. The accreting plate boundary system jumped to the south in the Middle-Upper Cretaceous; it resulted in the formation of a South Apulian seaway (Mesogea) and extended along the northern border of Arabia within the Neo-Tethys. This new accreting plate boundary was shortlived and its eastern Neo-Tethys portion was abducted over the Arabian margin at the end of the Cretaceous. During the Paleogene, the consumption of surface was mostly the result of oceanic subduction without oceanic accretion and at the beginning of the Neogene, with the collision of India with Eurasia, the Neo-Tethys ocean had essentially disappeared. From then on consumption of surface mostly occurred by shortening through continental collision processes. However, new oceanic accretion was initiated in the western Mediterranean. Thus, even in the Present mostly continental collision stage, the few remaining oceanic bodies (Mediterranean Sea, Black Sea and Caspian Sea, Gulf of Oman) still play a significant role in the establishment of the strain pattern.

D/130. Derry, L.A. & France-Lanord, D., 1996. Neogene Himalayan weathering history and river ⁸⁷Sr/⁸⁶Sr. Impact on the marine Sr record. *Earth and Planetary Science Letters* 142, 59-74.

Clastic sediments in the Bengal Fan contain a Neogene history of erosion and weathering of the Himalaya. We present data on clay mineralogy, major element, stable and radiogenic isotope abundances from Lower Miocene-Pleistocene sediments from ODP Leg 116. Nd and Sr isotope data show that the Himalayan provenance for the eroded material has varied little since > 17 Ma. However, from 7 to 1 Ma smectite replaces illite as the dominant clay, while sediment accumulation decreased, implying an interval of high chemical weathering intensity but lower physical erosion rates in the Ganges-Brahmaputra (GB) basin. O and H isotopes in clays are correlated with mineralogy and chemistry, and indicate that weathering took place in the paleo-Gangetic flood plain. The ⁸⁷Sr/⁸⁶Sr ratios of pedogenic clays (vermiculite, smectite) record the isotopic composition of Sr in the weathering environment, and can be used as a proxy for ⁸⁷Sr/⁸⁶Sr in the paleo-GB basin. The Sr data from pedogenic clays shows that river ⁸⁷Sr/⁸⁶Sr values were near 0.72 prior to 7 Ma, rose rapidly to 2.074 in the Pliocene, and returned to 0.72 in the middle Pleistocene. These are the first direct constraints available on the temporal variability of ⁸⁷Sr/⁸⁶Sr in a major river system. The high ⁸⁷Sr/⁸⁶Sr values resulted from intensified chemical weathering of radiogenic silicates and a shift in the carbonate-silicate weathering ratio. Modeling of the seawater Sr isotopic budget shows that the high river ⁸⁷Sr/⁸⁶Sr values require a ca. 50% decrease in the Sr flux from the GB system in the Pliocene. The relationship between weathering intensity, ⁸⁷Sr/⁸⁶Sr and Sr flux is similar to that observed in modern rivers, and implies that fluxes of other elements such as Ca, Na and Si were also reduced. Increased weathering intensity but reduced Sr flux appears to require a late Miocene-Pliocene decrease in Himalayan erosion rates, followed by a return to physically dominated and rapid erosion in the Pleistocene. In contrast to the view that increasing seawater ⁸⁷Sr/⁸⁶Sr results from increased erosion, Mio-Pliocene to mid-Pleistocene changes in the seawater Sr budget were the result of reduced erosion rates and Sr fluxes from the Himalaya. This contribution is on

samples collected in ODP rather than related directly to northern Pakistan, but it has relevance to the area and is therefore included.

D/137. Desio, A., 1953~1955. The Italian Expedition to the Karakoram (Himalaya): preliminary geological petrographical information on the basin of the Baltoro glacier.

After a reference to previous information, the authors give a preliminary description of the geological structure of the Baltoro basin, with particular stress on the main petrographic problems. The geological structure of this area is characterized by a big pluton of granitic nature outcropping widely in the western section. The metamorphic rocks (prevalently gneiss) of the K2 and Falchan Kangri are directly related. Another smaller intrusive mass, of a dioritic facies, occurs in the later group, while the semimetamorphic series, of sedimentary origin, and referable to the upper Paleozoic and Mesozoic, form the main part of the Gasherbrums group and a part of the Falchan Kangri and of the western slopes of the Godwin Austen glacier.

D/145. Desio, A. (Leader), 1954-1991. Italian Expeditions to the Karakorum (K2) and Hindukush. Scientific Reports, ISMEO, Milano.

The Italians have contributed to our understanding of the geology, geography, and other aspects of the Karakoram Mountains more than any other. Apart from the earlier voyages for scientific work, contributions of which are reported in this work at different places, a series of expeditions were conducted in the leadership of Professor Ardito Desio. The following account is a verbatim copy of the preface that Desio wrote for Volume 1.

This volume is the ninth in the series of Scientific Reports of the Italian Expeditions to the Karakorum and Hindu Kush organized under Desio's leadership from 1953 to 1975. The list of contents of this collection, which is given at the beginning of each volume, gives the first subject as geography, which means that this volume should in fact have been published first. However, for a number of reasons which will be mentioned later, it is one of the last to be printed. Here below are the titles of the eight volumes already published.

I.—GEOGRAPHY

- Vol. 1: 1st part – Geographical features of the Karakorum by A. Desio.
 2nd part – Meteorological observations of Desio's 1954 Expedition by F. Petrucco.
 3rd part – Geodetic and topographic survey of Desio's 1954 expedition.

II. - GEOPHYSICS

- Vol. 1: Geophysics of the Karakorum by Antonio Marussi, 1954.

III. – GEOLOGY – PETROLOGY

- Vol. 1:** Geology and Petrology of Haramosh-Mango Gusor Area by Bruno Zanettin, 1964.
Vol. 2: Geology of the Baltoro basin by Ardito Desio and Bruno Zanettin, 1970.
Vol. 3: Geology of Central Badakhshan (North-East Afghanistan and Surrounding Countries) Ardito Desio Editor, 1975.
Vol. 4: Geology of the Shaks gam Valley, North-East Karakorum, Xinjiang (Sinkiang) by Ardito Desio, 1980

IV. – PALEONTOLOGY – ZOOLOGY – BOTANY

- Vol. 1:** 1st part – Fossils of Karakorum and Chitral by M. Amoit, R. Ciry, N. Fantini Sestini, I. Premoli Silva, C. Rossi Ronchetti, P. Sartenaer, A. Vandercammen, A. Von Schuppe, C. Zanin Buri.
 2nd part – Results of the study of the entomological collection of the Karakorum and Hindu Kush (1954-1955) by E. Gridelli and G. Muller with collaborators.
 3rd part – List of Spermatophyta collected in the Karakorum above 4000 m (1953-1954) by L.H.J. Williams, 1965.
Vol. 2: Fossils of North-East Afghanistan: Carboniferous fossils by A. von Schoupe – Triassic Fossils by P.D.W. Barnard – Jurassic fossils by C. Rossi Ronchetti – Cretaceous and Paleogene fossils by A. Berizzi Quarto di Palo and I. Premoli Silva, 1970.

V. – PREHISTORY – ANTHROPOLOGY

- Vol. 1:** Prehistoric research in North-Western Punjab – Anthropological research in Chitral by Paolo Graziosi, 1964.

As can be seen from the list given above, not all the subjects planned were carried out in a uniform manner. This was the result of the fact that some of the research, such as the geological work, was given precedence. In actual fact other work, such as the geophysical research would have benefited from further collaboration in the scientific reports. It should be remembered with regard to this, that the only volume published on this subject refers principally to the results of the 1954 expedition, while the same research in fact also carried out geophysical research during the 1955 and 1961 expeditions. Only brief notes actually appeared on these expeditious though a further volume was to have been published on this subject. Again, in the Prehistory-Anthropology section, a second anthropological volume was planned on the population of the Hunza valley by Prof. Paolo Graziosi. Unfortunately, in 1954 when he tried to reach me a month later, he was unable to obtain a permit to travel to the valley.

I should like to point out that while the previous seven volumes of this series deal with the scientific results of my expeditions in the Karakorum and Hindu Kush area from 1953 onwards, the eighth book reports on an area I explored back in 1929 in the capacity of geographer and geologist of the Italian Geographical Expedition led by Aimone di Savoia-Aosta, Duke of Spoleto, and organized on behalf of the Italian Royal Geographical Society and the Milan City Administration. An official volume on this expedition was published in 1936 with the title 'La Spedizione Geografica Italiana nel Karakorum – 1929. Storia del viaggio 'Risultati Geografici'.

The reason why I thought it appropriate to publish the volume on the valley Shaks gam lies in the fact that the geological results of the expedition had been mentioned very briefly in the 1936 volume, which was basically devoted to illustrating the geographical results. On the other hand, I was in fact the only geologist on that expedition and it was therefore my task to detail the results achieved in field, despite the fact that there was very little to add in the way of new discoveries as I stated in the preface to the above volume. This is why I decided to include in the collection a work which refers to an earlier expedition, than those I organized.

Starting from 1953, I organized and led several scientific explorations in the Karakorum and Hindu Kush and more precisely in 1953, 1954, 1955, 1961, 1962, 1973, and 1975. The last two had purely geological aims, while the 1954 expedition had two programmes to fulfill: a climbing programme which led to the first ascent of K2, and a scientific programme which was carried out not only in the Baltoro glacier basin and in the Stak valley, an affluent of the Indus, but also in the territory, lying between the two.

The volumes so far published do not illustrate all the results of research carried out in that area. Owing to intense scholastic and scientific duties, nothing has been published on the far western area of the Karakorum and on the

eastern side of the Hindu Kush though I and some collaborations have published preliminary reports. Some information, however, is included in the volumes dedicated to Paleontology.

I am now planning the tenth volume of this collection to be devoted to the results of glaciological research carried out during my expeditions in that area of Central Asia which have so far only been occasionally and sporadically reported.

The purpose of this volume is to report the results of observations and measurements of different types made mainly during the 1954 expedition. The geodetic and topographic measurements carried out by the captain (now general) Francesco Lombardi of the Italian Military Geographical Institute are of particular importance. The Institute was entrusted with the task, and theirs is the merit of drawing up the four topographic maps included in this volume.

I considered it useful to include the meteorological data as a contribution to knowledge of the climate of the region as recorded day by day at the base camp of K2 and in the surrounding areas during the months of May, June, July and August of 1954, principally at an altitude of 5000 m. The data was processed by Dr. Francesco Petrucco during her undergraduate studies under the direction of Prof. Silvio Polli, professor of Technical Physics and Climatology of the University of Trieste.

Before concluding this preface I should like to thank all those who have collaborated on this volume, in particular the authors of the two chapters mentioned above and the Italian National Council of Researches and the Finmeccanica which contributed to financing this volume.

Ardito Desio

This is an account of paleontology of the Baltoro basin sedimentary rocks. Calcareous fossils of Early Paleozoic are described.

Key Words: Paleozoic, Baltoro, Karakoram.

D/148. Desio, A., 1955c. The ascent of K2. The Geographical Journal, vol CXXI, pte 3^a, 261-273pp., 6 fig., London, September 1955.

The Italian 1954 Expedition under the leadership of Ardito Desio was the first to climb K2, the highest peak (8611 m) of the Karakoram, second only to the Mount Everest (8840 m) in the Nepal Himalaya. The conquest was, indeed, unique because K2 is considered a very difficult peak from the point of view of mountaineering. This is one of several narratives of the expedition to which references are given above and in the following.

Key Words: K2 ascent, Karakoram.

The valleys of Chitral, Dir and Swat, now drained by the Kunhar, Panjkora and Swat rivers, respectively, were extensively affected by Quaternary glaciation. This is one of the earliest account of glaciation (morphology, glacial deposits, etc.) in the three valleys.

Key Words: Quaternary glaciation, Panjkora, Swat, Chitral.

D/155. Desio, A., 1962. Appunti geologici preliminary sui bacini dei ghiacciai Biafo e Hispar (Karakorum-Himalaya). *Bollettino della Societa Geologica Italiana* 81, fasc. 1, 69-84, 6 fig.

The Biafo and Hispar are two of the longest glaciers of the Karakoram Range. This is a preliminary account of the geology of the basins of the two glaciers. After having shortly examined the precedent studies on the considered territory, the Author illustrates compendiously the geological constitution of the basins of the Biafo and Hispar glaciers, by reporting the data which he collected in 1954 on occasion of a trip from the village of Askole as far as the Hunza town, crossing the Hispar pass.

The determinations of the samples collected along the way were made by B. Zanettin. The lower portion of the Biafo basin is composed by a metamorphic formation chiefly formed by gneiss, garnetiferous mica schist and crystalline limestone (Dumordo Formation). The upper portion is formed by granite followed by bands of migmatite. The Dumordo Formation appears also in the lower valley of the Hispar glacier. Upstream prevails another metamorphic formation, richer in gneiss (K2 Gneiss), and poorer in crystalline limestone. In the north-western portion of the Hispar basin and south of the Hispar pass outcrop the granite, here too followed by more or less thick bands of migmatite. The formations are folded; the Dumordo Formation more intensely than the other ones. In the Biafo basin there is a sequence of anticlines and synclines roughly directed east-westwards. Other folds with the same direction have been identified in the lower Hispar.

Key Words: Geology, glaciers, Biafo, Hispar, Karakoram.

D/174. Desio, A., 1977a. Correlation entre les structures des chaines du Nord Est de l'Afghanistan et du Nord-Ouest du Pakistan. *Societe Geologique France, Memoirs* 8, 179-188.

In order to proceed to the structural correlations between the mountain chains of NE Afghanistan and chains of the NW Pakistan, both the regions have been divided in tectonic zones, on the ground of their stratigraphic compos and of their tectonic structure which express their geological evolution. The tectonic zones have been grouped in relation to the age in which the last orogenic phase (that is to say Hercy Cimmerian and Alpine), happened. Each zone has been separated from the surrounding zones by some of the deepest and persistent faults.

The NE Afghanistan has been divided in two folding areas the Hercynian one west and south-westward, and the merian one east and south-eastward. In the first area three tectonic zones have been distinguished. From the west to the they are : a) Surkhab zone ; b) Fayzabad zone ; c) western Hindu Kush zone.

The mean fault of the Badakhshan and that of Herat (or Hari Rud) delimitate the Hercynian zones from the Cimmones. The last ones are represented by : a) Safed Khers zone ; b) South eastern Badakhshan zone ; c) Nuristan zone. All these are to be correlated with the tectonic zones of Pamir; except the western Hindu Kush.

In north-western Pakistan two tectonic zones have been distinguished: a) Eastern Hindu Kush zone; b) Karakorum: Southward there is the Kohistan zone. The former is included in the early Alpine folding, the latter in the late Alpine folding former represents the north-eastern part of the Nuristan zone, the latter doesn't find any correlation in Afghanistan, as its metral faults close before reaching the frontier. The Kohistan zone is to be related with the tectonic zones of the central south Afghanistan and then it's out of the examined area.

The present structure of the region is the consequence of the tectonic splitting up during the geological time reach and reelaborated in consequence of the collision of the Indian and the Arabic plates with the Euroasiatic plate.

Key Words: Structure, tectonics, Afghanistan, Pakistan.

Blueschist occurrence in Shangla area of Swat was the first of its type reported in the Indus suture zone. Dated at mid-Cretaceous, the blue amphibole occurs in a number of lithologies. Its occurrence is attributed to northward subduction of the Indian plate.

Key words: Blueschists, High-pressure metamorphism, Indus Suture, Swat.

D/177. Desio, A., 1978. On the geology of the Deosai Plateau (Kashmir). *Memorie dell'Accademia Nazionale dei Lincei*, Series 8, Volume 62, 15, 1-19.

Desio visited the Deosai area and studied the rocks previously described in some detail, (Wadia 1937). He provided additional details on the geology and structure of the area (also known as Little Tibet) and petrography of the rocks which show low grade alteration. He also mentioned the occurrence of andesite among the volcanics. Desio presented a geological map covering the area between Skardu, Astor, Kalapani, Dras, Kargil, and Parkutta, however, the central part of this area was not covered. He described a great number of rock types including sediments of various ages including Precambrian, cal-alkaline plutonic rocks, gneisses and schists and so on.

Key Words: Geology, maps, Deosai Plateau, Kashmir.

The Karakoram mountain range is divided into five zones. The central zone, a granitic batholith, is the core of an anticlinorium. The northern zone contains mostly unmetamorphosed rocks of the Paleocene to Late Cretaceous age. The southern zone is mainly composed of metamorphic Paleozoic (or Precambrian) to Upper Tertiary formations. Farther to the south are two other zones, one to the east (Ladak-Deosain zone), and the other to the west (Kohistan zone) of the Nanga Parbat Haramosh Massif. This massif is oriented perpendicular to the main Karakorum trend and penetrated deeply into the southern zones. It is interpreted as the most prominent spur of the old Indian continent. The tectonic evolution of the Karakorum is related to the Indian subcontinent's northward displacement and collision with Eurasia along the Upper Indus Suture Line and, to the west, the Kohistan line. The main tectonic phase began in Cretaceous and continued through the Tertiary; the upheaval of the mountain belt began in the late Neogene and is still occurring.

This article is a detailed account of the geography of the Karakoram and contains 59 illustrations. These and the text cover the origin of the names of the mountain, its orography, drainage, subdivision into mountain ranges, the boundaries of the Karakoram and the location of the range in regional tectonic framework. The author also gives a useful summary of the scientific activity of Italians in the exploration of the Karakoram before the Second World War (10 pages), followed by a brief history of Desio's expeditions to the Karakoram and eastern Hindu Kush (5 pages), and topographic maps surveyed by Italian expeditions in the Karakoram (14 pages). These last pages also show excellent maps of some major glaciers. The account is followed by an extensive, but not complete, list of publications (302) by the Italian expeditions to Karakoram, and NE Hindukush, and a list of the five major maps produced earlier.

D/200. Desio, A. & Martina, E., 1972. Geology of the upper Hunza valley, Karakorum, West Pakistan. *Bulletino della Societa Geologica Italiana* 91, 283-314.

The Paleozoic and Mesozoic sedimentary rocks of the area have been described together with some description of the Late Cretaceous granite intrusions. The authors produced the first geological map of the upper Hunza valley, and the sedimentary formations were shown as following:

Misgar Slate

Kilik Formation

Gircha Formation

Passu Slate

Gujhal dolomite

Shanoz conglomerate.

This paper describes the geology of the region explored during the summer of 1962 by the DESIO's Upper Hunza expedition. The northern boundary is represented by the Pakistan-China border; the southern boundary by the axial batholith of the Karakorum range. The igneous rocks have been divided as follows: Giraf Syenite (Eocene), Granodiorite of the axial batholith (Pliocene), with pegmatite and aplite stocks and dykes (Late Pliocene); Syenite porphyry and amphibolite dykes crossing the Misgar Slates, the Gircha Formation and the Gujhal Dolomite. The metamorphic rocks have been divided in the Dumordo Formation and the migmatic plagioclase-gneiss of unknown age outcropping to the south of the batholith.

The sedimentary formations of Palaeozoic and Triassic age have been sub divided as follows: Misgar Slate, probably the oldest, Kilik formation of uncertain stratigraphic and tectonic position, Gircha Formation with Permian megafossils and microfossils, Pasu Slates of uncertain stratigraphical position and Gujhal Dolomite, Triassic and possibly Lower Jurassic.

The tectonic structure of this region is characterised by overthrust, folded and faulted blocks with the fault-planes generally dipping south on the northern side of the Karakorum range (Batura ridge), and in the opposite direction on its southern side. The strike of the tectonic units is north-west that is parallel to the axis of the axial batholith.

The stratigraphy of the Upper Hunza valley is similar to the stratigraphy of the Shaksam valley. The two valleys are located to the north of the Karakorum axial batholith. In the Upper Hunza valley and in some tributary valleys, remnants (till) of two, and probably three, glaciations associated with fluvio-glacial deposits are present.

In the summer 1971 during the exploration of the middle Indus valley between Chilas and Besham Qila, three huge end moraines of the Pleistocene Indus glacier were discovered. The uppermost deposit blocks the bottom of the valley near Gunar (1220 m a.s.l.), the second near Dudishal (840 m), and the third near Shatial (800 m). The first is more recent than the other two. Some more recent end moraines were discovered in the lower Gilgit valley, near Dak Chanki and upstream of Gilgit town. The above end moraines are to be referred to three different Pleistocene glaciations for their different location and state of preservation.

Outcrops of blueschists occur in the Indus suture *mélange* at Shangla, Swat. Petrography and tectonic significance of the rocks is described. Blueschist metamorphism has an age of 85 Ma (K-Ar muscovite) and is related to subduction.

Key Words: Indus suture, blueschists, Swat.

D/212. Desio A., Tongiorgi, E. & Ferrara G., 1964. On the geological age of some granites of the Karakorum, Hindu Kush and Badakshan (Central Asia). *Proc. 22nd Int. Geol. Congress*, 11, 479-496.

The authors report Rb-Sr dates on 22 samples of granitic rocks of the region. Sample numbers and dates are plotted. The cores of the Karakorum and Hindu Kush ranges are mostly composed of granite and granodiorite, which form large arches around the vertex of Himalayan syntaxis. Smaller granitic bodies crop out laterally from the main arches.

Previously, the age of the granitic rocks was known only locally by means of stratigraphic methods. The authors present new data about the age of the granites obtained by the Rb/Sr method. They found granites of seven different ages belonging to the Lower Triassic (Hercynian); Upper Triassic and Upper Jurassic (Cimmerian); and Upper Cretaceous, Oligocene, Miocene and Pliocene (Alpine).

D/222. De Terra, H. & De Chardin, P.T., 1936. Observations on the upper Siwalik Formations and later Pleistocene deposits in India, Proceedings American Philosophical Society, 76, 791-822.

The authors detailed the relationship of the Siwaliks to later Pleistocene sediments deposited in from of the Himalayan orogeny. They consider the 'Boulder Conglomerate stage' as the uppermost unit of the Siwalik group. They place this unit in the Middle Pleistocene and associate it with the second glaciation of Kashmir. The Punjab erratics are closely correlated with the deposits of the Boulder Conglomerate stage. They are thought to have been jointly carried with the coarse deposits of the conglomerate during catastrophic floods due to the breakthrough of lakes dammed by the ice in the Upper Indus basin. This is likely to have happened during the withdrawal period of second glaciation when the erratics may have been moved along the Indus at a time when the river running at the foot of mountains followed the course of the present Haro river rather than at its present course. The authors deny the presence of a large lake in the northern Punjab at the time when erratics were scattered.

According to these authors, the 'Boulder Conglomerate stage' is followed with disconformity by the series 'Potwar silt' formed of sand and gravels at the base (known as 'Potwar gravel') and of silt for approximately 100 mIt is considered to be a deposit of the loess-type having been reworked by runoff and stream flow waters. The 'Potwar loessic silt' is attributed to the Late Pleistocene and correlated with the 3rd glaciation of Kashmir. [Authors' Comments: This description is a nearly verbatim copy of the account given in Desio and Orombelli, 1983, p. 141-142].

The Swat valley has been a cradle of the Gandhara civilization. There are many ruins, statues and artifacts, some of which are preserved in the Museum of Archeology and some in Butkara near Saidu Sharif. These have been the subject of long studies by Facenna and his colleagues. Many of the remains comprise low-grade metasediments (graphitic schists, greenschists, dolomite-talc rocks, serpentinite, granitic rocks, etc. These have been extracted from the nearby terrain belonging to the Indian plate and the Indus suture mélange north of Mingora.

Traces of ancient quarries are widespread in Lower Swat. Two type of quarry work were found: a) scattered excavations in the zone surrounding Buddhist sacred areas, which provided rocks (phyllites, calc-schists, gneisses) for common building use; b) intensive excavations in the areas with exposures of prized rocks such as soapstone, chlorite-schists, and talc schists, which were used for the facing of walls and for sculptures and decorations. In both types of quarry, blocks and discs were detached directly from the outcrop by chiseling and levering. A quarry village (Swegalai) was found in the main quarry area.

In addition to quarries, traces of excavation such as tanks for working «stucco» (a kind of plaster), small outcrops possibly for milling materials, and cooling instruments and cavities for preserving food were found. The map of the Indus suture is also given.

D/241. Din, F. & Rafiq, M., 1997. Correlation between compressive strength and tensile strength/index strength of some rocks of North-West Frontier Province (Limestone and Granite). *Geological Bulletin, University of Peshawar* 30, 183-190.

The use of the building stones is increasing day by day and engineering activities are also in progress. Therefore the mechanical properties of building stones such as limestones, marbles, granites etc are required to be investigated to estimate the strength and give recommendations in designing safe structures. The present research deals with the investigation and correlation of compressive, tensile and index strength of granites and limestones from different localities of North-West Frontier Province. The test results are given in table 1-2, which reveal suitability of Shahbaz Garhi micro granite for heavy constructions and in foundations of buildings while Malakand granite in light constructions, crushed stones, floor material and ballast under railway tracks. The strength values of Cherat and Kohat limestones are low, and very much suitable for cement, chemical industry and ballast under roads.

D/242. Din, F., Rafiq, M. & Mohammad, N., 1993. Strength properties of various building stones of NWFP, Pakistan. *Geological Bulletin, University of Peshawar* 26, 119-126.

Domestic resources of both dimension and crushed stones used for construction and adequate to fulfil the expected demand indefinitely in N. W. F. P. Various types of building and decorative stones including limestone, marbles, granite, granitic gneisses, slate, quartzite, dolerite, gabbro, serpentinite etc., are found in large amount in NWFP. Geotechnical properties of these rocks including compressive strength and tensile strength show compatible values to the recommended ASTM range for Thana marble, microporphyrates of Shewa Shahbaz Ghari, Marbles of Nowshera and Pir-Sabak, limestones of Kohat, Cherat and Nizampur areas, and granites of Ambela, Utlā and lower swat. Higher values for compressive, tensile and shear strength are for slate from Attock and Cherat ranges. Though the shear strength values for most of these rocks are low, they are free of geotechnical defects.

The data is useful not only for those using these rocks as building and foundation stone and crushed and broken material but also for those interested in designing openings in these rocks.

Key Words: Geotechnical, building stones, NWFP.

D/243. Din, F., Rafiq. M. & Mohammad, N., 1995. Triaxial study of granites and limestones from north and south of Peshawar Basin, NWFP, Pakistan. Geological Bulletin, University of Peshawar 28, 15-25.

Determination of uniaxial and triaxial strength of different building stones is important both from practical as well as academic point of views. Triaxial testing is the most appropriate method, which provides identical field conditions. In order to achieve this objective, granite and limestone from four different localities (Malakand granite, Shahbaz Garhi granite, Kohat limestone and Cherat limestone) were selected to carry out triaxial tests.

Four samples of each rock, having length-to-diameter ratio of about two were tested under confining pressure of 0-30 MPa range. The observations made and results obtained are plotted and after drawing Mohr's envelope for each rock shear strength is calculated corresponding to different triaxial confining pressure. The finding of the study are summarized in the form of conclusion and recommendations at the end of the manuscript.

D/245. Din, N., 1997. Petrography, geochemistry and provenance of Kuldana Formation, Kohat basin, Pakistan. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, 85-89.

The Kohat Basin constitute the westernmost part of the Himalayan foreland basin. It is bounded to the north by Main Boundary Thrust and to the south by Surghar Range Thrust. The Kalabagh Fault and Kurram Fault forms the eastern and western boundaries of the basin respectively. Stratigraphically the Kohat basin consists predominantly of Eocene and younger rocks. The Kuldana Formation is the part of Eocene strata and well-exposed in the whole Kohat basin. It generally consists of about 95% uniform red shale and 5% channel sandstone. The formation is continental and fluvial facies, and has been interpreted as a deposit of poorly developed system of small streams by Wells (1983).

A section of Kuldana Formation, near Bahadurkhel village in central Kohat basin, was measured and sampled. The section is 110 meters thick and consists of red clays with subordinate sandstone and granulestone. Sandstones are brownish red to red on fresh surface while dark red on weathered surface. Sandstones are fine to coarse grained, thin to medium bedded and calcareous. In sandstone various sedimentary structures, like cross-beddings, sole marks, graded beddings are present. The formation is devoid of any mega-fossil. The basal contact of the formation with Jatta Gypsum is mostly covered by recent debris while upper contact with Kohat Formation is conformable. The samples from the sandstone beds of the Kuldana Formation was studied in detail.

PETROGRAPHY: The petrography of sandstones of Kuldana Formation reveals that they are immature both mineralogically and texturally. The quartz and lithics are the dominant mineral along with subordinate feldspar. Quartz grains are mainly monocrystalline, however, polycrystalline variety is also present. Quartz grain are generally devoid of inclusions and show non-undulatory extinction. The detrital lithics consists of sedimentary and

volcanic lithics while metamorphic lithics are virtually absent. Sedimentary lithics constitute 80-85 percents of the total lithic fraction and include fragments of limestone, granules, shale and fossil. Volcanic lithics are mainly volcanic glass and altered rock fragments. The feldspar content of Kuldana sandstone is very low. Hematite, limonite and siderite are dominant opaque heavy mineral present. Calcite is the major cementing material. The texture of sandstones is typical of litharenite. The grains show point and concavo-convex contacts. The sandstones are poorly sorted. Grains are mostly subrounded to subangular.

Modal composition of ten sandstone samples of Kuldana Formation was determined by point-counting. The point-counting was done according to Ghazzi-Dickinson point-counting method (Ingersoll et al., 1984) to determine the proportion of monocrystalline and polycrystalline quartz types (Q), feldspars (F) and lithics (L). The modal composition of the sandstones is given in Table I. QFL diagram after Folk (1968; Fig. 1) shows that sandstones fall in litharenite category.

GEOCHEMISTRY: The geochemical analysis of sandstone of the Kuldana Formation for major elements was done by XRF (Table 2). The $\text{SiO}_2/\text{Al}_2\text{O}_3$ and $\text{Na}_2\text{O}/\text{K}_2\text{O}$ ratios plot (after Pettijohn et al. 1985, Fig. 2) shows that sandstones fall in "Sublitharenite" field. This difference in sandstone classification from the petrographic classification is probably due to slightly high values of Al_2O_3 contributed by clay. The chemical analysis shows that the variation in the proportion of major oxides across the sequence are appropriate to those of modal analysis. The higher content of quartz and carbonates (lithics) with small amount of feldspar in modal composition are compatible to higher quantity of SiO_2 and CaO , and lesser Al_2O_3 , Fe_2O_3 and Na_2O in chemical composition.

PROVENANCE: The textural and mineralogical immaturity of sandstones suggests a derivation of constituent materials under the conditions of greater mechanical disintegration and comparatively little transportation. The lack of feldspars and metamorphic lithics, and abundance of sedimentary and volcanic rock fragments imply the absence of any large area of eroding metamorphic and intrusive rocks. The presence of volcanic glass and rock fragments, and properties of quartz grains suggests a possible volcanic source. The sedimentary rock fragments that can be identified easily with the rocks of the Kohat basin section such as fragments of granules, limestone, fossil, and soft pelitic rocks, demonstrate that some materials were being supplied by local source area within the basin. In short, the petrographic studies suggests a volcano-sedimentary provenance of the Kuldana Formation.

The point-counting data was plotted on QFL provenance discrimination diagram after Dickinson (1985, Fig. 3). The data plots in the recycled orogen field of the diagram. It means that constituent material of sandstones have been derived from one of the following setting: Subduction complex; Collision orogen; Foreland uplifts (Dickinson, 1985). The high lithics percentage, high quartz ratio to feldspar, intermediate quartz content and low L_{vi} ratio indicate a collision orogen provenance (Dickinson, 1985). Thus, the modal composition of the Kuldana Formation indicates that constituent materials were derived from collision tectonic setting. The major element geochemical data when plotted on the provenance discrimination diagram after Bhatia (1983, Fig. 4) also indicate a similar tectonic regime. The paleocurrent analysis data of Kuldana Formation in whole Kohat basin reported by Wells (1983) demonstrates that depositing streams flowed into the basin from west and north. The flow from the edges of the former continental shelf of Indian plate suggests that orogeny on the continental slope had reversed the paleoslope. All these evidences from the petrography, modal composition, geochemistry and paleocurrent analysis suggests that detritus of Kuldana Formation has been derived from the collisional orogenic setting. It means that by the time of deposition of Kuldana Formation the India had collided against Eurasia or at least with Afghan microplate.

D/247. Din, S.M.U., 1990-92. Geological mapping of Nauseri-Muzaffarabad-Garhi Habibullah area and evaluation of landslide hazards on western limb of Hazara-Kashmir Syntaxis. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 52p.

A large scale (1:15,000) geological map of Nauseri-Muzaffarabad-Garhi Habibullah area was prepared and all the rocks type in the area from Pre-Cambrian to Recent were thoroughly studied and investigated. The northwestern part of Muzaffarabad and western limb of Hazara-Kashmir syntaxis is the area of high landslide hazards. Steep slopes

silty, sandy and clayey soils, heavy rainfalls, water seepages and under cutting of the river all contribute to the landsliding in the region. The instability of the area has been further increased by road widening and effect of Main Boundary Thrust (MBT), resulting in the form of major landslides such as, slumping, earthflows, rockfalls, sinkholes and combination of these. The active Lohar Gali landslide is investigated in detail because of its large size and proximity to roadways. Soil samples were collected to evaluate engineering properties of material involved in these failures. The investigated area is a limb of Hazara Kashmir Syntaxis of folded and faulted, low grade metamorphic rocks, which have been further deformed by the important Muzaffarabad fault and regionally significant Main Boundary Thrust (MBT).

D/249. Di Petro, J.A., 1991. Metamorphic pressure-temperature conditions of Indian Plate rocks south of the Main Mantle Thrust, Lower Swat, Pakistan. *Tectonics* 10, 742-757.

The Lower Swat rock sequence, in northern Pakistan, is composed of greenschist and amphibolite facies Indian plate rocks that crop out in a dome directly south of the Main Mantle thrust zone and Kohistan arc terrane. The metamorphism is Eocene to Oligocene in age and records the collision of the Indian plate with the Kohistan arc. This paper presents mineral assemblage, mineral composition and garnet zoning data on the Lower Swat rock sequence in order to estimate the pressure-temperature conditions of metamorphism and to infer a possible pressure-temperature-time path. The stratigraphic sequence consists of Precambrian to Cambrian (?) Manglaur formation unconformably overlain by late Paleozoic to early Mesozoic Alpurai group. The Alpurai group is further subdivided into the Marghazar, Kashala, Saidu and Nikanai Ghar formations. The Manglaur formation, in the core of the dome, is at kyanite grade. Metamorphic grade decreases in the overlying Alpurai group where a garnet "isograd" is mapped in calcareous schist of the Kashala formation. Mineral composition geothermometers and geobarometers indicate final metamorphic equilibrium conditions of about 600°–700°C and 9–11 kbar in the Manglaur and Marghazar formations. These conditions are associated with a phase of static recrystallization which postdates the main phases of deformation. Correlation of the structural-tectonic history with the pressure-temperature estimates, and with the garnet zoning analysis, suggests that in the Eocene the Lower Swat rock sequence was subducted to a depth of 35 to 45 km beneath the MMT suture melange. Subduction was followed immediately by exhumation. The initiation of exhumation is believed to have been triggered by a change from subduction to strike slip motion in the MMT, thereby allowing the relatively buoyant Lower Swat crust to rise. The entire metamorphic-deformational cycle lasted from 7 to 16 m.y., ending in the late Eocene about 38 Ma when the rocks cooled through the argon blocking temperature in hornblende ($\approx 550^\circ\text{C}$).

D/250. Di Pietro, J.A. & Ahmad, I., 1995. Tectonic setting of the Ahingaro serpentinite zone within the Kohistan arc complex, Swat, Pakistan. *Geological Bulletin, University of Peshawar* 28, 27-29.

In this report we discuss the tectonic significance of a large serpentinite zone that is present within the Kohistan arc complex approximately 10 km north of the Indus suture zone. We have named this the Ahingaro serpentinite zone for excellent exposures at Ahingaro Banda Kandao located along the road between Tutan Banda and Kitiarai. The serpentinite zone was first reported by Rehman & Zeb (1970) who suggested that it was tectonically emplaced within the Kohistan arc complex.

Key Words: Tectonics, ultramafics, serpentinite, Indus suture, Kohistan arc, Swat.

D/251. Di Pietro, J.A., Ahmad, I. & Hussain, A., 1997a. Field evidence on the emplacement of the Dargai mafic/ultramafic Complex, Malakand area, Pakistan. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 25-26.

The Dargai mafic/ultramafic complex is widely regarded as a klippe of Indus Suture Zone rock obducted onto the Indian plate in the Late Cretaceous or Early Cenozoic during or prior to continent-continent collision (Hussain and others, 1984, Lawrence and others, 1989). An alternative interpretation consistent with recent field mapping suggests that the Dargai mafic/ultramafic complex is not a klippe but is an imbricate slice sandwiched within Indian plate rock. This interpretation more adequately explains the contrasting stratigraphic sequences in Swat and in Malakand (Figure 1). The stratigraphy in Swat consists of Cambrian-Ordovician Swat augen/flaser orthogneiss unconformably overlain by Alpurai group which consist of Carboniferous-Permian Marghazar psammitic schist and amphibolite overlain by Early Mesozoic Kashala schistose marble and Saidu graphitic phyllite. Amphibolite and intrusive rock of any kind are virtually absent in the Kashala and Saidu Formations. The stratigraphy in Malakand consists of Precambrian Pinjkora complex unconformably overlain by Paleozoic (?) Mekhband Formation (both are new names). The Mekhband Formation consists of Kashala-like marble interlayered with amphibolite and intruded by Chakdarra orthogneiss. The abundance of both amphibolite and Chakdarra orthogneiss prevents a direct correlation with the Kashala Formation and suggests instead that the Mekhband is older than both the Kashala and Saidu Formations. Below the Mekhband Formation the Pinjkora complex consists of undifferentiated schist, marble, orthogneiss, and intrusive rock in which Swat orthogneiss is virtually absent. In the southeast part of the area the Mekhband Formation structurally overlies presumably younger Saidu Formation along a contact that is sharp but not intensely sheared relative to the surrounding rock. The contact is interpreted as a pre or syn-metamorphic fault that separates Swat stratigraphy below from allochthonous Malakand stratigraphy above. The Dargai mafic/ultramafic complex is an imbricate slice located between these two stratigraphic sections. In Figure 1, the Main Mantle Thrust (MMT) is shown as the series of faults that lie at separate amphibolite of the Kohistan arc complex from Indian plate rock and Indus melange. These faults show brittle deformation (post-Early Oligocene) with possible right-lateral oblique motion particularly in the Talash-Katgalai area where the Indus melange is cut out. The Ahingaro serpentinite zone represents a brittle deformation zone within Kohistan arc amphibolite that contains slices of serpentinite.

Key Words: Ultramafic rocks, Dargai complex, Malakand, Indian plate.

D/252. Di Petro, J.A., Ahmad, I., Hussain, A. & Isachsen, C.E., 1998. Tectonics of the Indus suture zone in Northwest Pakistan. *Geological Bulletin, University of Peshawar* 31 (Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop), 53-55.

The Indus suture zone in Northwest Pakistan is composed of three internally imbricated melange slices (Fig. 1). All three slices contain greenstone, serpentinite, talc-schist, and phyllitic schist. The "Swat" melange is characterized by blueschist; the "Dargai" melange by ultramafic rock, and the "Nawagai" melange by marble. The basal fault of each slice is the Kishora, Dargai, and Nawagai fault respectively. The Swat melange extends from the Indus syntaxis westward to Malakand where it is truncated by the Malakand slice which is an allochthonous block of metamorphosed Indian plate rock. Farther west, the Malakand slice is truncated by the Dargai melange which, in turn, is truncated by the Nawagai melange. All four of these fault slices overlie a coherent stratigraphy of metamorphosed Indian plate rock that extends southward to the Khairabad fault. The Main Mantle thrust (MMT) is the boundary between Indus melange and the Indian plate. It is therefore equivalent to the Kishora, Dargai, and Nawagai faults where these faults overlie the Indian plate and is equivalent to the Main Boundary zone (MBZ) of Beck and others (1996). The large-scale fold sequence on the Indian plate is syn-metamorphic, west-vergent, overturned folds followed by late-metamorphic, N-S-trending, open folds. This fold sequence implies that the Indian plate was affected by E-W compression throughout metamorphism and not N-S compression as is widely assumed. The Malakand, Kishora, Dargai, and Nawagai faults are syn-metamorphic faults that pre-date the metamorphic peak in the underlying Indian plate. The Swat melange appears to be the first of the slices to be emplaced. The existence of syn-metamorphic, west-vergent folds on the Indian plate suggests that emplacement may have been from the east or Northeast. Thus, the Swat melange, and the underlying Indian plate, may have been affected by the same west-southwest-vergent deformation that is preserved east of the Hazara syntaxis. The stacking sequence of the other slices suggests that the Malakand slice, the Dargai melange, and the Nawagai melange were emplaced from the west or northwest following emplacement of the Swat melange. Metamorphism on the Indian plate may have begun as early as 88 Ma based on a concordant U-Pb zircon age from Precambrian gneiss in the Indus syntaxis. This implies that metamorphism was a long-lived event that began with Late Cretaceous ophiolite abduction. Rather than initiate metamorphism, the India-Asia collision resulted in exhumation and cooling of the metamorphic pile between about 67 and 31 Ma. The Kohistan fault is a late- to post-metamorphic fault that cuts across the structural and

metamorphic fabric of the melange slices and the Indian plate. The Kohistan fault completely cuts out melange in areas east and north of the Indus syntaxis and in the area north of the Malakand slice. Final emplacement of the Kohistan is along the Kohistan fault probably occurred in the Oligocene. This emplacement, therefore, has no direct connection to the much older metamorphism that affected the Indian plate and gives no direct information to the timing of initial contact between India and Asia. West of Saidu, the Kohistan fault is a right-lateral strike-slip fault suggesting emplacement of the Kohistan arc from the west or Northwest. Following the emplacement of Kohistan, foreland structures including the Khairabad fault and the MBT transported the metamorphosed Indian plate, the Kohistan arc, and the three melange slices southward as a single block. In Afghanistan, the Kunar fault appears to truncate both the Kohistan arc and the Indus (Nawagai) melange. Indus Melange reappears south of the MBT but intervening faults suggest several 100 kilometres of displacement separating this melange from the three melange slices in the north.

Key Words: Tectonics, structure, Indus Suture.

D/253. Di Pietro, J.A., Baig, M.S., Pogue, K.R., Hussain, A. & Ahmad, I., 1995. Preliminary geologic map of the Indus syntaxis, Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

We present a preliminary geologic map of the Indus Syntaxis (Figure 1) based on 3-1/2 months field mapping by DiPietro and one month by Pogue during the Fall of 1994, unpublished mapping by the Geological Survey of Pakistan under the direction of Hussain, and previous work by the authors (Baig and others 1989, Baig 1990, DiPietro 1990, DiPietro and others 1993; Ahmad 1991, Pogue and others 1992). This research will continue, and the map revised, expanded, and completed during the next three years.

The main observations thus far are: 1) there is no major disruption of stratigraphy west of the Puran fault zone. 2) Stratigraphy is disrupted east of the Puran fault zone by post-metamorphic northerly trending faults. 3) The amount of recent uplift is greatest near the Indus River and decreases toward the west.

A large north to northwest plunging syncline dominates the area west of the Puran fault. This syncline deforms foliation and correlates with the F3 fold phase of DiPietro and Lawrence (1991). Stratigraphy differs slightly on the east and west limbs of the syncline. On the west side, the stratigraphy consists of Swat gneiss overlain by Manglaur formation (these two units are exposed west of the area shown in Figure 1) which, in turn, is overlain by a second layer of Swat gneiss. The Marghazar formation unconformably overlies the Swat gneiss and is followed by the Kashala and Saidu formations. The Kashala formation is unusually thin in the area north of Dosara (Figure 2). On the east limb of the syncline a sequence of interlayered schist, gneiss, amphibolite, and marble crop out along the west side of the Puran fault zone and form the base of the stratigraphic section. These rocks are similar to rock units in the Tanawal and Salkhala formations as described by Calkins and others (1975) along strike to the south. These rocks are intruded by an overlying layer of Swat gneiss except near Derai where the contact is a brittle fault. This layer of Swat gneiss correlates with the lower layer of Swat gneiss that is exposed on the west limb of the syncline. The Swat gneiss, in turn, is overlain by the Manglaur formation. A second layer of Swat gneiss is absent on the east limb. Overlying the Manglaur formation is a new formation named the Duma Formation. Near the middle of the area, the Duma Formation consists of an upper and lower marble member and a middle amphibolite-rich member. The marble is typically white, grey, or banded in appearance. Much of the marble is pure although phlogopite-rich marbles are common and tremolite or other calc-silicate minerals are locally abundant. Some of the marble is similar in appearance to marble in the overlying Kashala formation, however, marble in the Duma formation is interlayered with amphibolite, minor quartzite and biotite schist. These lithologies are not present in the Kashala formation within the confines of Figure 1. Where the lower contact has been observed, phlogopite-rich marble is consistently interlayered with, or gradational into, biotite schist of the Manglaur formation. Nowhere does the contact appear to be an unconformity. The upper contact is placed where white marble, banded marble, or phlogopite marble is in contact with garnetiferous marble typical of the Kashala Formation. The contact is interlayered or gradational and is consistently near the stratigraphically highest appearance of amphibolite within the Duma formation. The Duma formation can be traced southward around the nose of the syncline to the vicinity of Budal where white marble of the upper marble member pinches out or changes facies with typical dark grey marble of the Kashala formation such that the middle amphibolite member directly underlies the Kashala formation. In addition to amphibolite, the middle amphibolite member contains biotite schist and minor quartzite and marble. Lithologically it is similar to the Marghazar formation. The Marghazar formation and the middle amphibolite member are at the same stratigraphic position, therefore, they are probably the same age (Late Paleozoic). This leaves the age of the lower marble member unresolved. The middle amphibolite member thins and pinches out

toward the north where the Duma formation consists of marble with abundant thin interlayers of amphibolite. Excellent exposures of the Duma formation can be found south of Tangora and east of Alpurai. All of the rock units described above were metamorphosed at least to garnet-grade during Himalayan deformation.

The stratigraphy described above can be followed westward for at least 45 km without crossing a major fault zone (DiPietro and others, 1993). However, eastward, toward the Indus River, the stratigraphy becomes highly disrupted across a series of brittle, post-metamorphic fault zones. These include the Puran, Chakesar, Besham, and Thakot fault zones (Baig, 1990). All of the rock units within these fault zones are Precambrian in age, however, Paleozoic and/or Tertiary granitic rock intrudes the sequence particularly between the Puran and Chakesar fault zones. The faults cut across stratigraphy and show a complicated history that includes a strong component of strike slip displacement. The four major faults converge into a narrow imbricate zone in the vicinity of Kamach and Garhi. From west to east, these faults bring up progressively deeper-seated rock units that culminate with a thick section of Archean and Proterozoic basement gneisses of the Besham group between the Thakot and Besham faults. West of the Besham fault a basement-cover angular unconformity separates graphitic schists and marbles of the Karora group from the Besham group. This unconformity is probably the clearest example within the entire Himalaya of a depositional contact between true Indian shield basement rock and overlying metasedimentary rock. The stratigraphy is complicated between the Puran and Chakesar faults, however, a depositional contact between the undifferentiated Tanawal/Salkhala unit and the Karora group is exposed west of Chakesar. Thus, although disturbed by faults, it may be possible to piece together a complete stratigraphic section from Precambrian basement rock (Besham group) to the Mesozoic cover. However, the stratigraphy is further complicated by the presence of gneisses within the undifferentiated Tanawal/Salkhala sequence. In some areas, the contact between gneiss and schist appears depositional and is consistently marked by a thin sequence of marble and amphibolite. In other areas, the contact between schist and gneiss is knife sharp. One possibility is that these contacts represent pre or syn-metamorphic faults that were later reactivated and/or cut by the younger brittle faults.

The Karora and Besham groups are unique in that they do not show the strong Himalayan-age amphibolite facies metamorphism that affected all of the surrounding rock units (Treloar and others 1989, Baig 1990). The eastern limit of rock not affected by strong Himalayan-age metamorphism is sharply defined by the Thakot fault. The western limit, however, is not well defined. Rocks between the Puran and Chakesar fault zones appear to have been involved in Himalayan-age amphibolite facies metamorphism, therefore, the Chakesar fault zone is tentatively suggested as the western limit of rock not affected by this metamorphism.

The Indus syntaxis region is seismically active. Armbruster and others (1978) defined the Indus-Kohistan seismic zone as extending in a northwest direction through the Indus syntaxis at Besham as well as a second smaller seismically active area in the southern part of the Indus syntaxis surrounding Tarbela Lake. Baig (1990) identified uplifted terraces and deformed Holocene sediments near Besham and Yeats and Hussain (1989) identified late Quaternary deformation in the Tarbela Lake region. In addition, there is a clear increase in relative uplift as the syntaxis is approached from the west. The average height of stream terraces and mountain tops, for example, increases toward the Indus syntaxis. Near Budal well preserved stream terraces are 100 m above present-day stream level and, at one location, stream deposits are tilted 340° from the horizontal and are offset by about one meter along a N65E-trending fault. This fault may be part of a conjugate fracture/fault system that includes additional minor brittle faults trending N65E and N65W. It may be significant that the N65W faults are parallel with the trend of the Indus-Kohistan seismic zone.

A working hypothesis suggests that the Indus syntaxis is a strike-slip imbricate zone that formed as a tear fault associated with thrust faulting farther south in the foreland. The brittle faults may have reactivated old fracture and/or fault zones in the Precambrian basement and cut up through the overlying rock. The Besham gneiss may be a sliver of uplifted basement rock caught in the imbricate zone. The older fracture/fault zones may have formed during Late Paleozoic rifting and/or during earlier Precambrian deformation. Active uplift suggests that the Indus syntaxis is an incipient microcosm of Nanga Parbat.

Key Words: Stratigraphy, structural geology, deformation, Indus Syntaxis, Indian plate.

D/254. Di Pietro, J.A., Hussain, A., Ahmad, I. & Khan, M.A., 1999. The character of the Main Mantle Thrust in Pakistan. Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 32-33.

The Main Mantle Thrust (MMT) represents The tectonic boundary between the metamorphic shield and platform rock of the Indian plate hinterland, and dominantly mafic and ultramafic of the Kohistan-Ladakh arc complex in Pakistan. In some area, this boundary is a sharp planar fault with development of mylonite; in other areas, it is a

brittle-ductile imbricate zone; in still other areas, it contains large, discontinuous, slices of internally sheared and deformed ophiolitic melange. The major through-going fault is the Kohistan Fault, which marks the southern boundary of the Kohistan arc from the Afghan border eastward to the Babusar area (Figure 1). The Kohistan Fault is dominantly a right-lateral strike-slip Fault from the Afghan border eastward to Saidu. From Saidu to Babusar, it is a thrust fault with a strong, oblique, right-lateral component. Fault zone fabrics are dominantly brittle and cataclastic, suggesting that the Kohistan Fault is a late to post-metamorphic fault, active in the Oligocene to Early Miocene. East of Babusar, the Kohistan Fault merges with and is reactivated by, the active Raikot Fault, which marks the eastern boundary of the Kohistan arc along the western flank of the Nanga Parbat-Haramosh Massif. The Raikot Fault has been active since at least the Miocene with a strong component of right-lateral strike-slip displacement. The Raikot Fault appears to die out at the NW margin of the massif and it may be the Kohistan Fault that is folded around the north flank of the massif to continue southward as the MMT boundary between the Indian plate and the Ladakh arc along the eastern flank of the massif. In these areas, MMT is marked by a ductile mylonite zone that was active presumably in the Oligocene and Early Miocene, and which again shows a strong component of right-lateral displacement. This contact was subsequently folded, rotated to the vertical, and locally reactivated by brittle shears during exhumation of the Nanga Parbat-Haramosh Massif. Thus, along its entire trace, the Kohistan-Ladakh arc appears to have been displaced in a ESE-direction relative to the Indian plate in the Oligocene to Early Miocene.

From the Naran area eastward, the MMT is a narrow fault zone represented by the Kohistan-Raikot fault system and its continuation on the east side of the Nanga Parbat-Haramosh massif. In these areas ophiolite fragments are sparse. West of Naran, large discontinuous fault slices of ophiolitic melange appear south of the Kohistan Fault and form a separate terrane between the Kohistan arc and the Indian plate. The melange slices have traditionally been considered to be part of an MMT zone equivalent with the Indus Suture Zone. From east to west, the slices are the Shergarh, Kishora, Dargai, and Nawagai melange units (Figure 1). Also present south of the Kohistan Fault, and partly surrounded by melange, is a fault-bound slice of Indian plate rock referred to as the Malakand slice. All five slices are truncated by Kohistan Fault. Contacts between the fault slices and the underlying Indian plate are not intensely sheared relative to the surrounding rock and are folded by late-metamorphic, N-S trending folds that do not deform the Kohistan Fault. This suggests syn-metamorphic emplacement of all five slices. The age of metamorphism indicates that all of the fault slices were emplaced before 50-40 Ma. The maximum age of emplacement is unconstrained and could have occurred as early as the Late Cretaceous. Based on field relationships and stretching lineation data, we suggest that the Shergarh, Kishora, and Dargai slices correlate and that they were emplaced in a southwestward direction. The Nawagai and the Malakand slices are tentatively interpreted to have been emplaced in an E or SE-direction, implying that rotation from SW to ESE-directed transport occurred during metamorphism in western Pakistan, and well before final ESE emplacement of the Kohistan arc in the Oligocene to Early Miocene.

The Kohistan-Raikot fault system is the only through-going structure along the MMT zone. It marks the entire southern and eastern boundaries of the Kohistan arc complex and it may be the Kohistan fault that continues around to form the MMT along northern and eastern flanks of the Nanga Parbat-Haramosh Massif. The Kohistan Fault includes the best known location of the MMT at Jijal and it would seem logical to refer solely to this fault as the MMT. Restricting the definition of the MMT to the Kohistan-Raikot fault system would, however, exclude the large slices of ophiolitic melange which are part of the original definition and which are consistently referred to in the literature as part of the MMT. The Indus Melange, on the other hand, is discontinuous below the Kohistan Fault therefore, no single through-going fault could be considered to be the MMT.

Consistent with the previous usage, we suggest that the melange slices such that the MMT represents the series of faults of different age and tectonic history that collectively mark the northern edge of the Indian plate in Pakistan. Where melange slices are present, the MMT fault line would be placed south of the melange slices, and the northern boundary of the MMT (Indus Suture) zone would be marked by the Kohistan Fault. Where melange slices are absent, the MMT fault line would be represented solely by the Kohistan-Raikot fault system and its continuation along the east side of the Nanga Parbat-Haramosh Massif. This definition follows the original intent of the MMT and is consistent with how the term is used in the literature. The only difference between this definition and the original definition is that the history of the MMT is longer (extending to the active Raikot Fault) and more complicated.

Key Words: Tectonics, structural geology, Indus suture, Kohistan island arc, Indian plate.

D/255. Di Pietro, J.A., Hussain, A., Ahmad, I. & Khan, M.A., 2000. The Main Mantle Thrust in Pakistan: its character and extent. In: Khan, M. A., Treloar, P.J., Searle, M.P. & Jan, M.Q.

(Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 375-393.

The Main Mantel Thrust (MMT) represents the tectonic boundary between metamorphic shield and platform rock of the Indian plate hinterland, and dominantly mafic and ultramafic rock of the Kohistan-Ladakh arc complex in Pakistan. In some areas, this boundary is a sharp planar fault with development of mylonite; in other areas, it is a brittle-ductile imbricate zone; in still other areas, it contains large, discontinuous, slices of internally sheared and deformed ophiolitic melange. The character of the MMT along its entire trace discussed and it is concluded that there is no single continuous fault, which marks the contact between the Indian plate and the Kohistan-Ladakh arc. On this basis, we propose a revised definition for the MMT that is consistent with both the original definition and with the usage of the term in literature. We suggest that the MMT fault contact be defined as the series of faults, of different age and tectonic history that collectively define the northern margin of the Indian plate in Pakistan. On this basis, faults that define MMT vary in age from Quaternary to possibly as old as Late Cretaceous. Discontinuous lenses of ophiolitic melange that overlie the MMT fault contact, and which intervene between the Indian plate and the Kohistan-Ladakh arc, are considered to be part of an MMT zone that is equivalent with the Indus Suture Zone.

Key Words: Tectonics, structural geology, Indus suture, Kohistan island arc, Indian plate.

D/256. Di Pietro, J.A. & Isachsen, C.E., 1997. An Early Proterozoic age for Precambrian rock units in the Indus Syntaxis, NW Himalaya, Pakistan. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 137-138.

U/Pb zircon ages have been obtained from two intrusive rock complexes, the Kotla and Black Mountain complexes, that crop out in the Indus syntaxis region of the metamorphic hinterland of the Indian Plate (DiPietro and others, 1996). The Indus syntaxis is located along the Indus River generally between the village of Besham in the north and Tarbela Lake in the south. The Kotla complex occurs as sill-like bodies within and near the top of a Precambrian metasedimentary rock sequence that includes the Kotla complex, and the rock selected for zircon dating, is a fine-grained, muscovite-biotite-quartz-feldspar orthogneiss that typically contains small (<0.5 cm) feldspar augen. This rock, which is also found in the Besham intrusive complex, is associated with mafic dikes and sill, leucogneiss, migmatite, and pegmatite. Zircons from the Kotla sample are predominantly small (<100 microns), clear, and equant prisms that yield a preliminary U-Pb age of 1839 ± 9 Ma, which is interpreted as an intrusive age. A fraction of less common larger grains (100 to 200 microns) is discordant and gives a slightly older Pb-Pb age of 1881 Ma indicating the presence of an older inherited component. The age of Kotla orthogneiss corresponds with a U/Pb zircon age of 1852 ± 14 Ma from the Iskere gneiss in the Nanga Parbat region (Zeitler and others, 1989) and with $40\text{Ar}/39\text{Ar}$ and K/Ar ages of between 2160 and 1862 Ma on hornblende from mafic dikes in the Besham area (Treloar and others, 1989, Treloar and Rex, 1990, Baig and others, 1989, Baig, 1990). The argon ages from the Besham area were originally interpreted as metamorphic ages but were reinterpreted as intrusive ages by DiPietro and others (submitted).

The Black Mountain complex occurs along the crest of the Black Mountains, which border the eastern side of the Indus River, where it is completely surrounded and intruded by Late Cambrian Mansehra augen gneiss but where it also structurally and topographically overlies the Karora and Gandaf formations. The principal rock in the Black Mountain complex, and the one selected for zircon dating, is a dark, equigranular, fine-grained, biotite-quartz-feldspar orthogneiss. Other subordinate rock types include biotite and/or garnet-bearing gneiss, migmatite, pegmatite, and mafic rock. Zircons from the Black Mountain sample are also predominantly small equant prisms, but contain a greater proportion of larger grains (200 to >450 microns). Preliminary U-Pb data for fractions of large zircons from this sample appear to have experienced severe Pb-loss with a crudely defined lower intercept age of 739 ± 150 Ma. Further abrasion studies will be conducted to better delineate the upper intercept age for this orthogneiss, which is presently unconstrained by the data but consistent with an Early Proterozoic protolith age. Pb-loss may have been contemporaneous with intrusion of the Mansehra augen gneiss which has a whole rock Rb/Sr age of 516 ± 16 Ma (Le Fort and others, 1980).

The ages indicate that the Karora and Gandaf formations are Early Proterozoic or older and suggests further that probable correlative rock units, including the Dakhner Formation in the Attock-Cherat Range, the Manki Formation in the Attack-Cherat and Gandghar Ranges, and the Hazara and Salkhala formations in the Hazara-Kaghan-Kashmir region, are also Early Proterozoic or older and not Late Proterozoic as is widely assumed. The ages and correlations suggest that an early Proterozoic crust is widespread along the northern margin of the Indian Plate. An older

(Archean?) crustal component is exposed in the Besham area the Karora Formation unconformably overlies a sequence of granitic gneiss.

D/257. Di Pietro, J.A. & Isachsen, C.E., 2001. U-Pb zircon ages from the Indian plate in the northwest Pakistan and their significance to Himalayan and pre-Himalayan geologic history. *Tectonics* 20(4), 510-525.

U-Pb zircon isotopic ages of seven rock samples are combined with field data to provide constraints on deposition, intrusion, and metamorphism in the northwestern part of the Indian plate (Pakistani) hinterland south of the Indus suture zone in Pakistan. The results suggest deformation, intrusion, and regional metamorphism at ca. 2174 Ma, an event that may correlate with granulite facies metamorphism in the Nanga Parbat area. This was followed by erosion and deposition prior to a second Proterozoic deformation at ca. 1850 Ma, which was associated with widespread intrusion and possibly with low-grade regional metamorphism. Metasedimentary and intrusive rocks of this age are present within the Lesser Himalaya of Nepal but are apparently absent in the High Himalayan crystalline slab north of the MCT. This intrusive/deformational event was followed by erosion and Late Proterozoic (?) deposition with development, in the Cambrian, of an epicontinental, shallow marine shelf. Intrusion in Late Cambrian-Middle Ordovician resulted only in minor uplift/erosion and development of a disconformity. Marine shelf conditions were reestablished in the Middle Paleozoic prior to a widespread intrusive event in the Carboniferous-Permian and normal faulting, erosion, and syndeformational deposition and volcanism in the Late Permian. Marine shelf conditions were reestablished in the Triassic prior to the Himalayan orogeny. Zircons with a concordant age of 89 Ma coupled with field and published isotopic age data suggest that Himalayan deformation and metamorphism in the Pakistani hinterland began between 90 and 75 Ma due to subduction of the Indian plate beneath Indus ophiolitic melange and reached peak amphibolite facies conditions between 70 and 48 Ma. This metamorphism precedes Eocene (54–50 Ma) collision of India with the Kohistan arc complex. Field data suggest that the presently exposed Pakistani hinterland from Afghanistan to Babusar was never significantly overthrust or buried by the Kohistan arc. Rather than initiating the metamorphism, the collision of Kohistan with India resulted in uplift, exhumation, and cooling of the metamorphic pile.

D/258. Di Pietro, J.A. & Lawrence, R.D., 1991. Himalayan structure and metamorphism south of the Main Mantle Thrust, lower Swat, Pakistan. *Journal of Metamorphic Geology* 9(4), 481-495.

During the Eocene-Oligocene, the Indian plate collided with the Kohistan arc along the Main Mantle Thrust (MMT) zone. The structure of the Lower Swat rock sequence, on the Indian plate directly south of the MMT, is a dome with a basement of granitic gneiss and quartz-rich schist unconformably overlain by amphibolitic and calcareous schist. The earliest superposed small-scale folds (F1 & F2) represent a progressive F1/F2 deformation that is associated with a single set of WSW-vergent large-scale folds (termed F2). These folds are inferred to have developed during oblique, WSW-directed overthrusting of the MMT suture complex onto the Lower Swat rock sequence. Metamorphism began during F1/F2 as indicated by an S1 foliation that developed during biotite-grade metamorphism. S1 is preserved as a relict texture in porphyroblasts that grew during a subsequent interkinematic phase during garnet- and higher grade metamorphism. The dominant, regional foliation (S2) developed following the interkinematic phase. S2 is associated with transposition of S1 and rotation or dismemberment of porphyroblasts. Annealing recrystallization followed S2 and continued during F3 thereby destroying or masking possible pre-existing stretching fabrics. Superposed F3 folds are upright and open with N-S axial trends. They may correlate with early doming of the Lower Swat rock sequence and with strike-slip displacement in the northern part of the MMT zone, north of the Lower Swat area. F3 was followed by retrograde metamorphism and development of E-W-trending, S-vergent F4 folds. F4 may be associated with a final phase of southward directed thrusting and inactivity in the MMT zone. Correlation of published $^{40}\text{Ar}/^{39}\text{Ar}$ ages with the metamorphic fabrics suggests that F1/F2 and F3 occurred in the Eocene, and that F4 developed in the Oligocene. F4 is the earliest indication of southward verging structures on this part of the Indian plate.

D/259. Di Pietro, J.A., Pogue, K.R., Hussain, A. & Ahmad, I., 1996. Precambrian rock of the black mountains NW Himalaya, Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 44-45.

The Black Mountains area is a previously unmapped area composed of metamorphic Indian Plate rocks located along the Indus River (Figure 1). Precambrian metasedimentary rocks were variably intruded and metamorphosed in the Precambrian prior to strong Paleogene metamorphic overprint. The rocks are exposed in the south-plunging Indus River anticline which is a late fold that deforms foliation. Earlier deformations are evident by the existence of transposed beds and rootless folds. The anticline is cut by high-angle, post-metamorphic faults oriented roughly parallel with axial trace of the fold. The largest of these faults is the Chakesar fault but stratigraphic relationships suggest only a few kilometers of offset. Numerous minor faults and sheared contacts also occur but these cannot be traced along strike. The field relationships do not support a sharp structural or metamorphic break between the Precambrian rocks and the overlying Paleozoic/Mesozoic sequence. From the base up, the Precambrian metasedimentary sequence is Karora graphitic schist and marble, unnamed Precambrian garnet schist and metasammite and Manglaur/Tanawal quartz mica schist and quartzite. On the west side of the anticline, the Manglaur Formation is unconformably (?) overlain by Paleozoic Duma marble and amphibolite, and Mesozoic Alpurai marble, garnet-calcite schist and graphitic schist. The unnamed unit is a transitional unit with elements of both the Karora Formation (graphitic schist) and the Tanawal Formation (quartz mica schist and quartzite). It is characterized by a distinctive garnet schist marker bed that can be followed from the vicinity of Thakot southward to the southern edge of Figure 1 and around the nose of the anticline to the vicinity of Martung. The presence of Kotla granitic gneiss, which intrudes the unnamed unit, suggests that the unnamed unit is older than the Tanawal Formation. The contact between the unnamed unit and the Karora Formation appears depositional. The contact between the unnamed unit and the Manglaur/Tanawal Formation is obscured by intrusion of the Swat/Mansehra gneiss. The contact between the unnamed unit and the Mansehra gneiss is sheared in the vicinity of Thakot but southward the contact becomes discordant with abundant cross-cutting relationships. The discordant relationship continues to the southern edge of Figure 1 where Tanawal-like quartzite emerges from below the Mansehra gneiss. These rocks are shown as part of the unnamed unit until additional fieldwork clarifies the relationship between the two units. The Besham complex is composed of undifferentiated orthogneiss of Precambrian and possibly Paleozoic age. West of Besham village, the Besham complex consists of fine-grained biotite gneiss that unconformably underlies the Karora Formation. Elsewhere, the dominant rocks are fine to coarse-grained, leucocratic, biotite-bearing granitic gneisses that are associated with pegmatite. These rocks intrude the Karora Formation whereas other rocks intrude the Karora Formation. North of Martung, a pegmatite/amphibolite sequence, that probably correlates with the Besham pegmatites, intrudes the unnamed unit. The Kotla biotite granitic gneiss (new name) is a sill-like body that intrudes within and near the top of the unnamed unit. The Black Mountain biotite granitic gneiss (new name) is an isolated body within the Mansehra gneiss structurally above the unnamed unit. The Cambrian-Ordovician Swat/Mansehra augen granitic gneiss intrudes the unnamed unit, the Manglaur and Tanawal Formation, the Kotla gneiss, and the Black Mountain gneiss. The structural evolution of the Black Mountain area may parallel the early evolution of Nanga Parbat.

D/260. Di Pietro, J.A., Pogue, K.R., Hussain, A. & Ahmad, I., 1999. Geologic map of the Indus syntaxis and surrounding area, northwest Himalaya, Pakistan. In: Macfarlane, A., Sorkhabi, R.B. & Quade, J., (eds.), Himalaya and Tibet: Mountain root to mountain tops. Geological Society of America, Special Papers 328, 159-178.

The stratigraphic, structure and metamorphism of the hinterland area of the Indian plate in northwestern Pakistan is described in relation to a geologic map. We conclude that this is one of the few areas in the Himalaya where amphibolite facies rock can be traced southward from the Indus-Tsangpo suture zone to low-grade fossiliferous rock without crossing a major fault. The absence of a major fault provides an opportunity to constrain the depositional ages of the metamorphic stratigraphy by direct correlation with fossiliferous rock in conjunction with isotopic dating of intrusive rock. The stratigraphy is divided into the following age groups, each bounded by an unconformity: Early Proterozoic, Late Proterozoic; early-middle Paleozoic, late Paleozoic-Triassic, and Mesozoic. Within this stratigraphy there is evidence for plutonism in the Early Proterozoic, Late Proterozoic, early Paleozoic, late

Paleozoic; and Cenozoic; deformation in the Early Proterozoic and late Paleozoic; and volcanism in amphibolite facies metamorphism in the Late Cretaceous-Cenozoic as result of the obduction of Indus melange onto the Indian plate along the Main Mantle Thrust and the ensuing collision, thrusting, and final emplacement of the Kohistan arc complex along the Kohistan fault.

The Main Mantle Thrust is a pre-metamorphic or syn-metamorphic fault that dates the time of obduction as pre-late Eocene and possibly as Late Cretaceous. Obduction along the Main Mantle Thrust is associated with west-southwest-vergent folds on the Indian plate. Exhumation and cooling of the Indian plate following peak metamorphism may have begun by the late Paleocene or early Eocene in the Indus syntaxis, and by the middle Eocene in the Loe Sar dome. Cooling and exhumation are associated with the development of large-scale, north-south-trending folds that fold the Main Mantle Thrust. The time of initial collision of Kohistan with the Indian plate is unconstrained in the field area, but brittle-ductile fabrics along the Kohistan fault indicate that final emplacement occurred during retrograde metamorphism, probably in the late Oligocene. Final emplacement of Kohistan is associated with the initial development of south-vergent folds on the Indian plate. Neogene and younger deformation is present in the Indus syntaxis area, in contrast to the Loe Sar dome area, where deformation largely ended in the early Miocene. There is no conclusive evidence for pre-Cenozoic amphibolite facies metamorphism in rock as old as Early Proterozoic. Compare Di Pietro et al., 1995.

D/261. Di Pietro, J.A., Pogue, K.R., Lawrence, R.D., Baig, M.S., Hussain, A. & Ahmad, I., 1992. Stratigraphy and dome structure, Lower Swat, Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 21.

The metamorphic sequence in Lower Swat is described and placed into the geologic framework of Pakistan. The stratigraphic sequence consists of Precambrian-Cambrian(?) Manglaur formation unconformably overlain by the Alpurai group which is subdivided into the Carboniferous or younger Marghazar formation, and the Triassic or younger Kashala, Saidu, and Nikanai Ghar formations. Type sections are indicated for each rock unit. The rocks crop out in a dome that is truncated on the north side by the Main Mantle suture melange (MMT). The major structures and associated metamorphism are Eocene-Oligocene in age. The earliest structures are west-verging and upright folds, both with ~north-south axial trends. Later east-west trending cross folds produced the dome structure. Geothermobarometry on rocks in the center of the dome suggest peak metamorphic conditions at ~600-700 °C and ~9- 11 kbar during development of the early folds. Metamorphism decreases southward to lower greenschist facies in the Peshawar Basin. Comparison with the stratigraphy in the Peshawar Basin indicates that the Lower Swat area existed as a highland with active normal faulting during and perhaps before deposition of the Marghazar formation. The Marghazar formation appears to be a rift facies that correlates with the "agglomeratic slates" and Panjal Traps of western India. The Kashala and Nikanai Ghar formations represent a transition to a stable, shelf environment. These units may correlate, in part, with the Zaskar Super group of western India. The Saidu formation may represent drowning of the shelf as it was pulled down and overridden by the MMT. It may correlate with the Lamayuru Formation of western India. The Alpurai group thus records the entire history, from Late Paleozoic breakup of Gondwana, to development of a Mesozoic passive shelf, to drowning of the shelf during the Himalayan orogeny.

D/265. Dougloss, R.C., 1970. Morphologic studies of Fusulinids from Lower Permian of West Pakistan. US Geological Survey Professional paper 643G.

A suite of samples from the Amb Formation in the Salt and Khisor Ranges of West Pakistan has yielded an abundance of fusulinids previously assigned to several species. There are many obvious differences between specimens and between samples in this suite. Traditional comparisons based on measurements at each volution support the idea that the visual differences are real; however, comparisons made at equal radii show great similarities between specimens and between samples. The differences are related to the size of the proloculus and are not considered sufficient evidence for specific discrimination; thus, these specimens are assigned to one species, *Monodiexadina kattaensis*. A new species, *Codonofusiella laxa*, occurs in one of the samples with the larger fusulinids and represents the earliest known occurrence of this genus.

D/268. Drew, F., 1873. Alluvial and lacustrine deposits and glacial records of the Upper Indus Basin; part 1, Alluvial Deposits. Quaternary Journal of the Geological Society of London 29, 441-471.

The tract of country in which occur the deposits of which I propose to give a somewhat detailed though concise account, is that part of the Maharaja of Kashmir's territory which is drained by the Indus. The greater portion of this country has been visited by travellers whose attention has been drawn to the deposits in question, and who have recorded some observations upon them. While considerable light has been thrown by some of these observers, it has seemed to me well both to add my quota and to try to systematize the facts, so as to prevent the confusion likely to arise from mixing, in description, accumulations of various origin, though they may all be classed in one sense as alluvium, and to see what general conclusions can be drawn from all that we have learned. The writers who have told most about the alluvial and lacustrine deposits are Col. H. Strachey, Gen. Cunningham, Dr. Thompson, Major Godwin-Austen, and Dr. Stoliczka. Col. Strachey, whose paper on the Physical Geography of Western Tibet is a wonderful store of accurate and valuable information compressed into a small compass, has given in it a description of the alluvium of the neighbouring basin of the Sutlej, with some reference to the corresponding deposits of the Indus; his conclusions I shall discuss further on. Gen. Cunningham, in his book on Ladākh, has given some notices of lacustrine deposits and of the former extension of lakes, which bear on the subject

D/269. Drew, F., 1874. The upper Indus River. *Geological Magazine*. (Decade II)/ 1(02), 94-94.

Whenever Colonel Greenwood writes on the subject of rain and river action, we are sure to learn a good deal. I am very glad that he has noticed the facts about the Upper Indus alluviums which I laid before the Geological Society, and has entered into the discussion of their causes. With much that he has written I heartily agree; and if on one point I still differ, it is with a mind open to be convinced if the causes I proposed to account for the present state of the alluvial deposits should seem after further argument either inadequate or unnecessary.

I grant the "hard gorge and soft valley" theory of Colonel Greenwood generally; in some instances where I have observed the alteration, a difference in the rocks can be seen to account for it; in others the reason is less clear. Still I am ready to believe that further knowledge of the character and position of the rocks would show that this theory is applicable to most cases. But I feel great difficulty in agreeing that the accumulation and subsequent denudation of thick alluvial deposits were due only to the variation in slope of the river bed. In the first place I cannot see how hundreds of feet of alluvial strata could be formed one upon another in a wide valley ending in a gorge, while the bed of the gorge was sinking from erosion. Secondly, we have the alluvial gravels, to the great thickness, in the gorges as well. This is evident that at the accumulating time, alluvium (of varying degrees of fitness very likely) was deposited though not in all places to the same relative height above its rock bottom, nor probably with one uniform gradient.

Gravity data along a north-south profile from Kohistan to the Punjab plain of Pakistan have been incorporated into recent interpretations of the gross structure of the foreland fold-and-thrust belt of the Himalaya. In northern Pakistan, large deviations from Airy Isostatic equilibrium are observed. An excess of mass characterizes the northern Kohistan arc, and a deficit of mass underlies a broad area extending from southern Kohistan to the Salt Range, while to the south a slight excess of mass seems to prevail in the region of the Sargodha high. This anomalous distribution of mass can be understood if the Indian elastic plate, which is assumed to overlie a buoyant "fluid," is flexed down under the weight of both the overthrust mountains and the sediments eroded off the mountains and deposited in the foredeep basin. In many respects the intracontinental subduction of India beneath the Himalaya is similar to island arc formation, including the seismically active Sargodha high, a basement ridge analogous to the flexural bulge encountered seaward of oceanic trenches. Analysis of Bouguer gravity anomalies along a profile extending from the Sargodha high to the Main Mantle Thrust (MMT) shows that most of the negative-northward gravity gradient can be attributed to crustal thickening. In the Sargodha high area, an additional contribution of about 25 mgal appears to be due to excess of mass at lower crustal or upper mantle levels. The Moho discontinuity is interpreted to bulge up beneath the Sargodha high, then gradually increase in dip from 1° to 3° beneath the Salt Range and Potwar plateau (approximately equal to the change in dip of the basement surface). The Moho is interpreted to change from upwardly convex to upwardly concave beneath southern Kohistan. Finally, north of the Main Mantle Thrust it appears to bend down again, but at a steeper angle of about 15° .

Shorter wavelength anomalies, superimposed on the regional Bouguer gradient, are modeled in terms of upper crustal density changes, including those due to: (1) offsets of the basement surface; (2) variable thickness of the Eocambrian evaporite sequence that forms the basal décollement; (3) thrusting and folding of relatively high-density, older parts of the stratigraphic section to higher structural levels, particularly in the Salt Range and northern Potwar plateau; and (4) thickening of the low-density Neogene molasse sequence into the axis of the Soan Syncline, a structural depression between the Salt Range and northern Potwar plateau. Subsurface densities of the overthrust wedge, as well as the definition of the shape of the top surface of the Indian plate interpreted from seismic reflection and drilling data, place bounds on the flexural rigidity of such a plate and the forces that deform it. In northern Pakistan, a steeper Bouguer gravity gradient suggests that the flexural rigidity of the elastic plate ($D = 4.0 [\pm 2.0] \times 10^{23} \text{ Nm}$) is a factor of 10 smaller than the current values interpreted for the central and eastern Himalaya. Moreover, the maximum flexural stresses are probably concentrated within the crust, which may account for the seismic activity of the Sargodha high and southern Kohistan. At the end of the Indian elastic plate (arbitrarily chosen at the MMT), a large positive vertical shear stress, $9.2 \times 10^{12} \text{ N/m} < S_0 < 1.6 \times 10^{13} \text{ N/m}$, is applied to account for the topographic load north of the MMT. In addition, to fit the gravity constraints it was necessary to apply a large negative bending moment, $-1.4 \times 10^{18} \text{ N} < M_0 < -0.85 \times 10^{18} \text{ N}$, at the end of the plate. The negative bending moment can be explained by the combined effect of the northward migration of the Indian plate and the southward differential compressional force generated by the crustal rocks stacked at mid-upper crustal levels beneath the northern Kohistan arc. In addition, buoyancy of the crustal rocks at deeper levels beneath the Kohistan arc may contribute to the negative bending moment. Consequently, in southern Kohistan the surface of the Indian plate is

concave up; compressional stresses in the upper part of the plate are probably the primary source of the Hazara seismic zone, where incipient reverse faulting seems to take place. In contrast, the pronounced upward convexity developed along the flexural bulge can account for (1) tensional stress in the upper part of the Indian plate, which is large enough to produce basement normal faults interpreted beneath the Salt Range and Sargodha high; and (2) compressional stress in the lower portion of the crust, which causes the excess of mass and seismicity beneath the Sargodha high.

D/276. Durrani, K.P., 1992. Geology and petroleum potential of the Kohat-Bannu basin, NWFP, Pakistan. Geological Bulletin, University of Peshawar 25, 134-135.

The Kohat Plateau and Bannu depression, a part of the foreland fold and thrust belt of Pakistan, lies to the south of Himalaya and Karakorum mountains on the Indian Plate. The anticlinal structures of Marwat, Khisor, Surghar, and Bhattani Ranges, "the Trans-Indus Ranges", are the southernmost extension of the fold-and thrust-belt. Seismic study suggests that the Kohat-Bannu plateau has been overthrust to the south along a sole thrust fault, which has also been reported earlier. Many thrust faults, mostly verging to the south and southeast, cut the sedimentary strata, implying that the Kohat-Potwar plateau was thrust southward and south-eastward as a direct consequence of the crustal shortening that resulted from north-south (post-Paleocene) lateral compression.

A variety of reservoir rocks of carbonate and clastic origin are also present in area. Most of the hydrocarbons in the region have been found in Paleogene rocks but other rocks of Cambrian, Permian, Jurassic and Cretaceous age also show good reservoir qualities.

D/277. Durrani, K.P. & Ahmed, I., 1992. Evidence of salt-tectonics in the trans-Indus Salt ranges, NWFP, Pakistan. Geological Bulletin, University of Peshawar 25, 133-134.

The Kohat-Bannu basin is one of the most important zones in an active foreland fold and thrust-belt of Pakistan. It was originated by compressional tectonics at the northern margin of the Indian Plate. This basin is moving southward over a salt layer, which acts as a decollement surface between the Precambrian basement rocks and the Eocambrian-Neogene sediments of the Indian Plate. The Trans-Indus ranges (TIR) are the surface expression of the leading edge of a decollement thrust in which the crystalline basement is not involved. The decollement along the salt in the fold and thrust-belt of Pakistan is formed by the combining processes of sediment load and sliding as a result of north-south compression. Salt behaves like a viscous fluid under stress. When the horizontal compressive stresses exceed the overburden stress of sediment, movement along the salt occurs in the weak zone forming a decollement zone. Some of the salt moves upsection along the thrust faults as a detached salt wedge forming pinch and swell structures. Salt tongues also form in this process.

E/1. Eames, F.E., 1950. The position of the Laki Limestone in the Eocene succession in West Pakistan. *Geological Magazine* 87(3), 214-216.

This paper does not strictly concerns the area of the present work, however, it is included as a compliment of a series of related papers by the author as given in the following.

It has previously been thought that in Sind the Meting Limestone Laki Limestone succession was equivalent to the Bolan Limestone, and that argillaceous beds, which are occasionally developed above the Laki Limestone and below the overlying Khirthar, represented the Ghazij Shales. Recent evidence indicates that these higher argillaceous beds are the representatives of the Shales with Alabaster of the Western Punjab, that in Sind the Ghazij Shales are cut out at the Laki/Ranikot unconformity, and that the Meting Limestone-Laki Limestone succession represents calcareous horizons higher up in the Laki series than the Bolan Limestone.

Detailed descriptions are given of the geological successions in the Eocene of standard sections in the Rakhi Nala and at Zinda Pir in the western Punjab, and at Tarkhobi, Panoba, the Shekhan Nala and Sirki Paila in the Kohat district. The work forms the first stage in the reinvestigation of the classification and correlation of the Eocene in western Pakistan and western India. Comprehensive collections of fossils were made.

E/4. Eames, F.E., 1952a. A contribution to the study of the Eocene in Western Pakistan and Western India; Part C, The description of the Scaphopoda and Gastropoda from standard sections in Punjab and Kohat District. *Philosophical Transactions of the Royal Society of London, Series B*, 236, 1-168

The Scaphopoda here described comprise three new species. The Gastropoda here recorded or described comprise 138 forms, 117 of which have received specific names. Of the 23 previously named species, two had not been recorded from Pakistan or India before. Largely owing to the nature of some of the beds from which collections were made, 96 of the species described are new. Four new genera and five new subgenera are proposed, and also one new generic name to replace a pre-employed name. The fauna recorded, together with the Lamellibranchia previously described, forms part of the material constituting the basis for the consideration of the classification and correlation of the Eocene of western Pakistan and western India, which the writer has published elsewhere.

E/5. Eames, F.E., 1952b. A contribution to the study of Eocene in Western Pakistan and Western India: D. Discussion of the faunas of certain standard sections and their bearing on the classification and correlation of the Eocene in Western Pakistan and Western India. *Quaternary Journal of Geological Society of London* 107, 173-200.

Local paleontological subdivisions are established for the Eocene of the Rakhi Nala, Zinda Pir and Kohat areas as a result of the examination of extensive collections of fossils recently made in these areas. The distribution of the

different phyla in various facies developments is discussed. Comparison is made with the pre-existing major subdivisions of the Eocene in western Pakistan and western India. In the Rakhi Nala and Zinda Pir area, it is concluded that the Khirthar-Laki boundary has previously been taken at too low a horizon, and that beds previously referred to as lower Middle Khirthar include representatives of the upper Middle Khirthar, the Upper Khirthar, and still younger horizons of Upper Eocene age.

The lithological and mapping evidence and the paleontological evidence from the Rakhi Nala and Zinda Pir areas are each considered separately and finally synthesized in order to arrive at as precise a correlation as is possible. The evidence from the Kohat Eocene beds has been synthesized with that from the Rakhi Nala-Zinda Pir area in like manner, and it is evident that only the major palaeontological subdivisions can be correlated. The present investigations have confirmed the usefulness of the terms “Ranikot Series”, “Laki Series” and “Khirthar Series” for subdivisions of the Eocene in western Pakistan and western India. The writer considers that the basic and fundamental soundness of these terms is not affected by the fact that beds and faunas have occasionally been incorrectly allocated to one or other of them. Certain beds, which are here named the “Tapti Series”, and which are not of very widespread occurrence, contain a fauna which is distinct from that of the Khirthar Series below and is of Upper Eocene age. The fauna of this series, in addition to several species of Upper Eocene age and a number of new species, includes the genus *Pellatispira*, which is also of Upper Eocene age and has not yet been unquestionably recorded from horizons as low as those containing the genus *Assilina*.

A consideration of all the available evidence indicates that published information concerning the ranges of some species is incomplete and that in some cases the existing conception of a species requires modification. The author is of the opinion that the “zones” which have been previously proposed within the Ranikot, Laki and Khirthar Series are of local rather than regional value, and that there has been too great a readiness to assign regional chronological significance to local facies faunas. It is evident that further work is necessary before regional zoning of the series can profitably be attempted.

E/13. Edmond, J.M., 1992. Himalayan tectonics, weathering processes, and the strontium isotope record in marine limestones. *Science* 258, 1594-1597.

The time evolution of the isotopic composition of seawater strontium (the ratio of strontium-87 to strontium-86) over the last 500 million years has the form of an asymmetric trough. The values are highest in the Cambrian and Recent (0.7091) and lowest in the Jurassic (0.7067). Superimposed on this trend are a number of smaller oscillations. Consideration of the geochemical cycle of strontium and the dynamics of weathering shows that only Himalayan-style continental collisions can influence the isotope ratio on the scale observed. The contemporary Himalayan orogeny is by far the largest since the late Precambrian Pan-African event that produced the high in the Cambrian.

E/14. Edwards, M.A., 1998. Examples of tectonic mechanisms for local contraction and exhumation of the leading edge of India, southern Tibet and Nanga Parbat, Pakistan. Ph.D. Dissertation, State University of New York at Albany, 308p.

This is a detailed account of the structure and tectonics of the Nanga Parbat area. Attention has been paid to explain the rapid rise of the Himalaya during the late Tertiary and Quaternary. Some of the information has appeared in the publications of the author.

Key words: Structure, tectonics, Nanga Parbat, Himalaya.

E/15. Edwards, M.A., 1999. The "Marginal Areas" (e.g., Namche Barwa, Nanga Parbat, Tian Shan). Can they tell us anything truly significant about the collision? *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 44.

For the purposes of this discussion, regions that are not in the principal regions of the India Asia collision (i.e., Tibet and the Himalaya) are termed the "Marginal Areas". Under the term Marginal Areas are included (e.g.) Namche Barwa, Nanga Parbat, Tian Shan, all of which are being reported on elsewhere in the workshop.

Although the Marginal Areas have much to offer regarding tectonic interest in general, in particular because of the relatively recent nature of much of the tectonic activity, it is by no means clear if the recent accumulation of deformation in any of these areas is a predictable product of the India-Asia collision. Does the present information, and/or will further information significantly enlighten us as to the timing, thermal and mechanical evolution of the converging crust?

There are presently very active tectonics at Nanga Parbat at the western end ("syntaxis") of the Himalayan chain (e.g., 1.4 Ma age of Mazeno Pass leucogranite pluton at Nanga Parbat - Schneider et al., 1999), and also at Namche Barwa at the eastern end of the Himalayan chain (where cooling ages are also notably young, e.g., Burg, 1998). For Nanga Parbat, there is evidence to suggest that significant exhumation has been only within the last 10 Ma. -10 Ma

is also identified by some as an approximate date for the attainment of a gravitationally unstable thickness of the crust beneath Tibet. Are events at Nanga Parbat related to elevation increase in Tibet?

It has been proposed that there is a significant and predictable partitioning of strain, with arc-parallel extension accumulating at the in the "syntaxial regions" of the straining arc (Seeber & Pecher., 1998). It has been subsequently suggested that fossil Nanga Parbat-type features will be found in ancient collisional belts, and various types of modelling have been presented in which displacement or weakening is concentrated at the tips of the arc (e.g., Koons et al., submitted). On the other hand, it is known that a wide range of features can be generated by modelling using geologically reasonable input.

In the Tian Shan, there is some evidence for significant Late Oligocene exhumation (Hendrix et al., 1994). Modern exhumation rates in the Tian Shan are also high however, and these cannot have continued for the last ~25 m.y. How can these periods of deformation be a predictable or obvious result of the ongoing convergence of India & Asia?

Key words: Tectonics, collision, Nanga Parbat, Namche Barwa, Tian Shan.

E/16. Edwards, M.A. Kidd, W.S.F., Khan, M.A. & Schneider, D.A., 1998. Structural geology around southern Nanga Parbat; Synkinematic granite and truncation of MMT footwall in the SW, deformation styles in Rupal, and the Shonthar Thrust traced to the SE. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 61-64.

The Main Mantle Thrust (MMT) is the regional contact between collider India and the overthrust Kohistan-Ladakh fossil island arc in the Pakistan Himalaya². The Nanga Parbat-Haramosh Massif (NPHM). Pakistan [NW Himalaya syntaxial region] is a tectonic half window of partly re-worked, largely Proterozoic, Indian plate rocks that have been exhumed from beneath Kohistan-Ladakh³. Early Himalayan age, general MMT thrust displacement is modified by very young (e.g. 1.4 Ma leucogranite Th-Pb ages⁴) tectonism at Nanga Parbat Haramosh Massif (NPHM). Our investigations in SW NPHM reveal a complex interplay of features related to (1) MMT-convergence, and (2) subsequent NPHM general uplift and tectonism.

In the area that is encompassed by the N-S trending Bunar valley, and NW trending Diamir valley, the main fabrics trend mostly N to NNE. In this area, the Indian "cover" passive margin rocks that form the original MMT footwall include sequences of carbonates and amphibolites (probably the Permian "Panjal Traps") interlayered with metapelites. In Diamir valley, these are not more than a few 100's metres thick. Here, the regionally NW-dipping cover sequences and MMT hanging wall (Kamila amphibolite) are overturned to become SE-dipping. These overturned layers are traceable to a recumbent open fold (the Gashit fold) in Airl Gah near the village of Gashit, where they form the upper (overturned) limb. The hinge line and axial plane of the fold plunge gently NS of this fold, the lower limb is exposed, thus sequences are not overturned and are observed to dip moderately to steeply west. The thickness of the cover sequence increases markedly to the south; carbonates, amphibolites and metapelites of several kilometres of structural thickness are present in the W-E Airl-Nashkin section, 10 km to the south of Diamir valley.

Structurally lower in the MMT footwall, and to the east (fig. 3), the cover sequence passes into a dominantly plutonic, ~5 km thick crystalline sequence that forms a continuous, ~30 km long, ~N-S belt with vertical to steeply E-dipping fabrics. The Diamir and Airl Gah (both ~W-E) valleys offer almost continuous outcrop sections through the belt. From these valleys, it is clear that a coarse-, to medium-grained biotite granite (the Jalhari granite) grades into granitic and porphyroclastic gneiss due to syn- to post-plutonism deformation. Jalhari leucogranite lenses (10's - 100's m thick) showing little to no sub-solidus deformation are separated by 10's - 100's m thick layers of gneiss where deformation of the granite has been localised. These higher strain layers anastomose around the granite lenses, and mark reverse faults that "climb" to the west. The granitic gneiss shows significant sub-solidus strain, including S-C porphyroclastic fabric whose sense of shear consistently indicates east side (NPHM) up and over west. Well-developed ductile/brittle shear bands and local fault gouge horizons, both of the same range of orientations as the ductile fabric, are also common. Late strain is often indicated by narrow (metres) zones where hydrothermal flux has developed thick biotite accumulations. Spectacular asymmetric folding (cm-wavelength) of the biotite layers indicates East Side up and over west. In the eastern portions of the Diamir valley section through the granite, a series of highly stretched, constant width (10-30 cm) amphibolite sheets can be followed for >100's m in continuous outcrop. These are parallel to sub-parallel to the deformed Jalhari granite. If these amphibolite sheets pre-date the granite, they imply a very large contrast in mechanical competence both during and after intrusion of

the Jalhari granite. Th-Pb microprobe [UCLA's Cameca IMS1270] analyses of monazites separated from deformed and undeformed portions of the granite give ages ranging from 3-12 Ma.

Overall, the granite gneiss belt defines an N-S trending, W-vergent reverse sense shear zone ~5 km in width. We term this the Jalhari shear zone. The E over W displacement sense of the Jalhari shear zone is consistent with the development of the Gashit fold and with the upper limb that includes the overturned cover/MMT layers. This shear zone forms the mechanical continuation of the main Raikhot Fault (a NW-vergent reverse fault with NPHM in the hanging wall). The Raikhot Fault is much narrower (5-km) however, and represents more focused strain.

The geology between the Jalhari shear zone and the central portions of massif is well exposed in the Diamir and Airl Gah valleys. The zone boundary is marked by brittle deformation within layers/lenses of retrograde (highly chloritised) metapelite. These then pass to more typical basement gneisses (e.g. showing metric banding due to differing Fe-weathering & biotite content). From here to Rupal valley, structures are more complex. Across Mazeno Pass, the 1.4 Ma pluton shows evidence of some normal motion associated with its emplacement. (Top to NW on steep, NW-dipping fabric). Principal gneissic fabric is N-NE trending. In places this is cut by quartz-pegmatites, and by leucogranite dykes that stem from the Mazeno Pass pluton. Some of the leucogranite dykes cross-cut the quartz-pegmatites, and in both cases, wall rock margins show normal sense of opening, but this may not be significant if (e.g.) the granite remained super-solidus during much of the strain.

Normal structures (top-to-NNW) are seen throughout Rupal valley. All, however, are brittle, probably very late, and of minor displacement. Most are developed on older thrust planes that are ~W-E trending, the western portion of the Rupal Chichi Shear Zone (RCSZ). There is vast thickness of orthogneiss in Rupal showing top to SSE thrusting. The NW-dipping fabric is continuous throughout the Rupal Face, biotite gneiss dips ~43°NW at the summit of Nanga Parbat. The Rupal Face is very steep. Locally, a ~2 km thick leucogranite with irregular margins intrudes western Rupal Face, above Shaigiri village (between ~5000 & ~6800 m). This may be emplaced in the axial zone of a tight antiform with NW-dipping axial surface, and whose axial trace passes to the south side of the summit ridge. This antiform is seen on Chongra ridge (again NW-dipping) and can be traced to the "western antiform" (Edwards & Kidd, 1997) described from the Astor Gorge. In both of the valley walls, amphibolite, coloured marbles and metapelites are found as fairly homogeneously deformed meter-scale layers/lenses within the extensive orthogneisses. At lowest elevations in the valleys walls of central Rupal, numerous thick fault gouge zones are seen, possibly indicating that at least part of Rupal valley has provided a (topographic) local crustal weakness to focus late brittle deformation. In the southern portions of western Rupal (in Shaggin Glacier valley, and all along the south side of Rupal & Toshain Glaciers) gneissic fabric dips SW to S and shows excellent SW stretching lineation, typically with a clear top-to-SSW sense of shear. Intrusive, now-L-tectonised granite pods pre-date this fabric, which may be very young.

Part of our continuing work in Chichi Nullah (SE NPHM) has included mapping of the southern portion of the RCSZ whose margin is well exposed here. It is sub-parallel to the Chichi Nullah and marked by a contact between the non-coaxially sheared granitic orthogneiss (continuous north to central Rupal) and the extensive marbles, amphibolites and metapelites of local Indian plate cover sequences. The foliation of the cover rocks and the gneisses are largely parallel, and orientation switches from NW dipping (overturned) in northern Chichi, through vertical, to SE-dipping in southern Chichi. This is another example of southern NPHM "bulging out" in cross sectional view (c.f. 7). In southernmost Chichi, within the locally SE-dipping marbles and amphibolites, several reverse faults define a >200m wide, NW-vergent thrust zone. This is most spectacularly expressed by a clear box fold (box = 10's m² area of section) within the zone. The thrust is observed to continue SW over the southern wall of Chichi Nullah. Its surface trace can be drawn from here and confidently joined with the Shonthar (Gali) thrust that has been mapped in Azad Kashmir near the Pak-Indo Line of Control, 9. Also noteworthy is that in southern Chichi, the sheared orthogneiss of the RCSZ dies out. This is replaced (further south) by a largely undeformed, fine-grained leucogranite of several 100's km² area. The (apparently intrusive) margin of the granite does not visibly cut the foliation of the country rock (i.e. marbles). Close to the margin, the granite shows minor sub-solidus deformation; however, we found no part of the granite that can be termed gneiss. The granite forms dull brown craggy towers along the tops of the valley walls, exactly like the sheared orthogneiss to the NE. We are investigating whether the granite and the orthogneiss may be originally related in some manner.

Key Words: Structure, tectonics, Indus suture, Synkinematic intrusions, Nanga Parbat, Himalaya.

E/17. Edwards, M.A. & Kidd, W.S.F., 1997. Structural investigation around southern and eastern Nanga Parbat. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 29-30.

The western Himalaya syntaxis includes the Indian-plate Nanga Parbat Haramosh (NPHM). The contact between collider India & the overthrust Kohistan series (KLS) is regionally termed the Main Mantle Thrust (MMT). It forms a plan-view, “oxbow” shape around NPHM, yet NPHM is not a relict promontory of India that has acted as a horizontal indenter and “bowed out” the visible MMT. This is recognized by the absence of appropriate deformation of the northern margin of the KLS (Pecher et al., 1996). NPHM has enjoyed accelerated exhumation from beneath the KLS since ca. 10 Ma (Zeitler, 1985; Zeitler et al., 1993), and locally plutonism has been constrained as young as 1.4 Ma (Schneider et al., 1996), tens of kilometers of crustal section are required to have been removed from above Nanga Parbat. This has prompted speculation (e.g. Hubbard et al., 1995) that the NPHM may be another Himalayan core complex (c.f. Nyainqentanglha-Pan and Kidd, 1992).

Our structural mapping in the eastern and southern massif, coupled with geochronologic analysis, and previous mapping in NPHM (e.g. Butler et al., 1992) indicates that recent NPHM exhumation (<10 Ma) is not due to significant unroofing via a low-angle normal faulting. Large amounts of mass have not been tectonically denudation from NPHM drainage area.

Along the oblique (~NW-SE) NPHM section formed by the Astor River gorge, two antiforms with different lithology are apparent. The western antiform is asymmetric with thinned E-limb. The eastern antiform is asymmetric with a thinned W-limb. Both axial planes trend ~N-S. These thinned limbs mark the Dashkin Synform, a pulled-down isoclinal fold whose axial plane trends ~N-S, and dips steeply W. Migmatitic orthogneiss dominates the W antiform. Cross-cutting amphibolite dykes are more frequent close to the thinned limb. The KLS is exposed in the hills 2-3 km above the Astor Gorge on the crests of both antiforms. There is no petrographic evidence for part of the KLS in the core of the Dashkin synform within 1000m of exposure above the river, although obliteration due to stretching of the synform remains possible.

Gneisses and schist in the eastern antiform are steadily N-S trending, vertical to steeply dipping, with lineation typically plunging gently N. These rocks are largely non-granitic/migmatitic, and there is no magmatism which post-dates the N-S lineation that we (as others, e.g. Butler et al., 1992) regard as original fabric due to either thrust or normal motion on the MMT (Edwards et al., 1996). The sequence of gneisses and schists that from the E limb of the eastern antiform has been divided into several mappable units, including the KLS rocks at the contact. This sequence is fully continuous from Astor gorge north over Dichil Gali to the Indus gorge, and to the south. We mapped this sequence in seven ~E-W valleys between Astor village and Rattu. Nowhere was the NPHM-KLS contact marked by a significant brittle structure nor any evidence of significant kinematics features not attributable to the MMT. Between Astor Village and North Lower Rupal, the NPHM-KLS contact sequence dips 40-80° E. From South Lower Rupal to near Rattu, the sequence is overturned and dips 40-80° W: the NPHM here is “bulging out”.

We infer W side up; thrust sense localized ductile displacement to be represented by the Dashkin synform based upon the relative differences in height of the overlying KLS rocks and the migmatitic gneisses in the western antiform. Interpreted satellite imagery (TM, SPOT) shows this zone continuing and widening to Chongra glacier and the Rupal-Chichi shear zone (see below) where a strain is much greater. The two contrasting synforms are not inconsistent with the most recent data from the equivalent NPHM section along the ~W-S Indus gorge (Wheeler et al., 1995).

The Rupal-Chichi Shear Zone is a several km wide belt of granitic orthogneiss showing a pervasive. NW side up with dextral shear indicated by augen asymmetry and S-C fabric. Associated overprinting lineation plunges ~30-60°SSW to WSW. Foliation shows some change: NE-trending in Chichi; NNE trending at Tarshing; ~W-E trending near Tapp Meadow. Dip is to the north. Kinematics indicated by this pattern are consistent with SE “corner” of Nanga Parbat moving up and NE relative to the eastern margin. There appears to be a large contrast in ages across this zone (Schneider et al., this volume). West of Tapp Meadow to Toshe Gali at the head of Rupal valley (~20 km) there is a return to ~N-S trending foliation and lineation.

In the central Rupal Valley there is an increase in (deformed) granitic component to the gneiss, greater on the south side. It is noteworthy that the more granitic areas appear to be concordant to the local (regional?) ~N-S fabric and yet analyses of preliminary samples give <5 Ma (Schneider et al., this volume). Other areas of “unstrained” granite crosscut the local fabric. The Mazeno Pass pluton (~5400m) emplaced at 1.4 Ma (Schneider et al., this volume), is discordant to the local fabric. In Upper Rupal Valley there is large contrast in fabric: N-dipping lineation in more rich gneisses on the N side, as opposed to SW plunging lineation in gray gneisses on the S side that contain large (Dm-scale) pods or boudins of lineation parallel granitic L-tectonic. Although foliation in the gray gneisses is steep and NE trending, and although the SW-plunging lineation may be a rotated MMT (originally N dipping) structure, there may have been some top to SW shear in this area. To the SW is Azad Kashmir, outside of the NPHM drainage area, and this is a part of the massif where some tectonic exhumation could have occurred.

Between the NPHM-KLS contact near the mouth of Lower Rupal valley and the Rupal-Chichi shear zone at Tarshing, is found the Churit Fault. The Churit Fault is a diffuse zone of steep, W side up N-S trending brittle faults

~1.5 km wide. The fault juxtaposes sillimanite grade orthogneiss in the west over staurolite grade metapelites in the east. The Churt Fault lacks significant ductile overprinting of regional N-S lineation, and seems to represent relatively minor exhumation of the massif.

We conclude that deformation for NPHM is largely indicative of a pop-up structure. This is evidenced by (1) NE-vergent folding visible along the Astor section, and (2) overturning of the eastern margin of southern NPHM, consistent with greater differential uplift indicated by (3) the W or NW side up, E-vergent Churit and Rupal-Chichi structures. This is consistent with NW vergent, NE dipping thrust structures on the western margin (e.g. Raikhot/Liachar) that form the corresponding western part of the pop-up structure. Our proposal of an asymmetric pop-up (Edwards et al., 1996) is consistent with preliminary data from the seismic experiment (Meltzer et al., 1996) that indicate that the Raikhot/Liachar system continues as the SE dipping basal thrust below the massif soleing to an area of dense seismicity that is truncated at 6 km below sea level. This is consistent with a model invoking large NW-trending relative surface velocities for either the entire western Himalaya (e.g. McCaffrey & Nabalek, 1996) or simply at the syntaxis, due to arc parallel extension (Seeber et al., 1996).

E/18. Edwards, M.A. & Kidd, W.S.F., 1999. New map of southern Nanga Parbat. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 43-44.

A new structural and lithologic map (as part of the Nanga Parbat Continental Dynamics Project) has been made for the southern Nanga Parbat area in the Pakistan Himalaya. About 90% of the mapped area was hitherto unreported in recent geological literature, the remaining 10% being covered by preliminary work.

The portions of the massif where mapping was conducted include: (Clockwise from Mazeno Pass) Diamir, Bunar, Biji and Jalhari Gah area (in the SW), the Astor Gorge and Dichil Gah-including the two tributaries that intersect the Eastern margin, Rama, Bulan and Ghurikot Gah areas (including the two northern tributaries of Ghurikot Gah), The Lower Rupal Valley (Tarshing Area) and northern Rattu valley, Chichi valley (to the foot of the pass to the Kishanganga) and central and Upper Rupal areas (to the foot of Toshe Gali and up to and over Mazeno Gali).

Three major findings include (1) a major new shear zone, the Rupal-Chichi Shear Zone, (2) the Diamir-Rupal Shear Zone-a significant continuation of the Raikot system for >60 km to the SW, and (3) that the original MMT on the east side has not been significantly modified or displaced, only rotated to vertical (for all three see Edwards et al., and Schneider et al., this issue). The map originally appeared in Edwards (1998).

E/19. Edward, M.A., Kidd, W.S.F., Khan, M.A. & Schneider, D.A., 2000. Tectonics of the SW margin of the Nanga Parbat-Haramosh massif. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 77-100.

We present an analysis of the tectonic evolution of the southwestern portions of the Nanga Parbat massif, Pakistan Himalaya, based upon detailed mapping and structural analyses from the Bunar, Biji, Diamir, Airl, Niat and SW Rupal valleys. Mainly metasedimentary cover rocks of the Indian plate are divided into upper and lower cover. There is a marked structural thinning of the cover in the main Bunar valley from south to north, and this is attributed to a major frontal ramp in the original Main Mantel Thrust (MMT). A hitherto unmapped shear zone, the Diamir Shear Zone, is identified, that is associated with a syn-kinematically intruded belt of granitic rocks, the Halhari Granite. The shear zone is a several kilometer thick, generally W-vergent, ductile to brittle shear zone that is associated with local overturning of the entire MMT section, typified by the Gashit Fold. ⁴⁰Ar/³⁹Ar cooling ages from across the area indicate as steep cooling age gradient across the Diamir Shear Zone from >40 to <5 Ma. The Diamir Shear Zone is mechanically linked to part of the Raikhot Fault System and, together, they are seen to be crustal-scale reverse fault that has allowed relative uplift and overthrusting of the core of Nanga Parbat.

Key words: Tectonics, Nanga Parbat, Himalaya.

E/20. Edwards, M.A., Kidd, W.S.F., Khan, M.A., Schneider, D.A., Zeitler, P.K. & Anastasio, D., 1997. Structural geology of the southwestern margin of Nanga Parbat. EOS, Transaction of the American Geophysical Union 78, F651.

The Main Mantle Thrust (MMT) is the regional contact between collider India and the overthrust Kohistan-Ladakh series in the Pakistan Himalaya. Early Himalayan-age thrusting and some later (~20 Ma?) normal motion on/near the MMT is modified by very young (e.g. 1.4 Ma leucogranite Th-Pb ages) tectonism at Nanga Parbat-Haramosh Massif (NPHM); the Himalaya's western syntaxis. Our investigations in southwestern NPHM reveal a complex interplay of MMT-related (mostly convergent) structural features followed by those related to uplift and tectonism of NPHM. Across the Diamir/Bunar area, main fabrics trend N to NE. In Diamir Valley, Indian cover passive margin metapelites and carbonates in the MMT footwall are not more than a few 100's of metres thick. Here, the regionally NW-dipping Indian cover sequences and MMT hanging wall (Kamila amphibolite) are overturned (SE-dipping). These overturned layers are traceable to the Gashit fold, whose hinge line plunges ~N and axial surface dips gently-moderately east. The cover sequence thickness increases markedly to the south; several km structural thickness of carbonates, metapelites and amphibolites are present in the W-E Airl-Nashkin section, only 8 km to the south of Diamir valley. The cover sequence passes east into a dominantly plutonic 5-10 km thick crystalline sequence where coarse to fine grained granite (the Jalhari granite) grades, due to syn- to post-plutonism deformation, into granitic and porphyroclastic gneiss intercalated with gneissic basement. Regionally the cover and crystalline rocks follow the subvertical to steeply E-ESE dipping foliation, and displacement sense is consistently east side (NPHM) up and over west. Within Diamir valley, granitic and gneissic foliation, shear bands, and local fault gouge zones anastomose around less- to un-deformed Jalhari granite lenses of 10-100's metres width. Plutonism seems to be in part synkinematic, and may provide an older age limit for NPHM tectonism. The E over W sense is consistent with the development of the Gashit fold and the upper limb that includes the overturned cover/MMT layers. The sharp attenuation of the cover sequence in northern Bunar valley could be a result of excision by normal motion along the MMT but we find no compelling evidence for this. We propose that the attenuation is a result of (1) a large frontal ramp in the MMT and an underlying related duplex largely of Indian cover and/or (2) original MMT thrust belt morphology where a lateral ramp-related duplex system has imbricated (and/or infolded) local thin slices of the cover and basement.

E/21. Edwards, M.A., Kidd, W.S.F., Seeber, L., Pêcher, A., LeFort, P., Riaz, M., & Khan, M.A., 1996. An upwardly-mobile indenter? The Nanga Parbat Haramosh Massif viewed as a crustal-scale Pop-up structure. EOS, Trans., American Geophysical Union, 77, F692.

The western Himalaya syntaxis [Fig 1] includes the Indian-plate Nanga Parbat Haramosh Massif (NPHM) [Fig 2]. The contact between collider India & the overthrust Kohistan-Ladakh series (KLS) is regionally termed the Main Mantle Thrust (MMT). It forms a plan-view, "oxbow" shape around NPHM, yet NPHM is not a relict promontory of India that has acted as a horizontal indenter and "bowed out" the visible MMT. This is recognised by the absence of appropriate deformation of the northern margin of the KLS. Pervasive lineation in NPHM is ~N-S, and sense of shear on the eastern margin is often dextral where recognised. Although this agrees with horizontal indenter model predictions, the broadly antiformal nature of NPHM allows the steep N-S foliation near the margins to be the result of rotation of the original, ~E-W, gently north-dipping MMT system about an axis ~parallel to the pervasive lineation. Therefore, the eastern margin and dextral shear sense, respectively, can be restored and recognised as top-to-south, MMT zone Himalayan thrust structures, largely unaltered. Observations now extending to seven main valleys confirm that there is no large brittle fault defining the eastern NPHM-KLS contact; the contact is essentially unmodified MMT. The antiformal nature of the massif is illustrated by the degree of apparent exhumation. Within NPHM, exhumation of the central portions of the massif (e.g. Nanga Parbat) has formed a complete window through Indian plate cover sequence schist and gneiss (garnet-staurolite grade) into basement gneiss (sillimanite grade $\pm$ granulite facies, cordierite-bearing anatectic segregations). This exhumation has been accommodated in part by large ductile and brittle shear zones within SE NPHM. The Rupal Shear Zone is a wide belt of ~N-S trending orthogneiss showing a pervasive, west side up with dextral shear S-C fabric and overprinting lineation. Closer to the eastern margin, the Churit Fault in lower Tarshing valley juxtaposes sillimanite (?) grade orthogneiss in the west over staurolite grade metapelites in the east, but lacks significant ductile overprinting of regional N-S lineation. Near Raikot, the original MMT contact of the western margin is largely obscured by east-over-west thrusting with some

overprinting the regional ~N-S lineation. Qualitative changes in the relative development of some fault and shear zone features may indicate diminishing strain to the north. Within NPHM and in Kohistan, late, NW-vergent structures dominate (young pegmatitic dyke sets, fault propagation folds, antithetic faults) and are suggestive of an asymmetric pop-up or flower structure. The NW-vergence in NPHM late brittle structures is consistent with the direction of axes of maximum compression derived from brittle fault kinematics in both crystalline and quaternary rocks near and west of the Raikot fault. Our evidence confirms and strengthens the view that NPHM is an asymmetrical antiformal structure, verging NW.

E/22. Edwards, M.A., Schneider, D.A., Kidd, W.S.F., Khan, M.A. & Zeitler, P.K., 1999. Summary of selected tectonic and geochronologic observations arising from the Nanga Parbat Continental Dynamics Project. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 40-41.

The Nanga Parbat Continental Dynamics Project (c.f., Zeitler et al., this volume) employed various disciplines (e.g., Meltzer et al., this volume) to investigate the tectonic processes that have contributed/contribute to present situation at the Nanga Parbat Haramosh Massif (NPHM). This is a summary of some of our tectonic and geochronologic observations in Central and SE NPHM.

Astor valley and SE NPHM: Two antiforms (with broadly differing overall lithology) are observed in the main Astor Gorge; the Burdish Ridge and Dichil antiforms, in the west and east, respectively. The Burdish Ridge antiform is asymmetric with a thinned E-limb, while the Dichil antiform is asymmetric with a thinned W-limb. This is recognised by a very tight, pinched fold morphology of the accompanying (Dashkin) syform. The Iskere gneiss (Madin, 1986; Madin et al., 1989; Treloar et al., 1991) is present near the core of, and west of, Burdish Ridge antiform as a series of 100's m to < 2-km sections interlayered with the porphyroclastic and coarsely to finely laminated, occasionally calc-silicate gneisses. We suggest that the discontinuous nature of the Iskere gneiss in Astor Gorge compared to the Indus Gorge (ibid.) is largely due to "fingering" (thinning / pinching out of multiple tabular or elongated peripheral portions) of the edge of the main body that is seen along the Indus Gorge, and we note that the bodies should, in principle, be traceable northward to join the Indus Gorge main body (possibly in a non-continuous fashion, if certain Iskere layers are km-scale boudins or lenses). The original intrusive contact of the Iskere protolith may have been either inter-fingering or may have been planar.

The Dichil antiform includes various conspicuous gneisses and schists that can be followed (discontinuously) through the (~W-E trending) valleys of SE NPHM, including (e.g.) the "lath unit" (Edwards, 1998; Edwards & Kidd, this volume; Schneider et al., this volume; Argles et al., this volume; Foster et al., this volume). These form the footwall of the original MMT and present therein are impressive high strain zones related to both original MMT thrust-sense, and, locally, to MMT-normal sense (!) displacement (ibid.). There is no significant displacement fabric related to the uplift of NPHM, only overturning of the previous "high Himalayan" fabric that is part of the "bulging out of southern NPHM".

NPHM-uplift-related shear zones in the SE: The Rupal-Chichi shear zone (RCSZ) is a km-scale, dextral, W-side up, high strain zone defined by a continuous belt of non-coaxially sheared granitic orthogneiss with impressive C/S fabrics along its entire length. This hitherto unrecognised feature is a fundamentally important discovery for constraining the tectonics of NPHM; it is now clear that the RCSZ has acted as the conjugate, "retro-" shear zone to the southern Raikhot & Diamir shear zone system (see below) to define a crustal scale pop-up structure. Displacement along the RCSZ may have migrated "inwards" to the centre of the massif based upon the ages of (1) cross-cutting leucocratic\granitic dykes, and (2) total fusion Ar/Ar biotite-cooling ages of the orthogneiss, both of which show an overall younging towards the centre of the massif (Schneider et al., this volume - a & b). To the south of the RCSZ is the newly discovered early Miocene Southern Chichi leucogranite pluton (ibid.).

Shonthar Thrust: North and east of the Southern Chichi pluton, the cover sequences are marked by extensive marbles, amphibolites and metapelites of local Indian plate cover sequences. The foliation here switches from NW dipping (overturned) in northern Chichi, through vertical, to SE-dipping in southern Chichi. This may mark the southern limit of the NPHM "bulging out". Within the locally SE-dipping marbles & amphibolites, several reverse faults define a >200m wide, NW-vergent thrust zone. This is expressed by a clear box fold (box 10's m area of section) within the zone. The thrust is observed to continue SW over the southern wall of Chichi Nullah. Its surface trace can be drawn from here and confidently joined with the Shonthar (Gali)'thrust that has been mapped in Azad Kashmir near the Pak-Indo Line of Control.

Deformation in Rupal: Normal structures (top-to-NNW) are seen throughout Rupal valley. All, however, are brittle, probably very late, and of minor displacement. Most are developed on older thrust planes that are ~W-E trending; the western portion of the Rupal Chichi Shear Zone (RCSZ). There are vast thickness of orthogneiss in Rupal showing top to SSE thrust sense-of-shear. The NW-dipping fabric is continuous throughout the Rupal Face; biotite gneiss dips ~45°NW at the summit of Nanga Parbat. Locally, a ~2-km thick leucogranite with irregular margins intrudes the very steep western Rupal Face, above Shaigiri village (between ~5000 & ~6800 m). This may be emplaced in the axial zone of a tight antiform with NW-dipping axial surface, and whose axial trace passes to the south side of the summit ridge. This antiform is seen on Chongra ridge (again NW-dipping) and can be traced to the “western antiform” described from the Astor Gorge. In both of the valley walls, amphibolite, coloured marbles and metapelites are found as fairly homogeneously deformed metre-scale layers/lenses within the extensive orthogneisses. At lowest elevations in the valleys walls of central Rupal, numerous thick fault gouge zones are seen, possibly indicating that at least part of Rupal valley has provided a (topographic) local crustal weakness to focus late brittle deformation. In the southern portions of western Rupal (in Shagin Glacier valley, and all along the south side of Rupal & Toshain Glaciers) gneissic fabric dips SW to S and shows excellent SW stretching lineation, typically with a clear top-to-SSW sense of shear. Intrusive, now-L-tectonised granite pods pre-date this fabric. The orientation, petrographic texture, and sense of shear of the fabric resembles the mylonitic and high strain zones of the MMT footwall that we see elsewhere. We note that the top-to-SSW sense of shear is best explained by rotation (from ~N-dipping) of the original MMT thrust-displacement fabric; such a rotation is to be anticipated here on the SW flank of the uplifting massif.

The brittle normal faulting seen in a number of places in the massif indicates that the central part of southern NPHM is in a state of extension near the surface. It seems that there is a small value for normal stress on existing fractures of many orientations, and that only a small rotation of the stress field is required to switch from reverse to normal motion on pre-existing fault surfaces. Some focal mechanisms for resolvable seismic events within southern NPHM are consistent, showing extensional first motions occurring to ~6-km depth (Meltzer et al., this volume). Note, however, that there is no evidence for large-scale tectonic exhumation of NPHM.

E/23. Edwards, M.A., Schneider, D.A., Kidd, W.S.F., Khan, M.A. & Zeitler, P.K., 1999. Summary of selected tectonic and geochronologic observations in SW NPHM arising from the Nanga Parbat continental dynamics project. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 42-43.

This abstract is a summary of some of tectonic and geochronologic observations in SW NPHM arising from the Nanga Parbat Continental Dynamics Project (Zeitler et al.).

Truncation of cover sequence: In the area that is encompassed by the N-S trending Bunar valley, and NW trending Diamir valley, the main fabrics trend mostly N to NNE. In this area, the Indian “cover” passive margin rocks that form the original MMT footwall include sequences of carbonates and amphibolites (probably the Permian “Panjal Traps”) interlayered with metapelites. In Diamir Valley, these are not more than a few 100’s metres thick. Here, the regionally NW-dipping cover sequences and MMT hanging wall (Kamila amphibolite) are overturned to become SE-dipping. These overturned layers are traceable to a recumbent open fold (the Gashit fold) in Airl Gah near the village of Gashit, where they form the upper (overturned) limb. The hinge line and axial plane of the fold plunge gently N. South of this fold, the lower limb is exposed, these sequences are not overturned and are observed to dip moderately to steeply west. The thickness of the cover sequence increases markedly to the south; carbonates, amphibolites and metapelites of several km of structural thickness are present in the W-E Airl-Nashkin section, 10 km to the south of Diamir valley.

The abrupt northward thinning of cover sequences in SW NPHM is orders of magnitude too large to be original depositional variation and there must be some type of tectonic excision. Large amounts of STDS-type normal motion have not been reported from the MMT. Similarly, we have found no compelling evidence around NPHM for large-scale normal motion on the MMT (the MMT-normal motion seen in SE NPHM cannot account for several km of exhumation). Consequently, we suggest that a large-scale frontal ramp in the original MMT gave rise to a local duplex structure that imbricated thin slices of cover, and possibly basement. This model is consistent with our mapping in Niat Gah, the next main valley to the west of NPHM, where a basement slice occurring close to the MMT implies large-scale imbrication of the cover sequences.

Jalhari Granite synkinematic in Diamir Shear Zone: Structurally lower in the MMT footwall, and to the east, the cover sequence passes into a dominantly plutonic, ~5-km thick crystalline sequence that forms a continuous-along-

strike (>30 km), ~N-S belt with vertical to steeply E-dipping fabrics. The Diamir and Airl Gah (both ~W-E) valleys offer almost continuous outcrop sections through the belt. From these valleys, it is clear that a coarse-, to medium-grained biotite granite (the Jalhari granite) grades into granitic and porphyroclastic gneiss due to syn- to post-plutonism deformation. Jalhari leucogranite lenses (10s-100s m. thick) showing little to no sub-solidus deformation are separated by 10's-100's m thick layers of gneiss when deformation of the granite has been localized. These higher strain layers anastomose around the granite lenses, and mark reverse faults that climb to the west. The granitic gneiss shows significant sub-solidus strain, including S-C porphyroclastic fabric whose sense of shear consistently indicates east side (NPHM) up and over west. Well-developed ductile/brittle shear bands and local fault gouge horizons, both of the same range of orientations as the ductile fabric, are also common. Late strain is often indicated by narrow (metres) zones where hydrothermal flux has developed thick biotite accumulations. Spectacular asymmetric folding (cm-wavelength) of the biotite layers indicates east side up and over west. Th-Pb ion microprobe [UCLA's Cameca IMS 1270] analyses of monazites separated from deformed and undeformed portions of the granite give ages ranging from 2-8 and 12 Ma, respectively (Schneider et al., this issue). Overall, the granite gneiss belt defines a N-S trending, W-vergent, reverse sense shear zone ~5-km in width. We term this the Diamir Shear Zone. The E over W displacement sense of the Diamir Shear Zone is consistent with the development of the Gashit fold, and with the upper limb that includes the overturned cover/MMT layers (again note that here on the NPHM SW flank the massif is again "bulging out" in cross-sectional view). The Diamir shear zone forms the mechanical continuation of the main Raikhot Fault: at Raikhot Bridge, where last seen, the structure is marked by a NW-vergent reverse fault with NPHM in the hanging wall (Madin, 1986; Madin et al., 1989). The Raikhot Fault is much narrower (<<5-km) however, and represents more focused strain. We interpret the emplacement of the Jalhari granite to be at least partly syn-kinematic with exhumation of NPHM, intruded in discrete episodes between 2 and 12Ma.

Eastern margin of Diamir Shear Zone and Mazeno Pass section: The geology between the Diamir Shear Zone and the central portions of massif is well exposed in the Diamir and Airl Gah valleys. The zone boundary is marked by brittle deformation within layers/lenses of retrograde (highly chloritised) metapelite. These then pass to more typical basement gneisses (e.g. showing metre-scale layering due to differing Fe-weathering & biotite content). From here to Rupal Valley, structures are more complex. Across Mazeno Pass, the 1.4 Ma pluton (Schneider et al., this volume) shows evidence of some normal motion associated with its emplacement. (top to NW on steep, NW-dipping fabric). Principal gneissic fabric here is N-NE trending. In places this is cut by quartz-pegmatites, and by leucogranite dykes that stem from the Mazeno Pass pluton. Some of the leucogranite dykes cross-cut the quartz-pegmatites, and in both cases, wall rock margins show normal sense of opening, but this may not be significant if (e.g.) the granite remained super-solidus during much of the strain.

Conclusion: In conjunction with our observations of Central and SE NPHM (Edwards et al., this issue), we conclude that the uplift of the NPHM massif is accommodated upon two conjugate shear zones that define a pop-up structure. The RCSZ (on the eastern flank) is the "retro" structure while the Raikhot Diamir system (on the western flank) is the "pro" or "dominant" structure. The overturning (bulging out) of the massif is occurring on both flanks, however this occurs out with the main shear zone on the eastern flank (away from the centre of the massif); this is consistent with an overall more-diffuse focus of strain in the retro shear zone. We have recognized original "high Himalayan" features in the areas out with of central NPHM, including (1) the original MMT, and (2) evidence for Early Miocene plutonism that is ubiquitous to the main Himalaya and hitherto unrecognised in the NW Himalaya.

F/1. Faccena, C., Lorenzoni, S., Olivieri, L.M. & Lorenzoni, E.Z., 1993. Geo-Archaeology of the Swat Valley (NWFP, Pakistan), in the Charbagh-Barikot stretch, preliminary note. *East and West (IsMEO)* 43, 257-270.

The Charbagh-Barikot area lies along the Indus suture and contains rocks of the northern edge of the Indian plate as well as those of the suture mélange. There is a whole range of lithologies: pelitic schists (up to kyanite grade), calcareous schists, graphitic schists (commonly garnetiferous), granites and granitic gneisses, greenschists, phyllites, amphibolitized metabasites, and altered ultramafic rocks (serpentinites, magnesite-talc rocks). These rocks have been used in the manufacture of the archeological artifacts of the Gandhara age.

F/2. Faisal, S. & Afridi, S.K., 1996-97. Geology of the Kalachitta Hill Range at the western bank of the Indus River south of Nizampur, District Nowshera: Implications for the structural evolution of Main Boundary Thrust. M.Sc. Thesis, University of Peshawar, 70p.

For further details, consult the following account.

Key words: Structure, MBT, Kalachitta, Nizampur, Nowshera.

F/3. Faisal, S., Afridi, S.K. & Khan, M.A., 2001. Structure study at the western bank of the Indus River south of Nizampur, District Nowshera: Implications for the structural evolution of Main Boundary Thrust (MBT). Abstracts, 4th Pakistan Geological Congress, Islamabad, p.62.

The study area is a part of the western Kala Chitta Range, on the right bank of Indus river, around Jhungrai village, Nizampur. An area of about 110 km² was studied and mapped to work out the structural patterns. The area comprises, strata ranging in age between Jurassic and Miocene formations. Limestone, shale and sandstones make principle lithologies of the sequence. The region exhibits complex structural features including small and large-scale folds and thrust faults. Two phases of deformation are recognized in the area. An earlier D1 phase that resulted in the development of a large thrust sheet (MBT), which was displaced southward and have resulted in the horizontal shortening and vertical thickening of the region. This thrust (MBT) brings Patala Formation (Paleocene) over the Kuldana Formation (Eocene). The D2 phase not only caused the folding of MIBT but also the rocks underlying the thrust sheet. The subsequent erosion to the D2 folding has exposed younger footwall lithologies in the core of antiforms forming window structures. An open synform between the two such antiformal window structures represents a klippe.

Key words: Structure, Main Boundary Thrust, Indus River, Nizampur.

F/4. Falconer, H., 1842. Cataclysm of Indus. *The Asiatic Journal*, New Series 38, 39.

Falconer has furnished some additional particulars of the grand cataclysm of the river Indus, in the early part of last year. It would appear that the river had been observed, during several months, to be unusually low, so that its deep bed at Attock was converted to an easy ford. All at once, the river burst in an awful debacle through the obstacles which had impeded its course higher up, and rushed down the valley in a mighty flood, sweeping villages and towns away, with thousands of human beings. The Cabul river, which joins the Indus, above the fort of Attock, had its waters held up, and forced back, so as to inundate the towns of Noushera and Akora, in the plains of Peshawur. In the Hazara country, the flood is said to have swept away artillery gum, with many hundred Sikh troops, and the authorities on the Indus report many bodies washed down of a "very foreign" appearance. Dr. Falconer has little doubt that it was occasioned by some un-usual barrier temporarily established in the bed of the river somewhere high up its course, damming up its waters till they attained a volume which overcame the obstruction. He is of

opinion, that the place must have been higher up than Ghilgeet, on the Noobra-tsoh river, or Shayook, above its junction with the Ladakh, or great branch. "During my stay at Iskardoh," he says, "I learnt from the Rajah Ahmed Shah, that great floods occasionally take place, at irregular intervals, in consequence of the Noobra-tsoh getting blocked up by avalanches and masses of ice. This river has one of its principal origins in a great lake, as yet unvisited by Europeans, in the KaraKorum mountains. After winter seasons of unusual severity, the lake gets sheeted over with an enormous mass of ice, and the valley of the river below the lake is liable to be filled up with great avalanches of ice and snow. When events of this kind go together, the disrupted masses of ice from the lake, added to the avalanches, go on accumulating till a huge barrier is formed, which dams up the river, leading to tremendous floods when the water bursts through the obstacle."

F/9. Farah, A., Abbas, G., DeJong, K.A. & Lawrence, R.D., 1984. Evolution of the lithosphere in Pakistan. *Tectonophysics* 105, 207-227.

The geological setting of Pakistan in the framework of the modern concept of plate tectonics is unique in the sense that, within an area of about 800,000 km², critical tectonic junctions of different interacting plates and microplates are present in an environment where field exposures are excellent.

Here we discuss the dynamics of these various plate boundaries. Two types of active plate boundaries are conspicuous: (1) convergent boundaries characterized by continent-continent collision, obduction, and thrusting in the northern region of the Himalaya and by oceanic crust subduction with a volcanic arc and a wide accretionary wedge in the southern region of Chagai and Makran; (2) a transform boundary, the Chaman transform zone, characterized by very large strike-slip and lesser thrusting. The Chaman transform zone connects the Makran convergence zone, where oceanic lithosphere is being subducted beneath the Lut and Afghan microplates, with the Himalayan convergence zone, where the Indo-Pakistan lithosphere is underthrusting Eurasia. The Chaman zone is at present an intracontinental plate boundary with oblique motion, characterized by north-south strike-slip faults and eastward thrusting and folding in the Kirthar-Sulaiman mountain belt. This mountain belt, the northwestern margin of the Indo-Pak subcontinent, was an

Atlantic-type margin from the late Paleozoic until the Cretaceous. In the Cretaceous, the continental margin became a plate boundary; a thrust belt was formed in the Paleocene, and fragments of the oceanic crust were obducted, either as thrust sheets (Muslimbagh) or as an ophiolitic mélange (Bela and Waziristan).

F/12. Farah, A. & Mirza, M.A., 1984. Recent crustal deformation and seismicity in Pakistan. Abstract, First Pakistan Geological Congress, Lahore, p.63.

Recent crustal deformation in Pakistan is expressively noticeable along expansive active faults some of which have been the sites of major earth-quakes. Geological features indicating recent movements, historical and instrumental record of earthquakes provide proof of accumulation of crustal strain and deformation causing seismogenic failure of geological material in the zone of 'active faults'. The 'active faults' in Pakistan, comprising large thrusts and strike slip faults splayed into several small fractures, are associated with the Plate Margins where accumulation of strain is taking place. This is happening as a result of the stresses applied by tectonic forces which stem from northward plate motion estimated to be 3-4 cm per year. Evidence are also available for intraplate deformation in the subsurface zones of weakness.

Key words: Tectonics, seismicity.

F/14. Faridi, M.A.F., Anjum, A.R. & Anjum, G., 1981. Algae associated with alluvial gold of Indus at Attock. Geological Bulletin, University of Peshawar 14, 151-157.

Soil algal flora from auiferous alluvials of the river Indus in the vicinity of Attock Fort were studied. In all 31 species belonging to 18 genera were found. The blue green genera were Aphanocapsa (1 sp.), Calothrix (1 sp.), Chroococcus (3 spp.), Gloeotheca (1 sp.), Lyngbya (1 sp.), Merismopedia (1 sp.), Nostoc (1 sp.), Oscillatoria (8 spp.), Phormidium (3 spp.), Stichosiphon (1 sp.) and Symploca (2 spp.). The Chlorophyceae found belong to 6 genera viz., Gloeocystis (1 sp.), Microspora (1 sp.) and Ulothrix (1 sp.). Xanthophyceae was represented by a single plant, Heterococcus. This is the first study of algae found in relation with gold and may help in gold prospecting.

F/17. Farooq, A., 1985-87. The geology and petrography of upper Havelli (District Bagh) & Balligran-Manjhoter (District Muzaffarabad) with special emphasis on Panjal volcanics. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 90p.

The project area covers 150 square miles (417 square kilometers) located in District Bagh and Muzaffarabad, Azad Kashmir. The work has involved geological mapping of the area on a scale of 1:25,000 and 1:15,000 respectively.

This thesis deals with the geology and petrography of the Panjal volcanics. The geological sequence of the area consists of sedimentary, volcanic and metamorphic rocks. The area is tectonically highly disturbed being involved in Himalayan orogeny. Lithologically metamorphic rocks present in the area are schists, slates, phyllites, quartzite and marble. The volcanic rocks have been metamorphosed upto green schist facies. The mineral assemblage in volcanics is plagioclase+chlorite+ epidote $\pm$ quartz $\pm$ calcite.

The volcanic rocks belong to two distinct ages. Dogra trap are of Precambrian age and occur within the Dogra slates. Mineralogical studies show these rocks to be Basaltic. The Panjal trap flows are basaltic to andesitic and of Upper Carboniferous age. The pyroclasts occur in association with Panjal trap flows. Petrographic analysis of Panjal volcanics, Agglomeratic slates, limestone and marble have been carried out. Petrogenesis of Panjal volcanics is interpreted. Field evidences and laboratory data reveals that the Panjal volcanics are of submarine origin.

Key words: Petrography, volcanics, Muzaffarabad, Azad Kashmir.

F/18. Farooq, M., 1983-85. Litho-structural studies of Bhirina-Fitni-Paniali and Haddo Bandi Area, District Mansehra. M.Sc. Thesis, Punjab University, Lahore, 162p.

There is a specific relationship between the geological structures, landforms and the climate. This relationship can be worked out by qualitative as well as quantitative analysis of the topographic map. The most commonly exposed lithologies in the project area are schists from chlorite to garnet grade, Susalgali granite gneiss, Mansehra granite, quartzites and hornfelses. The rocks of the project area have been classified into nine lithologic units for the sake of mapping purposes at a scale of 9.2 Cm. to a kilometer on 5.8 inch to a mile. The area is deformed by different deformation phases, among which three are recognized on mesoscopic as well as microscopic scale and area is characterized by heterogeneous deformation. The rocks have been folded isoclinally and later being refolded into open folds. The area lies in the zone of brittle deformation and show extensive fracturing instead of folding. Mesoscopic and microscopic deformational features are well developed in the area. The rocks exhibit effects of polymetamorphism. The thermal metamorphism is superimposed on the regional metamorphism.

Key words: Lithology, structure, Mansehra.

F/19. Farooq, M., 1996. Depositional environments and provenance study of the Warchha sandstone, N.W.F.P., Pakistan. M.Phil. Thesis, University of Peshawar, 75p.

The Warchha Sandstone, of Lower Permian age is present in the Salt and Trans Indus Ranges. Three stratigraphic sections selected for detail study included Warchha Gorge and Zaluch Nala in the Salt Range

and Saiduwali Nala in the Khisor Range. The six lithofacies recognized in the Warchha Sandstone are: 1. Trough cross bedded pebbly sandstone; 2. Pebbly Sandstone/ conglomerate, 3. Cross bedded sandstone, 4. clay/siltstone, 5. Massive sandstone, and 6. Faintly laminated sandstone lithofacies. It is suggested that the Warchha Sandstone is an alluvial fan deposit. The similarity of Warchha Sandstone with the underlying Tobra Formation (in clasts collected and lithology) points either to a common source rock for both formations or indicates reworking and incorporation of Tobra Formation into the Warchha Sandstone. In thin section study; according to QFL triangular diagrams after Folk (1954-1980), the rocks are classified as arkose, with relative abundance of quartz, feldspars ($K > P$) and lithic fragments. In the QFL provenance discrimination diagrams of Dickinson et al.; (1982, 1983) the point count data occupy the field of continental block provenance. It is suggested by paleoclimatic and paleotectonic characteristics, that the Warchha Sandstone provenance was the area of low relief, humid and semiarid climate with lack of vegetation.

Key words: Sedimentology, provenance, sandstone, Warchha.

F/20. Farooq, M.A., 1985-87. The Geology of Parrai-Dodahera Area, District Swat, NWFP. M.Sc. Thesis, Punjab University, Lahore, 76p.

The topic of this thesis is Geology of Parrai-Dodahera Area with special emphasis on Mineralogy and Petrology. The prescribed area lies in the lower Swat Region. The area consists of about 35 miles². It lies between latitudes 34° 11' 30" to 72° 15' 00" in toposheet No. 43 B/2.

The area was mapped by the party through foot traverses on eight times enlarged toposheet at the scale 1:50,000. Notes were taken on different units, their lithology and contact relationship, and geomorphology and also on social set up of the people. Details regarding the structure of the area, i.e., folds, faults, fractures, joints, foliation and lineation were taken. Stations were marked on the map. Samples were also collected. Photographs of geological and geomorphic features were also taken. Back in laboratory, petrographic study of thin section was carried out by microscope.

The project area is not very rich in economic minerals. No mine is present. However, the following rocks and minerals are of economic importance. These are marble, graphitic schist, graphite and garnet.

Key words: Petrology, structure, Swat.

F/23. Farooq, S.A. & Jabbar, M., 1985. Geology and petrography of a part of Ambela granitic complex Malandarai area, District Mardan. M.Sc. Thesis, University of Peshawar, 58p.

Area under discussion occupies the south western part of the Ambela granitic complex, it covers about 20 sq. km. area and exposes granite, alkali granite, Biotite granite, Quartz syenite, quartz, chlorite, Carbonate schist, quartz mica schist, Quartz chlorite schist and Epidote muscovite schist. The schistose rocks are belonging to the lower swat Buner schistose group in which the granitic rocks are Implaced on a huge plutonic mass. The rocks are mainly exposed as elongated masses with a general trend, Of NEE conforming the regional trend of the granitic pluton, petrographic studies and field investigation reveals

that it is an alkaline complex and intruded as a large granitic pluton in the Pleistocene unit of the Indian Plate.

Key words: Petrography, petrology, granite, Buner.

F/27. Farukh, T.M., 1997-99. Geotechnical studies and geological mapping of left saddle embankment of Khanpur Dam Project Area. M.Sc. Thesis, Punjab University, Lahore, 90p.

The project area comprises of Khanpur Dam, its area around reservoir and some area of Haripur- Taxila Road near New Khanpur Town. There are three major aspects of the project work, first to do the geological mapping of the project area, to study the different problems of the dam, and third to perform different tests in detail on the material of the site to assess the properties and utility of these materials in connection with the construction of the dam.

HISTORY OF THE PROJECT

The idea of the dam was based originally, on the development of irrigation. The feasibility studies were undertaken in 1959-60 and an authentic feasibility report was submitted in 1962. After the careful investigation of expert and authorities, the project was started in 1963. The scheduled date of completion of the project was 1973. But the project work was stopped for long due to financial and certain political problems. Ultimately the F.W.O. was called to complete the project as a challenge within a period of one year and F.W.O. completed the project successfully in July 1983 and is onward construction that was completed in 1985.

PURPOSE OF PROJECT

Basically it was planned to construct 137 feet high earthen dam with a reservoir of 5,900-acre feet for irrigation purposes. But later on to meet the needs of municipal and industrial use of Islamabad and heavy engineering complex Taxila, the height of the dam was increased to 167 feet with a reservoir of 1,06,000-acre feet.

LOCATION

Khanpur dam is located on Haro River, about 1 Km South of old Khanpur Town, where the river flows through a comparatively narrow gorge. The site falls on; a topographic sheet No.43 C/13 of geological survey of Pakistan at coordinates 33degree 48.5' latitude and 72.56 longitudes. The altitude at the dam site ranges from 1830ft to 4450 ft. above sea level. It is very hot in summer, but very pleasant in winter.

F/30. Faruqi, F.A., Aslam, M. & Ayub, M., 1967. Mineralogy of the Swat kaolinite. Pakistan Journal of Scientific and Industrial Research 10, 58-67.

Fifty one samples of the raw and the beneficiated Swat Kaolinite have been analysed. Two representative samples of the raw and the washed kaolinite have been prepared from 79 samples received and their DTA and X-ray studies made. On the basis of the data obtained, the mineralogy of the deposit and that of the treated kaolinite has been ascertained. X-ray studies indicate that the mineral kaolinite in the raw samples is between 15 to 20%, whereas in the washed samples it is between 45 to 50%.

F/38. Faruqi, S.H., 1965a. Report on the Limestone and Dolomite Resources of Surghar Range and Adjoining area, for WPIDC's proposed Kalabagh Steel Mill.

Sizable deposits of workable grades of limestone and dolomite occur in Surghar Range. A total tonnage of 966 million of quarryable reserves of medium and good quality limestone occurring at four different localities has been proved in Chichali, Kalabagh, and Mari – Indus areas. While 921 million tons of quarryable reserves of good to average quality dolomite scattered over three localities, have been established in Gullakhel area (about 15 miles NWW of Jalalpur).

Abundant and cheap labour is available at the localities concerned and the deposits are connected through unmetalled / metalled roads with the chief towns of the area.

Key words: Limestone, dolomite, Surghar Range.

F/39. Faruqi, S.H., 1965b. Report on the Chichali Iron Ore Deposits and their Development.

The total proved and probable iron ore reserves of the workable grade of Chichali area are of the order of 165.5 million tons and 136.5 million tons respectively.

The deposits may be developed by three developmental tunnels namely the "Chapri low – level tunnel", the Muhabbat Khel low level tunnel" and the Muhabbat Khel high – level tunnel". The said tunnels would have to be driven for 5,892 feet, 10,385 feet and 857 feet respectively, to tap the main ore belt. It would be advisable to develop the south limb iron ore deposits, which have not been worked or explored so far, through a connecting drift in between the two low level tunnels. Precautions are to be taken against possible outcome of gas while tunneling the Makerwal stage, Lumshiwal beds and the lower part of Baroch beds.

Key words: Iron ore, Chichali, Lamshiwal.

F/40. Faruqi, S.H., 1966a. Report on the Fireclay Deposits for Kalabagh Steel Mill.

Sizable deposits of the workable grade of Fire Clay occur in Gullakhel, Musakhel and elsewhere in the 'Surghar – Range' and Salt Range at accessible localities. Any one or two of the four proposed deposits may meet the entire requirements of the steel mill for several decades.

Key words: Fireclay, Surghar Range.

F/41. Faruqi, S.H., 1966b. Report on the Sand Deposits for WPIDC's Kalabagh Steel Mill.

The sand horizon occurs as a continuous belt beyond Datta area in both sides along strike and the total reserves actually go to the 'unlimited' extent. However, as a possible source of sand for steel mill, only the triangular area in between the two main tributaries of Datta nala would be considered. This block is exposed from three sides and a considerable portion of the same may be worked open cast.

Key words: Sand, Datta.

F/44. Faruqi, S.H., 1969. Report on Graphite Deposits of Azad Kashmir and their development.

Azad Kashmir has been bestowed sizable deposits of the workable grade of amorphous (cryptocrystalline) and dense phanerocrystalline graphites. The amorphous type is, in general, pure enough to be marketed in as mined state while there are good prospects of concentrating the various phanerocrystalline graphites through the conventional methods of crushing, screening and flotation, on commercial scale. The deposits are comparable, in quite a few respects, to some of the commercial deposits of the world e. g. of Korea, the United States of America and at least some of Russia.

In view of the handsome amounts of foreign exchange involved in the import of graphite and graphite products, it is imperative to appoint some leading graphitic processing and marketing agency as WPIDC's consultants for feasibility studies of Azad Kashmir deposits, with the least possible delay.

Key words: Graphite, Azad Kashmir.

Key words: Steel, Indigenous resource.

F/53. Faruqi, S.H., 1972c. Pakistan Steel Mill Problem and its Solution. Proceedings of "First National Seminar on Metallurgy" at the Engineering University Lahore pages 43 - 49.

The main or basic part of the iron and steel industry is the separation of iron from its ore. There are several processes in use to achieve this purpose. Amongst these, under normal conditions, the easiest cheapest and much preferred one is the 'Blast Furnace Process'. If the ore is good enough to be directly charged into the blast furnace it is well and good. But in case, on account of the low grade (low iron high impurities) of ore, it may not be possible then the ore is first upgraded. For blast furnace use the ore should contain at least 35-40% iron with a reasonable amount and balance of other constituents present. It is also necessary that the ore should be in lump form and not as small grains or powder. But in most of the upgrading processes powder or small size results. As such, before charging the upgraded ore (the concentrate) in to the furnace, it is pelletised, briquetted or sintered. Some iron ores, on account of their mineralogical set up do not smelt as such in the blast furnace but they may behave very well in the furnace when converted into sinter. Our Kalabagh iron ore belongs to this type. It is why sintering process has been selected for the proposed Kalabagh Steel Mill.

Key words: Steel mill, Indigenous resource.

F/54. Faruqi, S.H., 1973. Report on the Pezu Iron Ore Deposits of Bannu, Northwest Frontier Province.

The results of a field and laboratory investigations conducted so far on Pezu Iron Ore Deposits are very encouraging and it may be safely reckoned that these deposits would play an important role in the economy of North – West Frontier Province if proper attention is paid to their development. From mining point of view at least, these deposits stand as the best iron ore deposits of the country.

Chemical and mineralogical studies of a number of representative samples collected from surface and underground workings indicate that this ore has a favorable composition from smelting point of view.

Average Iron contents of the ore are 31.3% silica constitutes about 19.8 %, calcium oxide 4.8 % and magnesium oxide 3.6 %. The ore is basically of limonitic-sideritic type. About 68.9 % of the total iron present is in the form of limonite (hydrated iron oxide) and about 27.8 % is in the form of siderite (iron carbonate), the remaining 3.2 % is owed by glauconite (hydrous silicate of iron and potassium with aluminium and magnesium)

With an ore bed thickness of about 16 feet, outcrop extent of about 2 miles and the fact that both ends of the outcrop are structural end rather depositional, the deposits show good prospects of substantial ore reserves capable of supporting a mini steel mill.

Key words: Iron ore, Pezu, Bannu.

F/55. Faruqi, S.H., 1977. Evaluating Rich Ruby Deposits in Northern Pakistan. "World Mining", California U.S.A.

F/56. Faruqi, S.H., 1978a. Find Report Hunza Ruby Project.

Nature has bestowed Hunza, like its scenic beauty, with an immense wealth of gemstones, both precious and semi-precious. With a thickness or breadth of 7000 to 10,000 feet, the Hunza Ruby Belt which mainly consists of a coarse crystalline richly mineralized marble criss crossed by acid dykes, extends for about 15 accessible miles in strike.

While the Hunza rubies of selected localities compare with or excel in colour and size their counterparts from any source of the world, they lag behind in flawlessness and transparency especially when it comes to bigger size and darker shades.

During the exploratory operations spread over 4.5 years, 1,17,670.695 carats (according to Project's weightment) of rubies, sapphires and ruby spinels were produced. This is in addition to hundreds of thousands of carats illegally extracted by the local people during pre – project period which found their way to the Pakistani and foreign gemstone markets bringing in turn good prosperity to some of the families of Hunza.

Unfortunately no worth considering portion of the rubies recovered during the exploratory operations has been cut or marketed in an open market till the completion of this report due reasons beyond the control of Project's staff. As such nothing can be commented safely regarding the feasibility of the Project.

However the sporadic valuation attempts made in the past of some of the rough and cut stones by some of the foreign and local experts have given quite encouraging results except of course the hurried valuation of the rough stones by the values of the State Gem Corporation of Sri Lanka in April 78 at Peshawar, which gives a rather gloomy picture of the feasibility of the Project.

Key words: Gemstones, ruby, North Pakistan

F/57. Faruqi, S.H., 1978b. Origin of Hunza rubies and nature of the deposits. National Seminar on Development of Mineral Resources, Lahore, 19-31.

The nature of Hunza rubies and their relation to the surrounding geologic environment suggest a hydrothermal origin instead of generally considered regional metamorphic one.

With thickness of 7000 to 10,000 feet, the Hunza Ruby Belt, which mainly consists of a coarse crystalline richly mineralised marble crisscrossed by acidic dykes, extends for about 15 accessible miles in strike.

While the Hunza rubies of selected localities compare well or excell in colour and size their counterparts from any other source of the world, they lag behind in flwlessness and transparency, specially when it comes to bigger size and darker shades.

Key words: Gemstones, ruby, North Pakistan

F/58. Faruqi, S.H., 1983a. Hunza ruby deposit and their genesis. 2nd National Seminar on the Development of Mineral Resources, Peshawar, 1.

Consult the preceding two accounts for further information.

Key words: Gemstones, ruby, genesis, North Pakistan

F/59. Faruqi, S.H., 1983b. Malakand chromite deposits. 2nd National Seminar on Development of Mineral Resources, Peshawar, 1, 5p.

Malakand chromite deposits have been discussed in this paper indicating their occurrences, reserves and grades. The involvement of the PMDC for the exploration and exploitation of these deposits and the beneficiation test work carried out at the PCSIR have also been described.

Key words: Chromite, Malakand.

F/60. Faruqi, S.H., 1983c. Nature and origin of the salt deposits of Pakistan. 2nd National Seminar on Development of Mineral Resources, Peshawar, 1, 18p.

Recent detailed geological investigations for salt in the Salt – Range and Kohat district have given an entirely new picture of the nature and origin of Pakistani salt deposits.

Identification of typical diapiric structures including salt walls salt dykes and “salt flows” over the denuded surfaces of younger formations clearly suggests a diapiric mode of occurrence as against the presently accepted bedded or in situ one.

Prospects of fresh reserves of salt and oil and techniques / approaches for their exploration and exploitation may have to be reoriented in view of the new picture.

Key words: Salt deposits.

F/61. Faruqi, S.H., 1983d. Special features of the geology of Makerwal coal fields. 2nd National Seminar on Development of Mineral Resources, Peshawar, 1, 4p.

Special features of Makerwal’s geology are: 1) A low angle thrust undercutting the entire or most of the Surghar – Range placing the Mesozoic and early Tertiary sequence together in a basin of the younger Siwaliks 2) Structural control of the thickness of Makerwal coal seam and 3) Shale diapirism displayed by the Patala Formation.

In view of the expected disturbances in the deeper workings of the left – over coal areas, future of Makerwal Collieries would depend on a very careful study of the prevailing geological conditions, prudent planning patient development work.

Key words: Coal fields, structure, Makerwal.

F/62. Faruqi, S.H., 1984a. The Salgi oil sand. Abstracts, First Geological Congress, Lahore, 21-22.

Key words: Oil, Sand, Salgi.

F/63. Faruqi, S.H., 1984b. Azad Kashmir ruby deposits. Abstracts, First Pakistan Geological Congress, Lahore, p.24.

Located at a road distance of 112 miles NE of Muzaffarabad in the Shontar valley, these newly discovered ruby deposits excel in some respects, when compared to the already known and worked Hunza deposits. However, both gem stone deposits appear to be analogous in age and genesis belonging to the same Darkot Group (Permo-Carboniferous) and of hydrothermal origin.

Since mother marble is well mineralized and extensively developed in the Shontar and adjoining valleys, there are good prospects of locating additional and richer gem stone deposits through intensive exploration.

Key words: Gemstone, ruby, Azad Kashmir.

F/64. Faruqi, S.H., 1984c. Structural similarities between Salt Range and Kohat salt area. First Pakistan Geological Congress, Lahore, p.28.

Structures at the eastern and western extremities of the Salt Range have been found to be surprisingly similar in detail to those at the Kohat Salt area in general, suggesting that these area have identical diapiric and tectonic histories, various evidence are presented in support.

Key words: Structure, Salt Range, Kohat,

F/65. Faruqi, S.H., 1984d. The heterogeneous “Jatta Gypsum” horizon of Kohat. Abstracts, First Pakistan Geological Congress, Lahore, 34-35.

Field investigation in the Kohat salt area have shown that the so called ‘Jatta Gypsum’ horizon of reportedly Eocene in age actually consist of bodies of gypsum-anhydrite and marl etc. it belongs to four different horizons, ranging in age from Recent to Precambrian (?). Detail of the rocks and subdivision are given.

Key words: Stratigraphy, Jatta Gypsum, Eocene, Kohat

F/66. Faruqi, S.H., 1986. Precambrian Oil in the Salt Range and Potwar Pakistan. Published in vol. 4 Kashmir Journal of Geology

Precambrian rocks, both sedimentary and non-sedimentary types, hold good promise of commercial resources of oil/gas in Pakistan.

Field evidences indicate important relationship between intrusive Khewra Trap and oil / gas shows of the Salt Range Formation (Precambrian). Future development of Precambrian hydrocarbons would, to a considerable extent, depend on the correct understanding of this relationship.

In addition to the conventional structures within immediately overlying reservoir rocks and the internal structures of carbonate zones within Salt Range Formation, there are quite good prospects of Precambrian basement reservoirs in all regions of Salt Range Formation and basement, at workable depths.

Key words: Petroleum resources, Khewra trap, Salt Range formation, Precambrian.

F/67. Faruqi, S.H., 1988. Brief Report on Recent Finds of Precious Metals in Pakistan.

Precious metals (gold, silver and platinum group elements) bearing rock types have been discovered at a number of localities under promising geological environments in Baluchistan, Gilgit, Azad Kashmir, Chitral, Hazara, Waziristan and Punjab.

Comprehensive geological investigations have been recommended at the concerned localities as well as in all regions of similar geology to assess actual potential of precious metals of the country. Side by side, beneficiation and processing tests have been proposed to be undertaken in and outside Pakistan at suitable laboratories on bulk samples to establish commercial processing and exploitation of these deposits.

Immediate drafting and promulgation of incentiveful mineral concession rules, in respect of precious metals, has been strongly recommended in order to attract local and foreign capital and know – how in this relatively new but highly important industrial field.

It has been suggested to commission suitable consultants of international repute to explore various promising precious metal regions of the country with the assistance of local geologists so that the nation could have a realistic assessment of what it has, in a reasonable period of time.

Key words: Precious metals, Gilgit, Hunza, Chitral, Baluchistan.

F/68. Faruqi, S.H., 1989a. Exploration of Precious Metals by PMDC. Seminar on Prospects and Problems of Minerals Based Industries in Pakistan, Peshawar.

PMDC's exploration department has been able to locate some interesting precious metals bearing rocks in different parts of the country. Main areas as per current knowledge are: Gilgit region in the north and the Volcanic Belt of Chagai District (Baluchistan) in the west.

PCSIR Laboratories, Lahore have already evolved, after necessary experimentation, a flow sheet for concentration of at least the precious metals bearing Chilghazi cupriferous magnetite of Baluchistan. Values of copper, platinum, gold and silver in the final flotation concentrate of PCSIR are 22%, 21.8 gms / ton, 5.3 gms / ton and 45.8 gms / ton respectively.

It is unfortunate that no mineral concession rules have as yet been promulgated in the country in respect of precious metals. This is considered necessary if we want any meaningful mineral development.

It is suggested that all prospective mineral deposits in Pakistan should be made open for the public, both local and foreign. This is considered necessary if we want any meaningful mineral development in the country.

Key words: Precious metals, Gilgit, Baluchistan.

F/69. Faruqi, S.H., 1989b. Rock Salt – The Most Potential Mineral Resource of Pakistan. Seminar on Prospects and Problems of Minerals Based Industries in Pakistan, Peshawar.

F/70. Faruqi, S.H., 1990a. Kalabagh iron ore deposits and there economic importance. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, p.9.

The Kalabagh iron ore deposits could play an important role in the economy Pakistan if they are duly exploited by the establishment of an integrated iron and steel project on the same.

The iron ore deposits are ideally located in respect of the co- occurrence of most other raw materials of the steel industry and in respect of the infrastructure facilities. The deposits are also suitably located with reference to the local markets of their steel mill's finished products.

It would therefore be in the fitness of things to revive the hitherto cold storage 'Kalabagh Steel Mill' and establish it with the least possible delay to initially meet the gap between the current production of the Karachi Steel Mill and the country's actual iron and steel requirements.

Key words: Iron ore, Kalabagh.

F/71. Faruqi, S.H., 1990b. The Kalabagh Dam Site: A critical study. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, p.14.

The Kalabagh Dam, if constructed at its proposed site, will be unique in the sense that it would be the first dam of its kind and size to have been located on the rim syncline of a salt dome.

Since the massive and still active 'Kalabagh salt dome' is chiefly being fed from the east by the area which is supposed to support the proposed Kalabagh dam and its vast water reservoir, it is feared that additional weight of that magnitude might disturb the present balance of salt extrusion and erosion and might in addition generate enough seismicity to destroy or seriously damage the colossal Kalabagh dam. Accelerated part- subsidence at dam site, simply due to the extra-weight at a particular locality aided of course by the reactivation of the already existing subsidence-fault at and close to the dame site, will be the other and equally important factors to play hell with the safety of the dam.

Prevailing geologic conditions in the Salt Range and the adjoining Kohat salt area suggest that no dam of such magnitude should be thought of in Kalabagh area upto roughly the confluence of Kohat Toi and the Indus located about 33 miles north-east of Kalabagh.

Key words: Damsite, Kalabagh.

F/72. Faruqi, S.H., 1990c. Carbonatite status in Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 27-28.

So far, according to the available geologic literature, carbonatite is known to occur in Pakistan only at four different localities which are linked together to form the so called 'Alkaline Province Pakistan'. This 'Province' is considered to extend arcuately around Peshawar from Warsak area in the west, Malakand in the north up to Tarbela dam in the east. The carbonatite localities are: Loe Shilman (64 Km NW of Peshawar), Malakand, Koga (S. Swat) and Tarbela. Of the four occurrences, Loe Shilman and Malakand are worth considering, the other two are too limited and only of secondary interest. Malakand has no associated alkaline igneous rocks except of course the carbonatite themselves.

Recent studies by the author indicate that the carbonatite situation in Pakistan may be very different as these rocks seem to be of quite widespread occurrence in Azad Kashmir, Northern Areas and possibly also in the Volcanic Belt of Chaghai district of Baluchistan.

Field and Lab evidences, though not decisive, indicate that a number of carbonate bodies or masses in northern Azad Kashmir and Gilgit, etc. which have so far been treated as marbles, calcareous schists or xenoliths of calcareous country rocks within the intrusives, could actually be carbonatites. Brief account is given of three such carbonatite (?) occurrences in Shardi-Doarian region of Azad Kashmir and Bagrot and Henzal areas of Gilgit.

There are grounds to suspect that the onyx marble (travertine) of Chaghai Baluchistan is mothered by burned carbonatite mass thus possibly establishing its analogy with the travertine bodies of the Arkansas River valley in Colorado (USA), which are also believed to owe their origin to the nearby occurring McClure Mountain Carbonatite Complex.

Key words: Carbonatite, Malakand, Loe Shilman.

F/73. Faruqi, S. H., 1990d. Export-Oriented Development of the Rock Salt Deposits of Pakistan. First SEGMITE Conference on Industrial Minerals, Peshawar.

Nature has bestowed upon Pakistan an inexhaustible wealth of high grade rock salt deposits in the Punjab and Frontier provinces. These deposits generally occur at and above normal ground level thus rendering themselves workable through cheap surface as well as sub - surface mining methods.

Rock salt alone may have favorable impact on the economy of this country provided we accept the dictates of nature and exploit these deposits to the optimum extent at competitive rates using modern methods of mining and processing.

There are bright prospects of the export of rock salt and its products by Pakistan to the international market including Japan which is the giant importer of salt and its chemicals in Asia.

Kalabagh Warcha and Makerwal salt deposits in the Salt Range (Punjab) and the Bahadurkhel deposits of Kohat / Karak salt area (Frontier Province) show brighter prospects of cheap large scale production.

Key words: Salt deposits, Bahadurkhel.

F/74. Faruqi, S.H., 1990e. Dolomite resources of Surghar and Salt Ranges. Proceedings, First SEGMITE Conference on Industrial Minerals, Peshawar, 29-33.

Inexhaustible deposits of industrial grade dolomite occur in the Northern Surghar Range and the Western Salt Range. The available dolomite belongs to three different stratigraphic horizons namely: the Salt Range Formation (Precambrian), the Jutana Dolomite Formation (Cambrian) and the Kingriali Dolomite Formation (Triassic).

Precambrian horizons are of academic and/or of 'Petroleum Geologists' interest only. Cambrian horizon though extensive but lacks desired purities. Triassic horizon (Kingriali) affords inexhaustible quarryable reserves of industrial grade (both chemical and metallurgical) dolomites both in the Surghar Range and Salt Range. Geology and chemistry of the deposit has been discussed with detailed field and laboratory data.

Key words: Dolomite, Surghar, Salt range, Precambrian, Cambrian, Triassic.

F/75. Faruqi, S.H., 1994. The unique Hunza ruby and sapphire belt. Proceedings, Second SEGMITE International Conference on Export Oriented Development of Mineral Resources and Mineral Based Industries, Karachi, 1994, p.44.

Rubies and Sapphires occur in association with ruby spinels in a coarsely crystalline marble formation with an apparent thickness of 2134 to 3050 meters and strike extent of more than 24 km. The marble is heavily criss crossed by dykes and sills of intrusive igneous rocks: aplite, granite and pegmatite as well as quartz veins.

Mineralization of ruby/sapphire and spinel apparently owes its origin to the intrusives and is considered to be a direct product of their mineralizing solutions acting along suitably positioned and favourably compositioned bedding planes, fissures, fractures and joints of host marble.

The colour of ruby/sapphire is in general, appealing and has a wide range of pink, purple violet to typical pigeon blood red. Transparency is also tolerable but the calcite partitioning, grooving and the general fractured nature of stones are the main drawbacks. However, the area yields the finest quality specimens of ruby, sapphire and spinel with enhanced beauty by the associated ruby mica, green mica (fuchsite) and graphite alongwith golden crystals of the fool's gold (pyrite).

The nature and origin of Hunza rubies is strikingly similar to those of the famous Mogok Ruby Belt of Burma (Myanmar) which has supplied the best rubies to the world for the last 700 years. Potential of the area is great and inexhaustible; systematic exploratory efforts at Hunza may be well rewarded. The exploratory efforts undertaken by PMDC and GEMCP have so far been restricted to simply mining the more accessible areas in crude and haphazard way.

Key words: Gemstone, ruby, sapphire, Hunza.

F/76. Faruqi, S.H., 1996. Granites of Pakistan. Proceedings, Second SEGMIITE International Conference on Export Oriented Development of Mineral Resources and Mineral Based Industries, Karachi, 1994, 35-43.

Nagarparkar in south (Sindh) and Mansehra in the north (NWFP) so far were the only source of granites of the country. But recent investigations by Eastern Technique for commercial granites in the Northern Area of Pakistan, specially the Gilgit region, have indicated great potential of variety, quality and quantity. The Karakoram Highway (KKH) with its much relaxed and relatively cheap downhill carriage has eased the transport situation greatly despite a fairly long lead of about 600 km from Islamabad. The unique white, jet black, a variety of shades and textures in white – grey and greenish types along with some of the typical greens bestow superiority to Gilgit granites over all other parts of Pakistan under the present state of geological knowledge.

Key words: Granites, mineral resources, KKH, Nagarparkar, Mansehra.

F/77. Faruqi, S.H., 1997a. The unique graphite glacier of Chapursan valley, Gilgit. In: Abstract volume Colloquium on Geology and the Human Life. Pakistan Academy of Geological Sciences, 29-30.

Key words: Glaciers, Chapursan.

F/78. Faruqi, S.H., 1997b. Nature and origin of Salajit. Colloquium on Geology and the Human Life. Pakistan Academy of Geological Sciences, 30-32.

Recent field and laboratory investigations for salajit collection and study of its complete and intact natural bodies along with host rocks have resulted in entirely new concepts regarding the nature and origin of this unique rock product of great medicinal value. Its often claimed origin as: 1) a member of petroleum family (asphalt) 2) latex of some nearby Plants, 3) an alteration product of entombed ancient vegetative material (fossil wood), 4) accumulated dropping of a mountain bird or 5) the urine residue of a rare mountain animal etc. may all be safely discarded on logical and scientific bases. There are quite appealing grounds to suggest the recent coniferous forests growing on hard and fractured igneous rocks and possibly also the mineral biotite $[K(MgFe)_3 AlSi_3O_{10} (OH)_2]$ and orthoclase feldspar $(KAlSi_3O_8)$ are responsible for the development of salajit. Schistose biotite granite, occurring along lines of major structural disturbances in the Himalayas specially around the peripheries of large intrusive masses of igneous rocks, is the most

favoured host rock, while very steep, vertical to over-hanging bare rock cliffs at high altitudes but still below or adjacent to the coniferous forests, are the most favoured sites of salajit occurrences in Gilgit region which is the largest producer of salajit in Pakistan.

It appears from the prevailing conditions that basically salajit is a bacteria-altered product of accumulated plant material. Possibly it develops at most of the coniferous forests of Northern Areas and elsewhere but comes out as seepages only under favourable conditions of rock and topography. In a hard and fractured or well-jointed but more or less non-porous rock like biotite granite it starts moving downwards along fracture/joint planes due to gravity and comes out at the surface as a seepage on encountering some opening which is invariably provided by some abrupt natural cutting. On the other hand, in porous sedimentary rocks or unfractured and inconspicuously jointed non-porous sedimentary and igneous rocks the salajit fluid is either completely absorbed by the underlying rock or is trapped down localised at or near the site of its origin thus disallowing any salajit seepage to occur. Absence of a steep cutting adjacently below the mother forest will also result in the absence of a salajit seepage despite a suitable host rock.

The slow moving thick acidic salajit fluid along with the still undigested plant material in the form of the fibrous woody pallets etc. and of course with out army of bacteria, apparently attacks the biotite and orthoclase feldspar of the biotite granite and partly dissolves and carries the same on its way downwards and laterally.

Key words: Salajit, Gilgit, Northern areas.

F/79. Faruqi, S.H., 1997c. The graphitized coal deposits of Chapursan valley, upper Hunza valley. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

A number of characteristics, partially graphitised coal seams have been found to occur in a thick formation of brown weathered, grey-black, thick bedded, hard and compact carbonaceous limestone of possibly Permian age in the Reshit area of Chapursan valley north of Gilgit. The vertically trending coal seams are variable in thickness over short distances apparently due to lateral stresses but are persistent for several kilometers in strike at both flanks of Reshit Nala. Normal range of thickness is from a few inches to 25 feet. At places, specially at the thicker coal/graphite seams, the amorphous to flaky "secondary" graphite has been found to show tendency of migration to relatively low stress areas and give rise to graphite pockets of considerable sizes. At least at one locality ejection of graphite has apparently taken place from a graphite bed consisting of partially graphitised coal with alternating bands of carbonaceous limestone. This ejection of graphite, apparently from some of the rich graphite pockets of the otherwise lean graphite bed, has given rise to a 'graphite glacier' a unique object in the geological realm of the earth. The said graphite glacier maintains a length of about 500 feet and a breadth of 15 to 50 feet. However it seems to be the result of apparently a one-time migration phenomenon rather a still continuous process.

Key words: Coal deposits, Chapursan valley, Hunza.

F/80. Faruqi, S.H., 2000. Feasibility Report Henzal White Granite, Gilgit. A joint report of ETL, GMC and ENFI China, prepared for Zaver Mining Co. Pvt Ltd Islamabad.

So far Nagar Parkar in the south (Sindh) and Mansehra in the north (NWFP) were known to be the only sources of workable granites in Pakistan. But the recent investigations by Eastern Technique for Zaver Mining in Gilgit have resulted in the discovery of a number of workable granite deposits at accessible localities and with inexhaustible reserves. Of these the Farphui's Black Granite deposit of Bagrot Valley occurring at a road distance of 37 km NE of Gilgit and the unique White Granite Deposits of Henzal Area located 20 km NW of Gilgit are most outstanding and promise to fetch good local and foreign markets. The Basin's massive grey granite deposits occurring under ideal conditions of working next door to Gilgit to the west show promise of being able to snatch a considerable part of the existing vast market of marble in Pakistan by making available abundant and cheap granite to the masses.

Two schemes of underground mining and open pit quarrying are recommended in this report:-

Total capital cost of the modest Underground Mining Scheme of the Henzal White Granite Deposits for a production of 5000 cubic meters or 100,000 m² of squared slabs of granite per annum is Rs. 420 million which is expected to be fully paid back within a period of 6 years.

For surface quarrying or open pit mining, around 930 million rupees would be required for the targeted production and a period of ten years would be required to bring the project into profit.

Key words: Granites, mineral resources, KKH, Nagarparker, Mansehra.

F/86. Fatmi, A.N., 1972b. Stratigraphy of the Jurassic and Lower Cretaceous rocks and Jurassic ammonites from northern areas of West Pakistan. British Museum of Natural History Bulletin (Geology) 20(7), 299-380.

The stratigraphy of the Jurassic and Lower Cretaceous formations and Jurassic ammonites from Hazara, Kala Chitta, Nizampur, Western Kohat (Samana range) and the Trans Indus ranges in Northern Pakistan are described.

A provisional zonal scheme is proposed and correlation is suggested with Spiti, Cutch, Madagascar, Mediterranean Province, Middle East, and East Africa. Failure to recognize certain ammonite zones in the area may be explained by non-deposition, slow deposition, unfavourable facies, failure of collection or some combination of these factors. Middle Calovian, Upper Oxfordian and Lower Kimmeridgian ammonites from the Trans Indus range, Upper Oxfordian-Tithonian ammonites from Nizampur, Lower Toarcian ammonites from Kala Chitta and Lower Tithonian ammonites from northern areas of Hazara are recorded and described for the first time. In addition, a definite Aptian ammonite fauna is recognized in parts of Western Kohat and the Kala Chitta range. The faunal studies indicate that the Jurassic passes into the Cretaceous without a break in most areas of northern West Pakistan. The major stratigraphical breaks are Pre-Toarcian, Intra-Jurassic (pre-upper Oxfordian, pre-Kimmeridgian or pre-Tithonian) and intra-Cretaceous (post-Lower-Middle Albian).

F/91. Fatmi, A.N., Anwar, M., Hussain, I., Saeed, G. & Latif, A., 1990. Stratigraphy of the Shinawari and Datta formations from the Shinawari Area (western Samana Range), Kohat District, Pakistan. Punjab University Geological Bulletin, 25, 47-55.

Stratigraphy of Shinawari Formation is described from the type area of Shinawari on the basis of newly described Boulcieras bed and the overlying maroon shale. Both these units show as key horizons indicating a Lower Toarcian transgression in most areas of Kohat-Potwar Province of the Upper Indus Basin and provide a facies basis of interregional correlation. The clastic shallow water marine sequence below the Boulcieras beds is placed in the Datta Formation. The Datta Formation in the Samana Range shows a facies change from the type area of Datta in the Surghar Range where the formation is mainly continental. In western Kohat (Samana Range) it is a shore-line to shallow marine sequence as is represented by the frequent carbonate beds with the molluscan and brachiopod fauna and closrics. The two Datta facie are comparable to the Lower Cretaceous Lumshiwai facies which show similar environmental change from continental in the south to marine in the north west of the Trans Indus Ranges.

F/94. Fawad, M., 1986-88. The geology and petrology of Chilas ultramafic complex in the vicinity of Chilas (District Diamar) with special emphasis on petrogenesis of the rock units. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 113p.

The project area covers about 368 sq. Km. located in the vicinity of Chilas, District Diamar. The work has involved geological mapping of the area on a scale of 1:50,000. This thesis deals with the geology, petrography and petrogenesis of the Chilas complex and adjacent southern rock units. The possible relation of Chilas complex with the southern Jijal complex has also been discussed. The geological sequence of the area consists of metadiorite rocks of the Chilas complex and granodiorite. The rocks of the Chilas complex are divided into two main associations, the ultramafic-anorthosite association and the main norite/gabbro-norite association. Both the associations represent lower and upper cumulates respectively and are in a complicated contact possibly due to syndepositional folding-and faulting. Diorite is the most evolved unit of the Chilas complex.

Field evidences suggest that Chilas complex was intruded into an old pluton, the metadiorite which was included in Kamila amphibolite by Coward (1982). The relationship of Jijal with Kamila amphibolite also shows that the Jijal complex was accommodated in the rocks represented by Kamila amphibolites, suggesting an older age of Kamila rocks than Chilas and Jijal complexes. The Chilas complex is unmetamorphosed and is present in an anticlinal position with ultramafics chiefly restricted to the core of the anticline. The ultramafics are overlain by more evolved rocks i.e. gabbro-norite association and diorite capped on both limbs by metadiorite roof rock. On the southern limb, the metadiorite roof rock unit is intruded by a granodiorite pluton which seems to be younger in age than the Chilas complex. Whole of the stratigraphic sequence of Chilas complex is fractionation product of hydrous, magnesian, island arc basaltic magma and there is a strong possibility of finding economic metallic mineral deposits in the Chilas stratified complex.

Key words: Petrology, ultramafics, petrogenesis, Chilas.

F/95. Fayaz, A., 1988. A short note on movement of Dih Glacier causing blockage of the Karakoram Highway. GSP, Information Release, 329, 8p.

On 12th September 1987. Karakoram Highway was closed due to damming of Khunjerab River resulting in a lake about 1 /2 km long. This problem cropped up due to the movement of Dih glacier in the form of mud flow through Dih nulluh.

Dih glacier is a type of surging glacier which creates problems after lapse of many years. Reasons of movement of glaciers, its effects and possible solutions to reconstruct and to keep open the affected part of the Karakoram Highway is the subject of this report.

Out of the three options suggested in this report, the author is obliged to put emphasis on the one that the army engineers are already working on. The method calls for the construction of a new segment of the road along the bank of the lake by filling the available material.

Key words: Glacier, Glacier surge, Karakoram Highway.

F/96. Fayaz, A. & Hussain, H., 1998. Geotechnical report on the proposals for the future planning of Astor valley road, Northern Areas of Pakistan. GSP, Information Release 642, 17p.

During the course of rehabilitation and metalling of the Astore Valley Road, a geotechnical study was carried out on the request of Frontier Works Organization. The aim of this study was to discuss the various proposals under consideration for the improvement of this road.

During the last ten years, more than 250 Million rupees were spent on this project, without achieving its main objective to make it truckable upto Astore. The only hindrance in the fulfillment of this goal is the road portion between Mushkin and Dushkin,

These Slides are complex and a source of constant problem, a detailed study of these slides indicates that the problem is so severe that control of these slides are prohibitively expensive. Instead of repairing these

slide zones, new alignment proposals are taken into consideration by shifting the road in this portion to the other side of the river by the construction of two or four bridges, to avoid the unstable areas of both sides. Keeping in view, the three alternative a comparison was made from the Engineering geology point of view and recommended the realignment of the road on the right bank with two bridges on Astore River.

It is also recommended that before undertaking the project worth of 1032.680 million (Construction of road- Thelichi, KKH -Gorikot-Chilam choki-Minimarg 140 Km), a detailed evaluation from the engineering geology point of view must be undertaken to appreciate the latest techniques available in this field for the future safety of this project.

Key words: Geotechnical, Astore.

F/97. Fayaz, A. & Hussain, S.H., 1999a. Engineering geological studies for road alignment and slope stability along Gupis-Shandur Pass road, Ghizar valley, Northern Areas, Pakistan. GSP. Information Release. 682, 30p.

This report presents data, from Gupis to Shandur Pass which is about 107 km long. The whole strip is divided into 30 sections on the basis of material, topography and prominent bridge locations.

The study includes road alignment considerations, land slide investigations, river bed erosion problem and identification of plantation sites. At the end of each section recommendations are proposed for the improvement of the road and remedial measures (or the control and stabilization of slopes).

Presently the road condition from Gupis to Shandur Pass requires improvement as only jeeps can cross the Shandur Pass to reach upto Chitral. The widening and realignment proposed in this report will help a great deal for better road link between Gilgit and Chitral, which will ultimately attract more tourists in the country.

Key words: Engineering, slope stability, Gupis-Shandur, Ghizar valley, Northern areas.

F/98. Fayaz, A. & Hussain, S.H., 1999b. Reconnaissance survey of slope stability and river bed erosion control along Naltar valley road, Northern Areas of Pakistan. GSP, Information Release 674, 21p.

Naltar valley is very famous Tourist resort in Northern Areas. Pakistan Air force (PAF) also maintains a Skiing Resort in this area. The Ministry of tourism and Culture has also proposed to truckable metalled road from the Karakoram Highway by constructing a bridge on Hunza River in front of NomaI village and improving the existing road upto the PAF Skiing Point in this valley. They also planned a tourist resort (five star) to encourage Tourism in this area.

The whole strip is divided into 20 sections depending upon the nature of material/problem envisaged. These sections are of different lengths. A brief description of bridges encountered are also mentioned in this report.

Keeping in view, the type of material/deposits, river position with respect to road, present condition of the road existing gradient of the road, width of the road, suggestions are proposed to improve the gradient, slope stability, river bed erosion to gain the required width. Wherever realignment of the present road found suitable, its proposed and comparison has been given to justify this realignment.

Key words: Slope Stability, erosion, Naltar Valley, Northern areas.

F/99. Fayaz, A. & Khan, K.S.A., 1988. Study of cracks near the village Bara Khaplu subdivision, District Baltistan, Northern Area. GSP, Information Release 363, 12p.

Geological investigations were carried out at Bara village near Khaplu, Baltistan in February, 1988 on the development of a crack about 3 km long in the out-washed material on the western piedmont slope of Bara Pien hills. The crack is about 2 meter wide and has shown down-warping of talus material by 1.5 to 2 m due to creep movement.

The exposed rocks are of granitic composition and are hard, massive and well jointed. The hill slopes show thick accumulation of talus material derived from the adjacent rocks and comprise big boulders embedded in a heterogeneous mixture of coarse sand and fine clay.

Causes of appearance of this crack and land subsidence is apparently due to excessive infiltration of water from the channels called “Kouhls” and slow insipient seepage of snow-melt water into the ground. These channels are unlined and allow the escape of water into the ground which subsequently causes settlement of unconsolidated talus material.

Further development and enlargement of crack and creep of talus material may be checked by controlling the excessive inflow of water into the ground by cementing the irrigation channels. The soil creep may be checked by plantation of quick-growing species of plants along the slope.

Key words: Cracks, Khaplu, Baltistan, Northern areas.

F/100. Fayaz, A., Khan, K.S.A., & Latif, M., 1985. Mudflows and avalanches along the Karakorum Highway. GSP. Information Release 247, 28p.

Landslide investigations were carried out along the Karakoram Highway during the field season 1983-84 on the request of University Grants Commission and the Frontier Works Organization. The problems of the area were thoroughly investigated and classified according to their origin and mode of occurrence.

Mud flows and avalanches along the Karakoram Highway (KKH) from Thakot to Khunjerab pass are discussed in this report. Study of slides include type of rock/material involved in the affected area, reason of its occurrence and remedial measures to check the mass movement phenomenon.

Specific recommendations for each of the affected area are made. These remedial measures are of two types; first, those which can be immediately implemented to check further deterioration; the other ones are for long term measures which will involve more funds and also some restructuring of the KKH plans. However, the second set of remedial measures are very crucial for further safety of the KKH.

Jaglot Gah Mudflow and Harbon avalanche are studied in detail due to their critical position on the KKH as well as their magnitude and repeated occurrences involving large amount of material fall. The recommendations made for these areas should thus be implemented soon.

Continuous maintenance of the KKH requires considerable efforts in terms of time and money. Proper execution and implementation of the recommendations proposed in this report may help a great deal in reducing the manpower and maintenance cost of the KKH.

Key words: Mudflows, avalanches, Karakoram Highway.

F/101. Fayaz, A., Khan, K.S.A. & Latif, M., 1986. Study of landslide problems in rural and urban areas of Murree tehsil. . GSP, Information Release 270.

Fifteen landslides on the link-roads connecting rural areas of Murree Tehsil and the urban area of Murree Town were studied and described in this report. Study of slides include plotting the location of the slides on the maps, type of rocks and material involved in the sliding area, origin and mode of their occurrences and remedial measures. The lithological behaviour of Murree Formation, overloading of soils by constructing heavy structures and unscrupulous cutting of trees are mainly responsible for the generation of slides in Murree area.

Proper execution and implementation of the recommendations proposed in this report may help a great deal in the control and stabilization of slopes in the affected areas.

Key words: Landslides, Murree formation, Murree.

Key words: Landslides, Karakoram Highway, Hasanabdal, Gilgit.

F/103. Fayaz, A. & Latif, M., 1984. Development of cracks in mountain around Sermik village Skardu Sub-division, Northern Area, Pakistan. GSP. Information Release 223.

On the request of Commissioner, Northern Areas, landslide investigations were carried out around Sermik village, Skardu Sub-Division, during the month of February, 1984. The work pertained to the development of cracks in the mountain terrace near Sermik village and probable danger to the life and property of the people of the area.

The affected terrace comprises heterogenous mixture of silt sand and gravel with large embedded boulders. The cracks have developed due to the subsidence of terrace material resting on a downthrown block of an intraformational fault in the granitic body. Excessive seepage and infiltration of rain and snow-melt water have added to the enlargement of these cracks.

The affected terrace may be stabilised by controlling the excessive infiltration of rain and snow-melt water by making catchwater drains, filling and tamping of all open cracks and by plantation of deep rooted and quick growing plants.

Key words: Landslide, Skardu.

F/104. Fayaz, A., & Latif, M., 1988. Rocks excavation problems along Gilgit–Gupis road, Northern Area, Pakistan. GSP. Information Release No. 364, 12p.

Rock Excavation studies along Gilgit Gupis road were carried out during the field season of 1986. The road is 110 Km long and is jeepable in fair weather conditions. Now the work is in progress to make it a metaled road. This report is based on identifying the geological structure and applying it for the excavation of major rock outcrops (locally called Pari). Four of them were measured on 1:200 scale and geological profile were prepared to know the distribution of joints, fractures, faults, shear zones, and other related structures and their impact on drilling and blasting. Based on the rock characteristic various drilling and blasting methods have been suggested for the future safety of the road and to minimize the hazards of land sliding after the construction of the road.

Key words: Excavation, Gilgit-Gupiz, Northern areas.

F/105. Fayaz, A., Latif, M., & Khan, K.S.A., 1985. Landslides evaluation and stabilization between Gilgit and Thakot along the Karakorum Highway. GSP. Information Release No. 253, 49p.

Ten major landslides and a few unstable zone s in a road strip of 350 km long from Thakot to Gilgit along the Karakoram Highway (KKH) are discussed in this report.

Study of slides include plotting of location of the landslide on road log map with respect to their distances from Thakot, types of rock/ material involved in the affected area, origin and mode of their occurrences and remedial measures.

Proper execution and implementation of the recommendations proposed in this report may help a great deal in reducing the man power and maintenance cost of the KKM.

Key words: Landslides, Gilgit, Thakot, Karakoram Highway.

F/106. Fayaz, A., Latif, M., & Khan, K.S.A., 1988. Geology and slope stability studies along Gilgit–Skardu road, Northern Area, Pakistan. Geological Survey of Pakistan. Information Release No. 379, 5p.

Engineering Geological investigations were carried out during 1987-88, along the Gilgit - Skardu Road. These studies included preparation of geological road log map, identification of landslide areas and evaluation of the suitability of various bridge sites under consideration. Contour plans already available were utilized as the base maps for further details of the proposed sites. In all 21 bridge sites and 6 landslide areas were studied and are described in this report.

Gilgit - Skardu road was started after the completion of Karakoram Highway, and the experiences gained at the KKH were effectively utilized during the construction of this road. It has greatly helped in limiting the landslide and slope stability problems on this road as compared to the KKH.

The recommendations proposed in this report may help a great deal in stabilizing the slopes and construction of safer bridges on the Gilgit - Skardu Road.

Key words: Slope stability, Gilgit-Skardu, Northern areas.

F/107. Fazali, A., 1969-70. Geological report on Dunga Gali-Kuldana Area, District Hazara. M.Sc. Thesis, Punjab University, Lahore, 90p.

This field report concerns about the findings of geological investigation carried out from Kuldana to Dunga Gali areas. Main emphasis has been placed on structural, stratigraphic and geomorphological aspects. The area shows high relief and for the most part covered with thick vegetation. The degree of exposures is low and the 'ground affords poor opportunity for geological mapping. The rocks exposed in the area range from Jurassic to Eocene in age. A study of the area shows that it has suffered strong tectonic disturbance. A number of folds with almost parallel axes were affected by numerous longitudinal and transverse faults. Different geological cross sections prepared are dealt in the descriptive geology along section C-D. Stratigraphic succession is established, and various formations have been correlated. The geological history of the area is made on the basis of their mineralogical enumerations and from the lithology, fossils and their sedimentary features and environment of the deposition are, also given in this chapter. Opinion is given about the regional tectonics of the Himalayan syntaxial bend on whose western limb area situated. Economically, the area contains a pure enough band of gypsum. Laterite, though economical in its composition, is very small in amount. Two main maps have been prepared by the author; one is lithological which is 3" = 1 mile, one part of the area from Changla Gali -Khaira Gali is enlarged by 9" = 1 mile. The other map is structural, showing main trends of folds and faults.

F/111. Felix, G., Michael, S., Pierre, B.J., Bernard, C. & Munir, G., 1999. Kinematics and dynamics of the Himalayan fold-and-thrust belt in Pakistan. *Terra Nostra* 99 (Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany), 59.

The NW Himalayan fold-and-thrust belt in Pakistan runs from the Hazara-Kashmir Syntaxis to the Afghan border. It includes the southern part of the Lesser Himalaya and involves, in places, parts of the Sub Himalaya lying south of, the Main Boundary Thrust (MBT). The MBT and the Hazara-Kashmir Syntaxis dominate the tectonics of this region. The MBT, running all along the Himalayan arc, separates the Indus Basin from the West-Himalayan mountain chain. The Hazara-Kashmir Syntaxis is one of the West-Himalayan Syntaxes where the whole mountain system is sharply bent. The MBT loops around the Hazara-Kashmir Syntaxis, to the east of which no equivalent of the NW Himalayan fold-and-thrust-belt is identified.

Our study area is located in the foothills of the Western Himalaya, 50-km NE of Islamabad, focused on the region between Murree and Nathia Gali (Figure 1). Obviously the development of the MBT and Hazara-Kashmir Syntaxis dominated the deformation of the fold-and-thrust belt, whose understanding required

more dynamic and kinematic arguments. Previous work had given evidence for an imbrication of several thrust sheets in a standard thin-skinned tectonic framework. However, complex models were proposed for the evolution of the Hazara-Kashmir Syntaxis. The area was thus suitable to study the tectonic relationship between thrusting and folding in this part of the Himalayas.

Our study included:

Detailed mapping: A new map with cross-sections will be presented (scale 1:25000).

Describing the lithologies by field observations and thin sections. The belt consists of Jurassic to Eocene low grade metasediments lying unconformably on a basement of Precambrian slates and limestones.

Evaluating the deformational character of the series involved: Imbrication is associated with strike-slip faulting. Carrying out a fault striation analysis using computer aided methods: Various tensors will be integrated in the deformation history. The map and sections show that the fold-and-thrust belt has developed in a multilayered system with layers having contrasting rheologies (e.g. thick limestones interlayered with shales). Lithologies were derived from a passive margin whose sequence is summarized in the following mega-sequences:

Precambrian Hazara slates and limestones (basement).

Unconformable lower Jurassic to upper Cretaceous shallow water marine shelf carbonates and clastics.

Unconformable Paleocene to middle Eocene shallow water limestones and shales, with an upper series of evaporitic marls and mudstones.

Late Eocene to Miocene sediments were deposited in the Himalayan foreland basin and are of shallow marine to continental origin.

Generally steep faults were found. Along the MBT, thrusting and wrenching occurred, but also normal faulting. Combined wrenching and thrusting resulted in positive flower structures well displayed on the map and sections. Folding shows a broad range of styles with most hinges being rather angular. Folds with opposite vergence are seen in several segments of the section. In Mesozoic and Tertiary Formations, synsedimentary normal faults were often reactivated.

The analysis of fault slip data revealed the importance of sinistral strike slip movements along SW-NE-faults. The structural data fit a transpressional regime that has involved the basement. Stress calculations from striations yield a dominant NNW-SSE compression, which, however, cannot explain the whole deformation pattern. A second tensor, with a principal WSW-ENE-compression, was obtained. These two tensors do not have to belong to different phases but instead are the result from a swap between σ_1 , and σ_2 in a constriction-dominated stress field. The two tensors were measured at different places, and no clear superposition was found in the field. In addition a constrictional stress ellipsoid was measured in several sites. Shortening across the anticlinal Hazara-Kashmir Syntaxis led to WSW-ENE-compression, which has influenced the region lying west of the syntaxis. The interaction with the SSE-ward Himalayan transport direction produced the regionally complex deformation pattern. This interpretation simplifies previous ones that proposed rotations in compression directions during the Syntaxis formation. The MBT was bent to its present shape under the influence of the multiple horizontal shortening induced by the constrictional regime. In the core of the syntaxis, shallow marine to continental sediments of the Subhimalaya were folded by an anticline growing vertically, parallel to the extensional axis of the constrictional regime.

Recent seismic activity, neotectonics and geomorphological observations point to the ongoing activity along the frontal Himalayan ranges. Landslides close to the MBT are frequent, and deeply incised valleys with fluvial terraces in a steep topography are common.

Our new maps, sections and structural information point out new features: normal faulting and wrenching along the MBT, inversion tectonics, consistent steep dips and positive flower structures due to combined wrenching and low-angle thrusting. Similar features were recently found in the nearby Kohat plateau by Sercombe et al. (1998).

F/112. Ferguson, R.I., 1984. Sediment load of the Hunza River. In: Miller, K.J. (Ed.), The International Karakoram Project 2, 581-598. Cambridge University Press.

The Hunza River drains 13200-km² of the western Karakoram Mountains, in which heavily-glaciated mountains rise 5-6000m above arid incised valleys. Measurements by the Pakistan Water and Power Development Authority show the Hunza contributes 22% of the runoff and 39% of the suspended sediment load of the upper 143,000 km² of the Indus basin. Its sediment yield of 4,800 t km⁻²a⁻¹, equivalent to a

denudation rate of 1.8mm a^{-1} , is amongst the highest in the world but the precise rate is uncertain because of infrequent sampling, considerable short-term and seasonal scatter about sediments rating curves, and big year-to-year variations in load. Ninety-nine percent of annual suspended load is carried in June-September when melt water discharge is maximum and concentrations exceed 10 kg m^{-3} . IKP measurements in summer 1980 showed sediment concentrations in a major proglacial tributary averaged only 12% of those at the basin mouth. This downstream increase, and the pronounced seasonal hysteresis in sediment rating curves, suggest fresh sediment stores are flushed and then depleted not only as melting extends to higher elevations but subsequently as swollen river overtop unvegetated valley floors and undercut terraces. Solute concentrations estimated from electrical conductivity also increase downstream but less so. At the downstream site annual solute yield is estimated as $90\text{ t km}^{-2}\text{ a}^{-1}$, three times the world average but only 2% of the solid load. Hydraulic properties calculated from gauging data suggest bedload transport could exceed $100,000\text{ t/day}$ in summer and forms 2-10% of total annual load.

F/113. Ferguson, R.I., Collins, D.N. & Valley, W.D., 1984. Techniques for investigating melt-water runoff and erosion. In: Miller, K.J. (Ed.), *The International Karakoram Project 1*, Cambridge University Press.

Meltwater runoff from glaciers and snow fields varies seasonally, with day to day hydrometeorological conditions, and diurnally. Suspended sediment transport is high in Meltwater Rivers but does not have a simple relationship with discharge, and solute concentrations depend on the englacial or subglacial path of the meltwater as well as on rock type. Quantitative understanding of meltwater runoff, solid load and hydro- chemistry in the Alps, Scandinavia, and North America has been improved by continuous monitoring of river conductivity and turbidity as well as stage, automatic water sampling at frequent intervals, and use of atomic absorption spectroscopy and ion-selective electrodes. The sediment removed by meltwater runoff may come from beneath, above or downstream from the glacier. Sources of suspended and dissolved sediment can be inferred crudely from changes in turbidity and conductivity along meltwater routes. They can also be investigated at the microscale by laboratory analysis of rock samples and weathered debris from different altitudes using scanning electron microscopy, X-ray diffraction, microprobe analysis and other techniques already applied to rock debris from the Alps and Hindu Kush. Rockfall contributions can be assessed by time-lapse photography, and bedload transport in meltwater rivers, may be predictable from hydraulic properties obtained during gauging by the velocity-area or dilution methods.

F/114. Fernandez, A., 1983. Strain analysis of a typical granite of the Lesser Himalayan cordierite granite belt: The Mansehra pluton, northern Pakistan. In: Shams, F.A. (ed.), *Granites of the Himalayas Karakoram and Hindu Kush*. Institute of Geology, Punjab University, Lahore, 183-199.

Mansehra pluton is a granite - gneiss complex that has been affected by a markedly heterogeneous deformation. From South to North, a general evolution from granite to thinly laminated gneisses is observed, the bulk strain being highest near the base of the M.M.T.

Three main structural domains have been recognised. In the Southern one, granite predominates over some scarce gneissic zones. Preferred orientation analysis of feldspar megacrysts in the granite reveals that an important flattening component was locally active during intrusion. The Central domain is characterized by coarse grained gneisses which frequently present a well-developed schistosity (s) and a flow cleavage (e), as well as a marked stretching lineation. The gneissification bulk strain evaluated from enclaves and quartz crystals in typical gneisses of this zone, gives a $\lambda_1 : \lambda_2 : \lambda_3$ ratio=75. In the Northern domain, the gneisses are thinly laminated and contain scarce feldspar relics. Bulk strain evaluated from enclaves shape data gives $\lambda_1 : \lambda_2 : \lambda_3$ ratios as high as 300.

Key words: Mansehra pluton, cordierite, granite, Lesser Himalayan, Mansehra.

F/115. Fielding, E.J., Burbank, D.W., Leland, J., Duncan, C.C. & Isacks, B.L., 1995. Geomorphic Responses of Rapid Denudation Rates in the NW Himalaya and Karakoram. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

Analysis of high-resolution digital topography for the Kohistan-Karakoram Himalaya area near Nanga Parbat provides new information on the geomorphic response to some of the fastest cooling and denudation rates on the earth. Apatite cooling ages (Zeitler, 1985) and cosmogenic strath terrace ages (Leland et al., 1994; Burbank et al., 1994) both indicate rapid rates of erosion in this area. Measured incision rates range from ~2 mm/yr east of the Nanga Parbat-Haramosh Massif (NPHM) to 6-9 mm/yr where the NPHM is cut by the Indus River gorge. The present topography presumably represents a balance between the tectonic and erosion processes, and the latter have been affected by Quaternary climate changes. Geometric arguments suggest that incision rates are approximately equal to bedrock uplift rates and that these rates have been sustained for ≥ 0.5 my.

Several quantitative geomorphic measurements have been derived from the digital elevation model (DEM-three arc-second or ~90 m grid), including hillslope angles, local relief, valley widths, and hypsometry. The hillslope angles and local relief were calculated with analysis windows of varying sizes from (~250 m to ~4 km across) to characterize their dependence on scale. The slope of a given window size is defined as the slope of the best-fitting plane to all of the points of that window, while the relief is defined as the difference between the maximum and minimum elevations within the window. Statistics such as slope histograms and hypsometry (elevation histograms) were determined for the studied regions.

Hillslope angles measured with ~250 m windows (the highest resolution reliably determined from this DEM) appear to reflect the dominance of landsliding in hillslope erosion, but not the variations in rock uplift rates in this area. There are no significant differences in slope histograms between the areas of very rapid (6-9 mm/yr) and rapid (~2 mm/yr) denudation. There is a small difference between the slopes in the non-glaciated valleys where slope histograms are narrowly peaked between 30~45° and the generally higher elevation glaciated areas where the slopes have a bimodal histogram with shallow slopes in the valley bottoms and steep slopes along the valley walls. Even in the glaciated zones, there are still only small areas with slopes greater than about 45°. This suggests that the rock-strength limitation on slope is perhaps 45-50° in this region where all of the units are medium- to high-grade crystalline rocks. The relatively narrow range of slopes may reflect a state of self-organized criticality where the rocks are everywhere close to slope failure as in sandbox experiments.

There are also some other areas with shallow slopes that appear to be remnants of low-relief surfaces now at elevations of 4000-5000 m. The most outstanding example is the Deosai plateau, but there are other surfaces with more subtle appearances. These surfaces are expressed as shallow-slope, low-relief areas with large peaks in their hypsometry at an elevation between 4000 m and 5000 m. To the west of the Indus River and NPHM and south of the Hunza and Gilgit Rivers is a low-relief surface at an elevation of about 4300 m, called the Gamugah or Kohistan surface. This surface is remarkably level in its more than 50 km east-west extension. If it is a remnant of a previous regional plateau, it would indicate little or no warping of that surface has occurred since it was formed.

F/117. Filippelli, G.M. 1997. Intensification of the Asian monsoon and a chemical weathering event in the late Miocene – early Pliocene: Implications for the Neogene climate change. *Geology*, 25, 27-30.

Several sedimentary, geochemical, and isotopic records indicate that the hypothesized intensification of the Asian monsoon at about 8 Ma triggered a physical and chemical weathering event in the Himalayan-

Tibetan Plateau. Records of sediment input and clay composition from the northern Indian Ocean reveal clear weathering changes in the plateau at this time, and Ge/Si ratios of opaline silica as well as biogenic sedimentation rates indicate that increased dissolved element fluxes from this weathering event had an ocean wide effect. It is likely that weathering intensity also increased in the Andes and Amazon Basin in this interval as well. Perhaps the most important impact of this weathering event was to increase the net flux of the biolimiting nutrient phosphorus to the ocean, as evidenced by a peak in phosphorus accumulation rates at this time. The temporary increase in nutrient inputs to the ocean triggered increased oceanic productivity and organic carbon burial (recorded in carbon isotopic records and paleoxygen concentrations). The net result of this weathering event may have been an increase in the rate of drawdown of atmospheric CO₂ through the late Miocene–early Pliocene, via direct silicate weathering reactions and increased burial of organic carbon in the ocean. This increased rate of atmospheric CO₂ drawdown may have destabilized the climate system by the late Pliocene, thus initiating a period of intense cooling and ice buildup leading to the present.

F/125. Finsterwalder, R., 1959. Recent German expeditions to Batura Mustagh and Rakaposhi. Jour. Glaciology, 3, 787-788.

In 1954 a German expedition under the scientific leadership of W. Pillewizer worked in the Batura Mustagh (Hunza-Karakoram) as far as the Rakaposhi Range. Extremely steep mountains are characteristic of this region, also very narrow valleys and gorges. The numerous glaciers have steep icefalls and their tongues are covered with debris except that of the Batura Glacier in the north. The Batura is the largest glacier; it is about 50 km. long. A photogrammetric survey of the whole area of about 3,000 km² was carried out. On several glacial tongues, especially on the Batura, ice velocities and ablation were also measured. However, owing to the great difficulties caused by the steep and high mountains the survey remained uncompleted. At the end of the expedition a disaster occurred. The geodesist K. Heckler fell to his death into the Hunza Gorge. The preliminary results of the expedition were published in *Erdkunde* by the geographer, K. Paffen, the glaciologist and photogrammetrist, W. Pillewizer, and the geologist, H. J. Schneider.

In 1959 another expedition, under the leadership of Schneider of Munich, worked in the same region in order to complete the work of 1954. The northern side of the Batura Mustagh could not be visited as an English mountaineering expedition, under the leadership of Dr. Warburton, was at work there. The surveyor of the German 1959 expedition was H. Baumeri of the photogrammetric institute at Munich. He completed the photogrammetric surveys of all the valleys, mountains and glaciers between the Batura Mustagh and the Rakaposhi Range, and again carried out ice velocity measurements in order to determine the mass balance of the glaciers.

Two remarkable events with tragic consequences must be reported. The first was the fact that the monsoon crossed the Himalaya on 2-5 July and reached the Batura Mustagh. This happens about once in 50 years according to the meteorological authorities in Pakistan. As a result there was very heavy precipitation in the valleys for three days and nights. Normally these valleys are very dry and practically without rain for years at a time. At high levels furious snowstorms raged. The Warburton expedition was then probably working on the highest peak of the Batura Mustagh. It must be assumed that Dr. Warburton with his four companions, two Germans among them, was buried by snow and avalanches. The German rescue party of the Schneider expedition could not find any sign of the mountaineers nor even of the four high camps. They had been installed by them on the same glacier which the German mountaineers of the Pillewizer expedition had tried to climb in 1954. The second tragic event took place on 21 August with the sudden burst of a lake dammed by the tongue of one of the big glaciers in the very remote Shimsal Valley, which is an eastern tributary of the Hunza River. It is assumed that it was the Malangutti or the Yazgil Glacier, first found by the Vissers in 1925 and surveyed by K. Mason some years later. The flood caused by the burst had a depth of about 30 m. at the junction of the Shimsal with the Hunza, about 40 km from the assumed position of the lake. The flood destroyed the village of Pasu near this junction, and further on the bridges over the Hunza River were swept away, causing heavy losses. The bursting of the lake had been expected three months before. Perhaps the bursting of the lake was caused by the extraordinary precipitation which had occurred seven weeks earlier. The glaciers of Batura Mustagh are very important for agriculture in the valleys and Alps many kilometres away from the glacier snouts. Irrigation channels lead run-off water to the very dry valley bottoms. These channels begin as near as possible to the end of the glaciers.

Fluctuations of the glaciers have therefore considerable influence on cultivation, but the most critical influence is caused by the damming up of lakes which occurs from time to time and was reported as recently as 1925 by Visser.

F/133. Fitch, T.J., 1970. Earthquake mechanisms in the Himalayan, Burmese and Andaman regions and continental tectonics in Central Asia, *Journal of Geophysics Rec.* 75(14), 2699-2709.

Focal mechanisms are presented for thirteen earthquakes between Hindu Kush and Sumatra, including four shallow-focus events along the Himalayan mountain front and two events at intermediate depth beneath the Burmese mountains. All mechanisms are based on first-motion P- and S-wave data recorded by long-period instruments. The mechanisms along the Himalayan front confirm the existence of thrust faulting for which there is post-Mesozoic geologic evidence. Additional evidence for thrust faulting in central Asia comes from focal mechanisms based on other seismic data published recently by Russian investigators. The axis of minimum compression (the T axis) at intermediate depths beneath the Burmese mountains is oriented approximately down the dip of the seismic zone, as are T axes at intermediate depths in several other

seismic zones. A mechanism solution consistent with strike-slip faulting and another consistent with normal faulting were derived from two shallow earthquakes in western China. One shallow earthquake within the Himalayas yielded a normal faulting mechanism, as did one event from the western margin and two events near the northern border of the Andaman Sea. Slip vectors consistent with under thrusting beneath the Himalayas have a nearly uniform north to northeasterly strike. This evidence, as well as the frequency of occurrence of large-magnitude earthquakes, suggests that seismic slip at shallow depths may account for the convergence between the Indian Ocean and the Eurasian plates along the Himalayan mountain front.

Stratiform Zn-Pb mineralization of probable Proterozoic age occurs in a structurally complex area near the northern margin of the Indian plate around Besham in the North West Frontier Province of Pakistan. The sphalerite and galena mineralization is associated with a well-defined stratigraphy of carbonate, layered calc-silicate quartzite, garnet-bearing quartz-feldspathic gneiss, feldspathic granulite and albite gneiss. Associated with the ore are varying proportions of pyrrhotite, pyrite, baryte, clinopyroxene, quartz, garnet, actinolite, pyroxmangite, feldspar, carbonate and magnetite. The Mn-rich composition of the silicate minerals and the widespread enrichment of Ba in the rocks associated with the ore form a distinctive signature of the mineralization recognizable in reconnaissance exploration. This signature is distinct from that of skarn minerals formed later in carbonate rocks as a result of the intrusion of pegmatites. The recognition of the stratiform nature of the deposits within a well-defined stratigraphy enhances the exploration potential of the mineralization over a much wider area.

From the upper Artinskian and/or lower Kungurian of the Hunza region (Pakistan) and the Shaksgam valley (China) coral fauna with genera *Ufimia*, *Paracaninia*, *Duplocarinia*, *Yatsengia*, *Verbeekiella*, *Euophyllum*, *Lophophyllidium* (*Lophillidium*), *allotropiochisma* (?A) and *Amandophyllum* (?) are described. In addition two new species of the new genus *Petraphyllum* are named *P. hunzaianum* and *P. columnum*. *Petraphyllum* is characterized by a fanlike arrangement of their septa of naostyp and a septobasal columella. The genus belongs to the new family *Petraphyllidae*.

The coral fauna shows very close similarities to the cold water "Lytvolasma"-fauna of the Lower Permian of the lhasa- and the Kunlun-Terrane and the Permian corals faunas of the Himalaya-Timor zone, but no affinity to the *Waagenophyllum*-fauna of the Maokou of the Qiangtang and Lhasa Terrane of Tibet.

A long depositional sequence from northern Pakistan provides a good fossil record of terrestrial vertebrates for the interval of 18-7 Ma. Making allowances for possible range extensions, we use this record as a direct measure of species longevities. There is a correlation between body size and longevity, smaller mammals frequently being short-lived and larger taxa showing durations up to ca. 10 m.y. The distribution of small mammal longevities indicates an exponential decrease in frequency from a high modal value in the smallest

increment measured (0–200,000 yrs). The most frequent value for large mammals is also the smallest increment measured (1 m.y.), but that distribution may not be unimodal. Small mammal taxa of short duration are concentrated late in the sequence, after 9 Ma especially. The middle Miocene fauna is more stable, with species showing longer durations. The contrast in longevities corresponds with hypothesized greater environmental stability in the middle Miocene. For comparison, the Paleogene sequence of Wyoming indicates short median species durations, with few surveyed taxa lasting over 2 m.y. Siwalik mammals show diverse modes of evolution, but stasis in at least some features is usual, with species boundaries corresponding to morphological breaks. Up to half of the Siwalik rodent and artiodactyl species surveyed likely immigrated from outside the biogeographic province, and for a few, historical data are sufficient to stipulate when and by what route they came to the Indian subcontinent.

F/146. Flynn, L.J., Pilbeam, D., Jacobs, L.L., Barry, J.C., Behrensmeyer, A.K. & Kappelman, J.W., 1990. The Siwaliks of Pakistan: time and faunas in a Miocene terrestrial setting. *Journal of Geology*, 98 (4), 589-604.

Magnetostratigraphy provides unparalleled chronologic precision for long terrestrial sedimentary records. The Siwaliks of the Potwar Plateau, northern Pakistan, present perhaps the best example of a sequence of well dated faunal horizons spanning most of the Neogene in a single terrestrial biogeographic province. Temporal control on fossil localities tied to multiple paleomagnetic sections is ca. 0.1 m.y., less given special conditions of short magnetozone duration or superpositional relationships. New correlations are presented for two long sections in the lower Siwaliks showing the power and the limitations of magnetostratigraphic correlation within the Siwalik depositional setting. Correlation of Potwar fossil localities to those of an East African section, also dated paleomagnetically, are established with fossil localities from those two biogeographic provinces shown to be coeval on a scale of 105 yr. The composite biostratigraphy rendered by the thick, well exposed, well dated Potwar Siwaliks enables definition of sequential bio-chronologic units without gaps. Utility of the biochronology lies in correlating isolated deposits to the Potwar composite; for studies within the Potwar, locality relationships and the biostratigraphy itself are the operational units. The history of the Siwalik fauna shows turnover episodes, but they differ in intensity, diversity of groups affected, and coincidence of first and last occurrences, probably reflecting different causes. Studies on the evolution of lineages are rendered more powerful by magnetostratigraphy: temporal control tests patterns of speciation, yields confident estimates on true temporal ranges of fossil taxa, and shows that rodent species longevities exceeded 2 m.y. on average.

F/148. Fontan, D., Cosca, M.A., Schoupe, M., Gourirane, A., Hunziker, J.C., Kervyn, F., Martinotti, G. & Verkaeren, J., 1995. Geology and Tectonometamorphic Evolution of Neelum Valley (Azad Kashmir, NE Pakistan). Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

This study is focused on the stratigraphy and the tectono-metamorphic history of the Higher Himalayan Crystalline (HHC) and the Lower Himalayan Crystalline (LHC) in the Neelum Valley. Over 20 samples of phengite white mica, biotite and phlogopite have been analysed by the ⁴⁰Ar/³⁹Ar method and help to constrain the tectonothermal history of the Neelum area.

The HHC and the LHC units have the same stratigraphic features. In both we have distinguished a cover overlying a basement. The basement is composed of an older granulitic complex stratigraphically overlain by a thick metasedimentary sequence; both are intruded by later granites. The granulitic complex mainly

consists of medium grained biotite, garnet-bearing gneisses with interlayers of amphibolite, interpreted as very old (Precambrian?) basic dykes. In accordance with Pognante & Lombardo (1989) we have distinguished between the basic dykes of type A, which are intruded only in the granulites (they are cross-cut by pegmatites referred to granites), and those of type B, which cross-cut the basement/cover regional banding and can be correlated with the Permian Panjal Traps. Acid granulites can presumably be correlated with the Iskhere Gneiss of Zeitler et al. (1989). The metasedimentary sequence (Salkhala Series) is represented by a thick flysch-like sequence that can be correlated with the Precambrian Hazara slate (Wadia, 1934; Wadia, 1952; Greco, 1989). The granites have been considered equivalent to the Mansehra Granite (516 ± 16 Ma, Le Fort et al., 1980) and to the Shengul Gneiss in the Nanga Parbat area (400 to 500 Ma, Zeitler et al. 1989), situated north of our area.

The cover (Upper Carboniferous ? - Jurassic?) unconformably overlies the basement and can be correlated with the Kaghan Burawai Fm. of Greco et al. (1989) and with the First and Second cover of Spencer (1993). We have distinguished, from the bottom to the top, a siliceous, a carbonatic and a pelitic units.

In the Salkhala Series, old andalusite blasts (now pseudomorphosed by white mica) have grown on an older foliation have been interpreted as relics of pre-Himalayan tectono-metamorphic events. The foliation was probably formed during the Hazaran orogenesis (Baig and Lawrence, 1987) while andalusite blast are related to intrusion of Mansehra-type granitoids.

The rocks forming the basement and the cover have been deformed and metamorphosed during the Himalayan Tertiary events. The HHC and LHC tectonic units are characterised by a metamorphic zoning: in the HHC unit the metamorphic grade increases toward NE from upper greenschist facies to kyanite and sillimanite amphibolite facies and in the LHC unit the metamorphic grade ranges from greenschist to lower amphibolite facies.

The Tertiary metamorphism can be divided into three thermobarometric stages: an early stage of high pressure conditions, well preserved in the basic rocks outcropping in the medium grade terrains, characterised by omphacite + garnet, with estimated temperature and pressure of $600 \pm 50^\circ\text{C}$ and 15-18 Kbar (Gourirane, 1993), and by muscovite-bearing pegmatites that give upper Cretaceous $40\text{Ar}/39\text{Ar}$ cooling ages. Analogous thermobarometric results and an Eocene age have been found in the adjacent Kaghan valley (Pognante & Spencer, 1991; Villa et al., 1992; Spencer, 1993).

The second stage is a Barrovian prograde sequence defining the main rock fabric. The metamorphic grade ranges from greenschist to upper amphibolite facies and is the result of the decompression coupled with increasing temperature. The greenschist event is responsible for the formation of biotite and garnet while the amphibolite facies event formed typical garnet, biotite, kyanite and staurolite assemblages. With the increasing temperature kyanite and staurolite are replaced by sillimanite and garnet and in the Palaeozoic granites incipient melting is visible along narrow shear zones.

$40\text{Ar}/39\text{Ar}$ cooling ages of muscovite and biotite yield middle Oligocene ages for the greenschist facies rocks and upper Oligocene to Lower Miocene cooling ages for the amphibolitic assemblages.

The third stage is characterised by further increasing temperature and drop pressure. It is responsible of formation of post-cinematic biotite in the greenschist facies rocks and coronitic rim (garnet around biotite) in the amphibolite terrain.

The structure of the basement and cover rocks of the Neelum Valley record the ductile nature of complex Himalayan deformation. Four successive phases of folding have been distinguished in the field.

A widespread penetrative schistosity (S1) associated with isoclinal folding (F1) is constrained by $40\text{Ar}/39\text{Ar}$ analyses on white mica present in shear zones as upper Eocene. A second isoclinal and asymmetrical phase (F2), associated with 100 meters wide shear zones north dipping is coeval with movement along the Main Central Thrust (MCT). This thrust crosscuts the previous mylonites as well as the isograds. $40\text{Ar}/39\text{Ar}$ data on these mylonites give a Middle Oligocene (≈ 30 Ma) ages. Later, a third phase developed a crenulation cleavage (S3) while the fourth folding phase produced open folds with a wavelength of several kilometres (F4).

Key words: Tectonics, metamorphism, Neelum valley, Azad Kashmir

F/149. Fontan, D. & Schoupe, M., 1994. Contribution to the Geology of Azad Kashmir (NE Pakistan): Mapping of the Neelum valley, recent geological results. *Journal of Nepal Geological Society* 10 (Abstract Volume, 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu, Nepal), 42-44.

Because of its central position between the Hazara Kashmir Syntaxis (HKS) and the Nanga Parbat Syntaxis (NPS), the Neelum Valley represents a very attractive section through the major tectonic elements of the Western Himalayan mountain belt.

From 1991 to 1993, the NW flank of Neelum Valley has been systematically mapped at the scale 1:50,000 (from Tithwal to Kel: ± 1500 km²). From the HKS to the higher structural levels, we have distinguished three units separated by two main thrust faults. We have found successively the Sub Himalaya (SH) inside the HKS, the Main Boundary Thrust (MBT) near Nauseri, the Lesser Himalaya (LH) up to Luat, the Main Central Thrust (MCT) crossing Man Nala, Jagran Nala and Ghurial Nala, and further north, the Higher Himalaya (HH).

The 1993 fieldwork has made it possible to locate a very good pretender to be the MCT connection between the MCT identified near Batal in the Kaghan Valley by Ghazanfar and Chaudhry (1985), near Musa Gali by Greco (1989), and near Luat in the Neelum Valley (Ghazanfar, Baig and Chaudhry, 1984). The newly detected MCT portion is recognized on the field by a >100 m thick shear zone expressed by dark mylonites in the schists and by light schistose mylonites in the granites. From place to place, rocks close to the MCT enclose numerous traces of metasomatism (scheelite bearing skarns). In Neelum Valley, the MCT, which demarcates the LH from the HH, crosscuts a single stratigraphic sequence. Consequently, the HH and the LH units do show the same stratigraphic features.

The pre-Himalayan basement comprises an older migmatite complex (embrekites, agmatites, anatexites) unconformably overlain by a thick meta-sedimentary sequence (the Precambrian Salkhala series of Wadia, 1934). The metasediments consist of psammitic to pelitic schists, in alternance with minor intercalations of impure marbles. Both formation are intruded by later granitoids, presumably of the early Palaeozoic age (Manshera-type of granite of Le Fort, 1988). The Himalayan cover (Upper Carboniferous-Jurassic?) lies unconformably on the basement. From bottom to top, it mainly includes gneisses and micaschists (Unit A), marbles, amphibolites, and calcschists (Unit B) and garnet micaschists (Unit C).

In Neelum Valley, the prevalent Himalayan metamorphic zoning ranges from lower to upper greenschist facies to kyanite and sillimanite amphibolite facies. The metamorphic grade increases towards NE.

Data collected in Neelum Valley suggest the following succession of geological events:

A very old metamorphism associated to an early Proterozoic orogenic event (1900-1800 My) generated the migmatite complex of the Pre-Himalayan basement. The metasedimentary Salkhala series was deposited subsequently unconformably on the migmatites. The leucogranite (Manshera type) intruded the whole basement (migmatites+Salkhala series). After uplift and erosion of the basement, the deposition of the Himalayan cover started in the region (Upper Carboniferous?-Jurassic?).

Later (About 250-300 My), basic dykes were emplaced through the whole cover-basement sequence.

The Himalayan deformation and metamorphism affected the basement and the cover.

Two subparallel penetrative schistositys S₁ and S₁₋₂ were elaborated during the transposition of the basement-cover sequence and during the development of the MCT. The MCT brought to the north the LH as a hanging wall over the HH. This step marks the peak of the Himalayan deformation. A Barrovian-type stage of the Himalayan metamorphism follows an early stage in high-pressure conditions (eclogites discovered in Gumot Nala). Further strain generated tight to open folds (wavelength <1-km) associated with a crenulation cleavage S₃. It was followed by a third stage of Himalayan retrometamorphism (growth of post-kinematic chlorite basalts). The next phase, characterised by regional open folds with a wavelength of several km, disturbed regionally the geometry of all the previous structures. Brittle deformation started with a set of N500E trending subvertical faults.

Finally, late deformations, including kinks, fracture sets and subhorizontal local thrust planes, affected particularly the HH. The scientific and technical collaboration of J. Verkaeren and D. Daduron (Université Catholique de Louvain), G. Martinotti (Università di Torino), R. Malik and his collaborators (Azad Kashmir and Industrial Development Corporation), during this work (EEC Grant No C11-0571-M (GDF) is gratefully acknowledged.

F/150. Fontan, D., Schoupe, M., Hunziker, C.J., Martinotti, G. & Verkaeren, J., 2000. Metamorphic evolution, ⁴⁰Ar-³⁹Ar chronology and tectonic model for the Neelum valley, Azad Kashmir, NE Pakistan. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 431-453.

This paper describes the geology, tectonometamorphic history and geochronology of part of the northern flank of the Neelum Valley in Azad Kashmir, NE Pakistan. Metamorphic crystalline rocks in this area belong to the Lesser and Higher Himalayan Crystalline complexes. Geological mapping of about 1500 km² confirms the presence of three main tectonic units characterized by similar lithostratigraphic sequences but with different tectonometamorphic histories. Whether these tectonic units belong to the Lesser or Higher Himalayan Crystalline depends on the, still controversial, position of the Main Central Thrust. A tectonic model, involving syn-convergent exhumation, is suggested that is consistent with new petrographic and geochronological data, and with a revised interpretation of the Main Central Thrust.

Rapid Pliocene denudation in the Karakoram, Pakistan, as revealed by fission-track dating of rocks from K2 (Godwin Austen) was probably caused by tectonic uplift. Apatite separated from samples collected from elevations of 5300 to 8611 yielded fission-track ages of 2.1 ± 0.6 to 4.3 ± 1.4 Ma, and suggest an initial, apparent denudation rate of 3-6 mm/yr commencing after 5 Ma. One zircon separate from 6600 m gave a mean fission-track age of 32 ± 6 Ma. The mid-Tertiary zircon age delimits the maximum amount of Pliocene denudation to ≤ 7000 m. The total amount of denudation at the present mean surface elevation of 6000 m was estimated to be 6000 m.

F/153. Foster, G., Kinny, P., Vance, D., Harris, N., Argles, T. & Whittington, A., 1999. The Pre-Tertiary metamorphic history of the Nanga Parbat Haramosh Massif, Pakistan Himalaya. *Terra Nostra* 99 (Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany), 44-45.

It is often assumed that within active orogenic zones, such as the Himalaya, metamorphic and tectonic fabrics exposed at the surface today relate to the most recent phase of orogenesis. However, for collision-related orogenesis this assumption is only valid for metasedimentary lithologies deposited immediately prior to the most recent event, e.g. sediments deposited on the continental margin of the now-closed ocean basin. The basement rocks on which these sediments were deposited, are almost inevitably polymetamorphic, and tight chronological controls on their thermal and deformation histories are required to avoid erroneous tectonic interpretations. The Nanga Parbat-Haramosh-Massif (NPHM), a basement terrain exposed by recent exhumation of the western Himalaya, is unique in the orogen in that it has experienced recent (2-10 Ma) and rapid (approaching 4 mm/yr.) exhumation with associated decompressive melting and leucogranite intrusion (Zeitler et al. 1993; Whittington, 1996). Approximately 90% of the rock exposed within the massif has been termed "basement" on the basis of zircon chronometry (Zeitler et al., 1989) and textural investigations (Wheeler et al., 1995), yet, due to the difficulty of unravelling polymetamorphic terrains, the Pre-Tertiary metamorphic history of the massif has yet to be established. Therefore, the true thermal significance of both the Himalayan (Foster et al., 1998) and the Neogene (Smith et al., 1992) metamorphic events cannot be accurately assessed until the pre-Himalayan fabrics and assemblages can be identified. Here we present the results of a systematic investigation into the thermal history of the basement rocks of the NPHM and draw important conclusions upon the nature of Pre-Tertiary events that affected this segment of the Himalayan orogen.

Our approach has been to combine detailed field and fabric studies with a range of chronometric approaches that include: (i) U-Pb SHRIMP chronometry of basic dykes that clearly cross cut migmatitic fabrics within basement gneisses; (ii) U-in-Pb SHRIMP analyses of monazites within granitic bodies; (iii) Sm-Nd garnet analyses of metamorphic assemblages coupled with a thermobarometric treatment of these assemblages; (iv) Sm-Nd whole rock analysis of critical lithologies. As a result of these investigations we are able to recognise the following chronologies within the basement lithologies of NPHM:

Iskere Gneiss (Madin, 1986). This unit is exposed generally on the western and central portions of the massif and has a source age of around 2.5 Ga (Nd model age) and $\epsilon(\text{Nd})$ of around -18 to -27 (Whittington et al., 1999). Migmatization occurred at 1852 ± 14 Ma (Zeitler et al. 1989), closely followed by basic dyke intrusion at 1824 ± 14 Ma as identified by the age of zircon cores within the dykes. Field relations suggest that in some cases, this intrusion occurred while the surrounding gneiss were still hot. A Sm-Nd whole rock-garnet investigation and further concordant zircon analyses also indicate a significant reactivation of this gneiss at around 1300-1000 Ma.

Shengus Gneiss (Madin, 1986). This unit is exposed generally in the eastern portions of the massif and has a similar source age (~ 2.7 Ga; Nd model age) to the Iskere Gneiss with inherited zircons of around 2.5 Ga (Zeitler et al., 1989). Intruding the metasediments of the Shengus Gneiss along the western margin (Schneider, pers. comm.), in the north along the Indus gorge (Zeitler et al., 1989) and on the eastern margin (this study), are 500 Ma granitic bodies. Of particular importance is a megacrystic intrusion along the eastern margin. Here field investigations and Th-Pb ages of concordant monazites indicate this body was intruded at 467 ± 6 Ma, around 40 Ma after the main intrusive phase, thus suggesting correlation with the Manshera granite dated at 468 ± 12 Ma (Zeitler et al., 1989).

Based on the above data it is clear that these two components of the Nanga Parbat Haramosh massif are geologically distinct. What is not clear however, is how (if at all) they correlate with the well-documented terranes of the main Himalayan orogen. It is often assumed that the majority of fabrics and assemblages exhibited by the gneisses of the NPHM formed during the recent syntaxis-related metamorphic event. However, this has been shown not to be the case for the garnet-grade cover sediments exposed along the margins of the massif (Foster et al., 1998) and the data presented here suggest that pre-Himalayan fabrics and assemblages are also present in the basement lithologies. Our results not only document the resilient nature of the ancient continental crust but also illustrates the necessity of a systematic and chronologically well constrained approach to the study of polymetamorphic terrains.

F/154. Foster, G., Vance, D. & Harris, N., 1998. The prograde thermal history of the Nanga Parbat Haramosh Massif, Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 64-65.

The Nanga Parbat Haramosh Massif, in Pakistan, is unique in the Himalaya in that it has experienced recent and rapid exhumation (approaching 4 mm/yr.; Whittington, 1996) with associated decompressive melting and leucogranite intrusion (Zeitler et al., 1993). Zircon rims and monazites recovered from high-grade basement gneisses have yielded young ages which have been interpreted by some workers (e.g. Smith et al., 1992) to indicate that a Neogene partial melting event was also related to this rapid uplift. However, it remains to be established whether the entire massif underwent this event, and whether there is any part that preserves the earlier metamorphic history of this polymetamorphic terrane. The discovery of relatively low-grade metasediments along the margins, in particular in the south-eastern corner of the massif, allows an investigation of this problem. The best exposure of these rocks occurs in the lower Rupal valley where they form a sequence of kyanite + staurolite + garnet mica schists with associated garnet amphibolites and calcsilicates. Nd model ages and $\epsilon(\text{Nd})$ values of these and other such metasediments cluster around 1.8 Ga and -14 respectively, allowing them to be correlated with the High Himalayan crystalline unit exposed elsewhere in the central Himalaya rather than with the basement gneisses of the massif, which are more readily correlated with the Lesser Himalayan Unit (Whittington et al., this volume). Here we present new garnet-whole rock Sm-Nd ages for these rocks and show that they experienced garnet - grade metamorphism at about 20-50 Ma. These data, together with P-T determinations, demonstrate that the assemblage has followed a "prograde" Himalayan P-T-t path significantly predating the recent exhumation-related event. This study illustrates the power of garnet Sm-Nd chronometry to see through late stage overprinting events, and the importance of a systematic approach to the study of polymetamorphic terranes.

F/157. Fox, C.S., 1926b. Geological consideration which appear to affect the safety of Khyber Railway. North-Western Railway Press publication, Lahore.

This report concerns the geological consideration for the safety and sustainability of the Khyber Railway. The rail tracks pass through a gently sloping level ground up to Jamrud, from where on there is a steady climb up to Landikotal, followed northward by a steep descent to Torkham on the Pak-Afghan border. There are several bends and tunnels on the way between Jamrud and Landikotal. The track passes through sedimentary rocks, comprising mostly slates, phyllites and limestones.

The Karakoram Metamorphic Complex forms the southern most margin of the Asian Plate with the northern limit of the complex in Hunza being marked by a tectonic contact with the Hunza Plutonic Unit. (Desio, 1964; and Crawford and Searle, 1993). This granodiorite is a pre-collisional batholith that exhibits a strong foliation at its southern contact with the underlying metamorphic rocks. The southern margin of the complex is marked by the Shyok Suture Zone as described by Pudsey, 1986.

A detailed map of the middle Hunza valley has been produced that illustrates the principal lithologies, structural features and locations where detailed petrology and thermobarometry has been carried out.

Rocks ranging from staurolite through kyanite to sillimanite grade occur in the middle Hunza valley and exhibit an inverted metamorphic sequence with structurally higher units exhibiting the highest metamorphic grade. This is reflected not only in the mineral assemblages present, as previously noted by Broughton et al., 1985, but also in pressure and temperature estimates throughout the slab, extending previous work carried out by Okrusch et al., 1976. This inversion appears to be a consequence of south directed ductile and semi-ductile shear and later brittle thrusting which emplaced higher grade units over those of lower grade in agreement with earlier work of Crawford and Searle, 1993. P-T work shows a small variation in values for staurolite grade rocks, but those of sillimanite grade rocks show greater variation in pressure estimates. Retrograde reaction textures have been observed in those sillimanite grade samples that have yielded lower pressures of 5.8 ± 1.2 and 4.4 ± 1 Kb. Temperatures are typically 628 ± 41 to 674 ± 49 C. These P-T patterns may reflect those seen in the Baltoro, reference Searle and Tirrul, 1991; Allen and Chamberlain, 1991; and Lemennicier et al., 1996.

F/164. Fraser, J., Searle, M., Parrish, R. & Noble, S., 1999. U-Pb geochronology on the timing of metamorphism and magmatism in the Hunza Karakoram. Terra Nostra 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 45-46.

U-Pb dating has been carried out on samples of regional metamorphic rocks and granites of the Hunza Karakoram in northern Pakistan with the aim of deciphering the thermal and magmatic evolution of the thickened Asian plate crust. The pre-collisional (India-Asia collision) origin of the Hunza plutonic unit granodiorites forming the main component of the Karakoram batholith in this part of the range has been confirmed by three concordant zircon analyses yielding a U-Pb crystallisation age of 105.7 ± 0.5 Ma. The Hunza dykes consist of a co-genetic suite of granodiorites, monzogranites and leucogranites, which intrude the early phase of the batholith, as the sillimanite grade rocks to the south. Zircon and uraninite from the early set of Hunza dykes parallel to the regional north-dipping schistosity have concordant U-Pb age of 51.5 ± 1.5 Ma.

One sample of a garnet + biotite leucogranite dyke from the later set of Hunza dykes which emanate from the southern part of the granite batholith and cross-cut sillimanite gneisses and phlogopite $\pm$ ruby corundum marbles, has been dated using zircon, monazite and uraninite at 35.1 ± 0.6 Ma, similar to the age of the Mango Gusar pluton (37.0 ± 0.8 Ma; U-Pb on zircon), south of the Baltoro plutonic unit to the east. Monazites from a sillimanite grade meta-pelite from Baltit gave a U-Pb age of 68 ± 0.5 Ma, which is

interpreted as the timing of sillimanite grade peak metamorphism and deformation in the Karakoram metamorphic complex south of the Karakoram batholith. Sillimanite grade metamorphic rocks in the Hunza valley structurally overlie kyanite and staurolite grade rocks which have been emplaced southwards over low-grade rocks of the Shyok suture zone forming an inverted metamorphic field gradient. Monazites were separated from these highly graphitic garnet-staurolite schists and yield an interpreted crystallisation age of 16.0 ± 1.0 Ma. The somewhat large error ellipses are due to the numerous inclusions in these monazites. All presently available U-Pb geochronological data from the Hunza and Baltoro Karakoram suggest that two metamorphic episodes are present: (1) a long-lasting latest Cretaceous to late Eocene sillimanite grade event south of the batholith in Hunza and (2) a mid- to late Miocene ~ 16 Ma staurolite -kyanite grade event along the southern part of the metamorphic complex. The youngest phase of crustal melting is dated at 9.2 ± 0.5 Ma from U-Pb ages of zircon, xenotime and uraninite from the Sumayar tourmaline leucogranite south of the Karakoram batholith.

Key words: Geochronology, metamorphism, magmatism, Hunza, Karakoram.

F/165. Fraser, J., Searle, M. Parrish, R.M. Noble, S. & Thimm, K., 1998. U-Pb geochronology on the timing of metamorphism and magmatism in the Hunza Karakoram. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 66-67.

U-Pb dating has been carried out on samples from the regional metamorphic rocks and leucogranites of the Hunza Karakoram with the aim of deciphering the thermal and magmatic evolution of the thickened Asian plate crust. The pre-collisional origin of the Hunza plutonic unit granodiorites forming the main component of the Karakoram batholith in this part of the range has been confirmed by three concordant zircon analyses yielding a U-Pb crystallisation age of 105.7 ± 0.5 Ma (sample K94-24). The Hunza dykes consist of a co-genetic suite of granodiorites, monzogranites and leucogranites, which intrude the early phase of the batholith, as well as the sillimanite grade rocks to the south. One sample (K 94-23) of a garnet+biotite leucogranite dyke emanating from the southern part of the granite batholith and cross-cutting sillimanite gneisses and phlogopite±ruby corundum marbles, has been dated using zircon, monazite and uraninite at 35.3 ± 0.4 Ma, similar to the age of the Mango Cusar pluton south of the Baltoro plutonic unit to the east (37.0 ± 0.8 Ma, U-Pb on zircon; R.Parrish data in [11]. These two ages put an upper time constraint on sillimanite grade peak metamorphism and deformation in the Karakoram metamorphic complex south of the Karakoram batholith.

The Sumayar leucogranite is a small isolated tourmaline leucogranite with minor biotite and garnet intruding staurolite grade schists south of the Karakoram batholith in the Nagar region east of Hunza. It is a water-saturated, minimum-melt leucogranite similar to many High Himalayan granites, probably derived from melting of a pelitic lower crustal source [21]. U-Pb dating of zircon and uraninite yields an age of 9.2 ± 0.1 Ma, whereas xenotime intergrown with zircon yields 8.55 ± 0.15 Ma. The apparently distinct ages of intergrown zircon and xenotime could be explained by two periods of mineral growth (and partial resorption?) or by Pb loss in xenotime. This shows that this is the youngest crustal melting event in the Karakoram, and it cannot therefore be linked temporally to the Mango Cusar or Chingkiang-Ia plutons, south of the Baltoro granite, as previously thought. Several phases of granitic dyke intrusion are present in the Hunza section and dykes emanating from the Sumayar pluton must be a younger phase than the Hunza dykes.

Metamorphic monazites were extracted from a staurolite+garnet mica schist (K94-20) from Nasirabad in the Hunza valley. The $206\text{Pb}/238\text{U}$ age of monazite is $15.5\text{--}16.5$ Ma and due to probable excess 206Pb , we interpret the crystallization age as $14\text{--}16$ Ma. This must date the timing of monazite growth during staurolite-grade metamorphism, and is considerably younger than the previous estimates of a pre-37 Ma age for metamorphism of all the southern Karakoram metamorphic complex [3]. All presently available U-Pb geochronology from the Hunza and Baltoro Karakoram suggest that two metamorphic episodes are present: (1) a pre-37 Ma late Eocene-Oligocene sillimanite grade event south of the batholith in Hunza and the Baltoro region, and (2) a mid- to late Miocene ~ 16 Ma staurolite - kyanite grade event along the southern part of the metamorphic complex.

F/167. Friend, P.F., Raza, S.M., Baig, M.A.S. & Khan, I.A., 1994. Geological Evidence of the ancestral Indus from the Himalayan Foothills. In: Meadows, A. & Meadows, P., (Eds.), *The Indus River, Biodiversity, Resources, Humankind*. Linnean Society, Symposium on the River Indus. Proceedings, Burlington House, London, Oxford University Press 103-113.

Northern Pakistan contains classic outcrops of Himalaya-derived 'Siwalik' river sediments, rich in mammal fossils, and dating from between twenty million years ago and the present. The sediment logical analysis of local structures in these sediments has made it possible to reconstruct the flow directions of the depositing rivers. In outcrops west of the present Indus, the depositing rivers are seen to have flowed with Indus-like trend, towards the south. East of the present Indus they are seen to have flowed with a more Ganga-like trend, towards the south-east and east. The Sargodha 'high' of basement outcrops may represent a structure that caused the divergence between these two trends. From about eight million years ago, there is evidence that a particularly large river emerged from the mountain front in approximately the position of the present Indus, and this is identified as the ancestral Indus.

F/168. Friend, P.F., Raza, S.M., Geehan, G. & Sheikh, K.A., 2000. Intermediate-scale architectural features of the fluvial Chinji Formation (Miocene), Siwalik Group, northern Pakistan.

The Lower Siwalik, Chinji Formation (Late Miocene) of the Chinji Village area, northern Pakistan has provided remarkable material for the study of terrestrial fossil faunas, magnetic reversal stratigraphy and fluvial sedimentology. This paper considers patterns in the sedimentary stratigraphy, using magnetic reversals to constrain the time framework, and focusing on an intermediate (kilometre) horizontal length-scale. The project aimed to determine the architecture and time relationships of the channel sandstone bodies in a panel 300 m in stratigraphic thickness, and 11 km in horizontal length (along stratigraphic strike). This panel (the 1990 Fence) trends at a high angle to the flow direction of the Late Miocene river channels, and represents about 2 Ma of sediment accumulation. There is a continuous range in thickness of the sandstone bodies, but they can be usefully classified into (i) microbodies, (ii) minor sheets, (iii) thin mega-sheets and (iv) thick mega-sheets. The microbodies are probably mainly marginal features of the thicker bodies. The minor sheets were formed by small river channels, and the mega-sheets were formed as the deposits of the largest, generally braided, channel belts. Two aspects of the intermediate length-scale architecture of the Chinji Formation are analysed: (1) the presence in the Fence of three thick mega-sheets separated by two mudstone-dominated intervals that lasted for about 0.5 and 1.0 Ma, respectively and (2) the abrupt upwards increase in sandstone/mudstone proportions that defines the upper stratigraphic boundary of the Chinji Formation. We suggest that each of the three thick mega-sheet episodes resulted from avulsions into the area of large-channel belt complexes that formed central features of the Chinji river network and were each constrained by scarps or valley-side slopes during episodes of net deposition that lasted for about 100 ka, and may have resulted from climate and/or sea-level changes. The regional upward change from mudstone- to sandstone-domination at the top of the Chinji Formation resulted from a similar, but one-off, and more widespread, change in plan-view style of the river network, produced either by tectonic change in the mountain source area, or by climatic change.

F/171. Fuchs, G., 1999. The evolution of the Himalayan orogenesis. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 47-48.

Orogenesis is a complex process involving tectonics, sedimentation, magmatism, metamorphism etc. Many problems arise: When did orogenesis start; how did tectonisation propagate; what happened in different tectonic zones contemporaneously? We must come to a vivid picture of the growth of the mountain chain. I am giving such a picture-admittedly subjective and the number of aspects is certainly not complete-but I hope that it will invite discussion.

Research of the last two decades has shown that the orogenesis started already in the Maastrichtian: The blockflysch of the Tsangpo region (Burg, 1983) is an orogenic sediment formation, which documents that the northern margin of India was already close to the subduction zone. Overlap of the Lamayuru basin facies onto the Zaskar Shelf followed by folding of the Tethyan Zone indicates a short period of down bending in the Maastrichtian when the continental margin reached the subduction zone and collided with the Asian Plate (Fuchs, 1982). The overlapping euxinic sediments, however, are connected with the underlying Campanian Fotu La Formation and do not represent an early thrust sheet as proposed by Corfield et al. (1996). In Pakistan, Beck (1995) found Upper Paleocene beds transgressing the accretional wedge of the MMT.

This early collision of India was not with the Asian Continent but with trapped oceanic lithosphere of the Asian Plate (Dürr 1995; Fuchs and Linner 1996). The latter was consumed in the course of continued convergence in Maastrichtian-Early Eocene times along a second melange zone north of it.

Connections between Asia and India, as early as at the Cretaceous/Tertiary boundary, are also documented by floral and faunal exchange (Prasad et al., 1988; Jaeger et al., 1989). Palaeomagnetic research also suggests that collision occurred around the Cretaceous/Tertiary boundary in equatorial latitudes (Klootwijk et al., 1991) and that the extended northern margin of India reached the subduction zone earlier than assumed previously (Appel, 1989; Patzelt, 1996).

Thus pre-Eocene collisions are well-documented. The continent/continent collision along the whole suture, however, occurred in the Early Eocene. Then the MMT was sealed in Pakistan (Beck, 1995) and the Spontang thrust mass was emplaced on the Zaskar Shelf (Fuchs, 1982; Fuchs and Willems, 1990). That event put an end to the marine sedimentation and initiated the deposition of terrestrial molasse along the Indus-Tsangpo Suture Zone. Compressional phases with uplift and denudation alternated with extensional phases and molasse transgression. Rather late ultrabasic masses came to rest on the molasse, which was folded and imbricated with the underlying beds. It seems that the Miocene nappe tectonics in the southern Himalaya coincide with extensional tectonics in the north.

The Miocene age of the Lesser Himalayan nappe stacking is proved by the Dagshai Formation exposed in windows, the cooling ages of the Crystalline nappes and the start of Siwalik sedimentation in the foredeep. Later the Lesser Himalayan nappe pile was folded, which led to windows and outliers. The scene of thrusting shifted further south to the MBT. Siwalik sedimentation was accompanied by the formation of new thrusts, which became younger southwards (Heraïl et al. 1986).

In the Lesser Himalaya a mature relief was formed by denudation. Quaternary reactivation of older lineaments led to the steep southern flanks of the Great Himalaya, Panjal, Dhauldhara and Machabhat Ranges. This does not mean that the MCT is a young thrust, as suspected by Raiverman (1997).

Latest molasse deposits in the Tethyan Zone (Plio-Pleistocene) are non-folded but disturbed by faulting and tilting during the uplift of the Great Himalayan Range (e.g. Sutlej, Takkhola).

The above is a rough picture of the complex orogenic development commencing along the suture, propagating towards the south and thus involving more and more rock series of the Indian passive margin. This process spans a period of approximately 70 m.y. and has not yet ended.

Within the marly respectively calcareous dolomitic beds of the Hazira Formation there are sporadic phosphate airs rich in biogenic matter. Obviously they are replacement products, as all the organic remains are replaced by apatite.

The microfauna yielded by maceration indicates Cambrian age. The fossils cited below, according to present knowledge, point to Lower Cambrian age; porifera (*Archiasterella pentactina* SDZUY, *Allonnia tripodophora* DORE and REID and "stauractine" archiasters; *Calyptoptomatids* (*Hyolithes* EICHWALD and *orthothecides*) and forms of doubtful systematic position (*Hyolithellus* EICHWALD). Further there are forms probably belonging to the annelids (? *Lapworthella* COBBOLD, ? *Rushtonia* COBBOLD and *POCOCK*).

G/4. Gaetani, M., 1990. The sedimentary sequence of the Shaksam valley (Karakoram and Aghil Ranges). In Abstract volume, 5th Himalaya-Karakoram-Tibet Workshop, Milano, 14.

Sedimentary rocks of the Shaksam Valley (Karakoram and Aghil Ranges) are arranged in large south-west verging folds, disrupted by several thrusts and faults aligned NW-SE. Though field data are uncompleted, three different stratigraphic sequences may be described. Everywhere, the base of the succession is thrust.

The better documented is the northern eastern sequence. Above a clastic wedge, marine shallow water carbonates begun in the Arthinskian. Drowning, resulting in cherty carbonates occurred in the Late Permian, with huge resedimentations from active platforms during the Djulfian. Deep-water, thin-bedded carbonates persisted in the Early and possibly Middle Triassic. The re-sedimented calcirudites helped the recovering of the carbonate platform, which persisted to the Early Jurassic. Lateral Liassic equivalent are dark-gray bedded limestones, which continued up to the Middle Jurassic. Red conglomerates and sandstones spread over in Bathonian, followed by mostly terrigenous fine rocks, interpreted as distal turbidities. Yellow polymict conglomerates with mostly carbonate clasts, end the succession. In the middle, till the main fault of the Karakoram Fault Zone (KKFZ), black shales and sandstones, most probably of Permian age, represent the base of the sequence. Then, pelagic gray limestones constitute a relevant sheet, in which also Carnian conodonts were found. Finally, west of the main fault of the KKFS, black shales and several hundreds meters of the Urdok Conglomerate. Crop out. The conglomerate contains prevalent red sandstones, but also gneiss pebbles. The inferred age of the Urdok Conglomerate is Cretaceous or younger.

G/6. Gaetani, M., 1994. The Karakoram Block from Ordovician to Jurassic: A progress report. Abstract Volume, 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu, Nepal, 53-54.

The Karakoram Block was a part of the Peri-Gondwanian fringe during the Paleozoic. The most ancient unmetamorphosed sediments are of Early Ordovician (Arenig) age, consisting of sandstones and shales, transgressing over a crystalline basement. Rare carbonatic intercalations point the succession up to the Middle Devonian, when a wide peritidal platform spread over, temporally stopping the terrigenous deposition. Sedimentation rates were low, 10-20 m/Ma. The mixed terrigenous/calcareous sedimentation resumed in the Late

Devonian, with brachiopod shell lags and coral patches. The Early Carboniferous is poorly documented, probably still calcareous. No data instead on the Late Carboniferous.

Starting with Permian, sedimentation rate increases and thickness of Permian rocks is between 1 and 2.5-km. They record a variety of environments. The Larger differentiation occurred from the Late Permian to the Middle Triassic, when a peritidal carbonate flat developed at southwest, facing a deeper basin at northeast. With Carnian, the carbonate platform resumed everywhere. This evaluation is interpreted as the passive margin stage of the Karakoram Block, when it followed the fate of the Mega Lhasa continent, which drifted northwards on the Tethyan Transit Jurassic, the Eo-Cimmerian deformation, more severe in SE Pamir, is recorded also in Karakoram, mostly to northeast, with two arenaceous bodies. Below, Quartzo-lithic sandstones characterized by mafic volcanic detritus and serpentinite grains suggest the nearby presence of a collisional belt. They are sutured by red sandstones with sedimentary and metasedimentary clasts, feeded by an uplifted sedimentary succession. From the Aalenian, this orogenic episode was out and shallow water carbonates ramp aggraded onto the previously emerged area, probably developing for most of the Late Jurassic. This episode is interpreted as the first docking of the MegaLhasa spur represented by SE Pamir to the Eurasia margin, followed by an anticlockwise rotation.

The Karakoram Block is also characterized by a very wide occurrence of black slates, the "Karakoram", fringing externally to the range the previously recorded Paleozoic succession, from the Chitral, through Whakan and SE Pamir, to the W Qiang Tang in Tibet. They are considered as the alluvial and submarine fan of a large drainage system. Such a huge pile of terrigenous sediments may be fed only by a large continent and not by a small block, like the Karakoram. Consequently the "Karakoram" are considered as of Gondwanian origin. When the MegaLhasa continent was isolated by the Neo-Tethys opening, various carbonatic environments developed in Karakoram. The deeper basin starved, with cherty, nodular to platy limestones and shales, at low sedimentation rate, as are the rare occurrence of Triassic conodont bearing layers in Wakhan and SE Pamir. However, any paleogeographic reconstruction is severely hampered by Cretaceous to Cainozoic tectonics, which affected the area, causing also important lateral displacements.

The early deformations of Northern Karakorum have at least three age peaks. The older is Jurassic, spanning from Liassic to early Middle Jurassic, as evidenced by red and grey thin to coarse arenites, forming tens to hundreds m-thick multiple bodies. Petrographic composition indicates the orogenic character of these sandstones. The terrigenous bodies increase in thickness from west to east, and north to south, being mostly reddish with emersion evidence at west in Chapursan valley (Yashkuk Fm.) and exclusively gray with marine fauna intercalations south and eastwards (Kundil and the area between Shimshal to Shixnshal pass). More details are reported in the Jadoul et al. abstract (This Workshop). The occurrence of these arenites and shales is interpreted as connected to a nearby deformation and uplift, related to a first docking of Cimznerian microplates.

A strong deformation instead directly affected the whole sedimentary sequence in a time comprised between the Late Jurassic and the Late Cretaceous. The polymictic, mostly fluviatile, Tupos Conglomerate seals verticalized and

folded Triassic and Jurassic sedimentary rocks. Upper Paleozoic clasts were also detected. These were considered till now the youngest pre-India collision sediments of the Karakorum Range, and they were related to the final welding of the Karakorum microplate to the Asian continent, due to the Neothethys active subduction at south. The deformation was tentatively ascribed to a Mid Cretaceous time. It should be also considered the large occurrence of granitoids plutons, with 110-100 Ma age in Northern Karakorum.

During the 1991 expedition, we found a marine reddish to gray nodular limestone some hundred m thick, onlapping with angular unconformity (10 to 20m) the highly irregular surface of the Tupo Conglomerate. These scaglia-like deep-water sediments contain Inoceramid phosphatized particles and very rare Nannofossils. The identified species *Ceratolithoides verbekii* and *Calculites obscurus* till now are considered as coexisting only in the Early and Middle Campanian. This finding represents the youngest marine sediment so far detected in Karakoram, the only Late Cretaceous marine evidence and makes possible some connection with the Late Cretaceous evolution of Western Tibetan Plateau.

G/10. Gaetani, M. & Garzanti, E., 1991. Multicycle history of the Northern India continental margin (Northwestern Himalayas). *American Association of Petroleum Geologists Bulletin* 75, 1427-1446.

The geologic evolution of northern India is best recorded in the stratigraphic succession of the Zaskar Range (northwestern Himalaya), which represents the most complete transect through this ancient continental margin. Sedimentary history began in the late Proterozoic, and recorded a late Pan-African orogenic event around the Cambrian-Ordovician boundary, when the Gondwana supercontinent was eventually assembled.

The following long period of epicontinental deposition in shallow seas linked to palaeo-Tethys lasted until the Early Permian, when a neo-Tethyan rift began to open between paleo-India and the Cimmerian microcontinents. Neo-Tethyan history can be subdivided into two sedimentary megasequences, both recording a major tectonic and magmatic event in the lower part. The first one began with breakup in the Late Permian and lasted until the end of the Jurassic. The second one started in the early Cretaceous with the final detachment of India from Gondwana and the opening of the Indian Ocean, and ended with the India-Eurasia collision in the Early Eocene. The two megasequences can be in turn subdivided into six transgressive/regressive supersequences bounded by tectonically enhanced unconformities.

Basal sandstone units of Early Permian, Late Permian, Norian, Callovian, Early Cretaceous, and Paleocene age are invariably associated with oolitic ironstones or reworked glauco-phosphorites, and mark the transgressive part of each supersequence. Next, condensed nodular carbonates or shales with pelagic fauna are typically overlain by thick shallowing-upward marly units capped by regressive platformal carbonates. The six tectono-eustatic supercycles reflect successive rifting episodes which punctuated the progressive separation of India from the rest of Gondwana, and document the combination of plate/microplate reorganizations and eustatic, climatic, and oceanographic changes in the Tethyan domain.

After the onset of collision between India and Asia close to the Paleocene/Eocene boundary, obduction of the remnants of the neo-Tethys ocean floor onto the Indian margin began, and the latter underwent multi-phase deformation with fold-thrust shortening followed by heating and extension. After the main metamorphic event, ophiolitic nappes were re-thrusted and finally emplaced with their sedimentary sole on top of the passive-margin succession.

An Italian geological team visited a remote and in part never studied area in the northern Hunza region (Pakistan), which represents the link between the Karakorum and Pamir Ranges. The north Karakorum sequence commences in the Permian with terrigenous sediments, followed by shallow- to deep-marine carbonates deposited on a newly formed passive margin. Deep-water sedimentation continued till the end of the Middle Triassic, when carbonate platform conditions resumed. An episode of deltaic red sandstones with orogenic provenance is interbedded in the Liassic, and it is transgressed by a Middle to ?Upper Jurassic shallow water marine unit. Eventually, all of the sequence was faulted and folded, with weak metamorphic imprint, before fluvial red polygenic conglomerates sealed the succession, in a spectacular unconformity.

The north Karakorum provides an example of a microplate that rifted away from Gondwana in the Permian, reached deep-marine conditions in the Early Triassic, and marginally recorded compressive movements in the Liassic. A subsequent orogenic episode points to a reorganization of the southern Asian margin possibly around middle Cretaceous time. Finally, the north Karakorum was affected by strong fold-thrust deformation and low- to very low-grade metamorphism in the Cainozoic, related to the India-Asia collision.

During September and October 1988, a geological and geophysical expedition, sponsored by the Consiglio Nazionale delle Ricerche (CNR) and assisted on the field by the Chinese Mountaineering Association (CMA), made a reconnaissance from Mazar (Yarkand Valley) to the north side of the Karakoram (K2 and Gasherbrum).

South of the Kun Lun Crystalline, six units, all bounded by tectonic contacts, have been detected. North to south, they are:

Bazar Dara Slates and related granitoids. Gray dark slates and fine litharenites, several thousand meter thick, intruded by km-sized granitoid bodies.

Surukwat Thrust Sheets. Non-metamorphic red sandstones and anhydrites thrust together with metadiorites, micaschists, orthogneisses, and metapelites. Aghil Dara Granodiorite. Large body of granodiorite, and subordinated porphyritic granites, quartzdiorites and gabbros. Shaksgam Sedimentary Belt. At least 3-km thick sedimentary sequence, with marine fossils from Permian to the Jurassic. Sughet Granodiorite. Granodiorites and tonalites.

Sarpo Lago-K2 Metamorphics. Ortho- and paragneisses, marbles and pegmatoids, with less metamorphosed sedimentary thrust sheets containing fusulinids. Unit 1 and 2 are attributed to the Kun Lun and Qiantang micro plates, separated by a great fault, interpreted as the W Kun Lun Fault. Units 5 and 6 belongs to the Karakoram microplate, whilst the correlation of the sediments of Shaksgam valley is uncertain. The Karakoram Fault Zone affect the Sughet Granodiorite and the sediments of the Shaksgam Valley.

G/17. Gaetani, M., Jadoul, F., Erba, E. & Garzanti, E., 1993. Jurassic and Cretaceous orogenic events in the N Karakoram: age constraints from sedimentary rocks. In: Treloar, P.J. & Searle, M.P. (Eds.), *Himalayan Tectonics*. Geological Society, London, Special Publications 74, 39-52.

At least two major episodes of tectonic deformation are recorded in the Mesozoic sedimentary succession of the North Karakoram. The older event took place between the Liassic and the early part of the Mid-Jurassic, as documented by tens to hundreds of metres thickness of dark grey litharenites (Ashtigar Fm.). The latter are sharply overlain by 35 m to 150 m thick red sandstones, interbedded with shales and siltstones (Yashkuk Fm.). Terrigenous bodies increase in thickness from west to east, and from north to south. Petrographic composition indicates the orogenic character of these quartzo-lithic sandstones, characterized by mafic volcanic and serpentinite detritus, being replaced upwards by sedimentary and subordinate metasedimentary clasts. The Ashtigar Fm. may have been deposited in a collisional basin close to a newly-formed suture belt. Contribution from allochthonous oceanic rocks was significant in the first stages of collision, whereas detritus was subsequently derived mainly from uplifted sedimentary successions. Terrigenous units were conformably transgressed by shallow-water limestones in the Aalenian, and later on marine conditions persisted until the earliest Cretaceous.

The second event of tectonic deformation occurred between the earliest and the Late Cretaceous, when the fan delta Tupo Conglomerate, mostly derived from uplifted carbonate and clastic rocks, sealed the strongly folded and faulted underlying succession. Mid-Cretaceous granitoid plutons are also widespread in the North Karakoram. This orogenic event is interpreted as related to the final welding of the Kohistan arc and Karakoram microplate to Asia.

The highly irregular topography of the Tupo Conglomerate is overlapped unconformably by reddish to grey nodular limestones, some hundred metres thick and containing phosphatized inoceramids and nannofossils of Campanian age (Darband Fm.). These are the youngest marine sediments detected in the Karakoram to date.

G/18. Gaetani, M., Le Fort, P., Tanoli, S., Angiolini, L., Nicora, A., Sciunnach, D. & Khan, A., 1996. Reconnaissance geology in upper Chitral, Baroghil and Karambar districts (northern Karakoram, Pakistan). *Geologische Rundschau* 85, 683-704.

During the summer of 1992 a geological expedition crossed the northern Karakorum Range in northern Pakistan, from the Chitral to Karambar valleys, from the villages of Mastuj to Imit. Some of the areas visited were geologically unknown. A number of structural units were crossed, belonging to the Karakorum block or to other crustal blocks north of it. They are: (a) the axial batholith, in which three plutonic bodies have been identified, and (b) the northern sedimentary belt (NSB), in which three major tectonostratigraphic units form thrust stacks dipping to the north. Their internal stratigraphy and structural style are partly different. The most complete contains a crystalline basement, transgressed by a marine succession during the Early Ordovician. The youngest strata are represented by the Reshun conglomerate, of inferred Cretaceous age. The northernmost unit of the NSB is tightly folded, whereas the central one forms a monocline. Vertical faults, mainly strike-slip, dissect the thrust slabs. Metamorphic deformation is absent or reaches only the anchizone in the studied sector of the Karakorum NSB. To the north of the Karakorum proper there are several other tectonic units, separated by vertical faults. They are, from south to north: (a) the Taş Kupruk zone, with metavolcanics of basaltic to latibasaltic composition; (b) the Atark unit, mostly consisting of massive carbonate rocks of Mesozoic age; and (c) the Wakhan slates which consist of a thick widespread succession of dark slates, metasiltites and sandstones. The fine-grained elastic rocks are supposed to be Palaeozoic to Early Triassic in age. The Wakhan slates are intruded by plutons belonging to the East Hindu Kush batholith, from which a single K/Ar age on muscovite gave a Jurassic age.

G/19. Gaetani, M. & Leven, H., 1993. Permian stratigraphy and fusulinids from Rosh Gol (Chitral, Hindu Kush). *Rivista Italiana di Paleontologia e stratigrafia* 99, 307-326.

Chitral (Pakistan), geologically, includes the eastern termination of the Hindu Kush and its transition to the Karakorum. The position of the boundary is not precisely defined, and may be located provisionally at the Chitral Fault, or at the Tirich Mir Fault. Four main tectonostratigraphic units are identified. From SE to NW they are: 1) Lun Shales (shales and slates with Devonian calcareous intercalations) and Devonian to Permian carbonates. 2) Metabasites, consisting of amphibolites and green tuffs, locally associated with carbonates. 3) Atark Group, mostly metacarbonates in which Permian, Triassic and Cretaceous intervals have been detected. 4) Wakhan Slates, a very thick terrigenous succession of dark colour, partly of Paleozoic age. Huge granitoid bodies have been intruded into this unit. This 4-fold subdivision is here proposed for the first time.

A terrigenous-calcareous succession of Permian age has been measured and sampled in the Atark Group at Rosh Gol. Seven lithostratigraphic units have been identified. Six of them contain fossils, mostly fusulinids, allowing identification of Yahtashian, Bolorian, Kubergandian and Late Murgabian or Midian. The most significant species of fusulinids are illustrated; these have close affinities to the Central Pamir.

Key words: Stratigraphy, Fusulinids, Permian, Chitral, Hindukush.

G/20. Gaetani, M. & Muttoni, 1991. Preliminary notes on the high Chitral geology. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Auris, France, 43.

The High Chitral area, from Mastug to Tirich Gol and Morich Gol valleys, i.e. from SE to NW, consists of the following units.

Lavas and volcanoclastics of the topmost Kohistan arc.

Chitral Slates (gray phyllitic slates) and marbles possibly covered with angular unconformity by 500-m thick polymict conglomerate, including abundant volcanic pebbles.

Shogram-Kuragh Unit. It includes the classical Silurian to Cretaceous succession, sealed by the Reshun Conglomerate, described by Hayden (1915), Desio (1959) and Talent et al. (1981). Disrupted in several blocks, the more complete successions lie northwestwards. It is separated of the following units by the Mt. Shogram Fault.

Lun Slate Unit. Extremely thick unit of gray dark slates, with subordinated marls and marly limestones, with metamorphic grade increasing from SE to NW. In the Morich Valley, it reaches the low-grade with phyllites and micaschists. This belt, wide 15-20 km, was formerly considered as Carboniferous, but Talent et al. discovered in several places Devonian Conodonts.

Uzhnu Gol Metavolcanics. Bounded by regional faults, a metavolcanic body (amphibolites according to Buchroithner, 1980), some 20-km long and up to 1-km wide, has been observed. It disappears westwards.

Attak Sedimentary Unit. The term was introduced by the Austrian authors, Gamberith and Buchroithner. It forms a carbonate belt, from the upper reaches of the Rosh Gol to just south of the Tirich Mir. Its contact with unit 4 and 5 is due to a regional fault with significant sinistral component. The metamorphic deformation mostly hampers any detailed stratigraphy. However, in the Zundrangram area, along the Rosh Gol, a Permian sequence of about 600-m was measured. It consists of an arenite-carbonate to claystones sequence, very rich in Fusulinids in the central part that may be interpreted as passive margin succession, drawing during the Middle Permian. Moreover very thick shallow-water carbonates are testified by the presence of Megalodontids and Rudists. Previously considered only as Paleozoic, the age of this unit should be extended up to most of Mesozoic. The sedimentary sequence is crosscut by sills oriented NE-SE, subsequently penetrated by rarer NW-SE dykes.

Whakhan Slates. Separated from the previous unit by another regional fault, dark gray or black slates follow, with subordinated arenites, microconglomerates and rarer pebbly mudstones. Sure turbiditic sequences have not been observed. Along the Rosh Gol a horizon packed with Bryozoan possibly of Paleozoic age has been sampled, together with poorly preserved Brachiopods. The slate may be intruded by granitoid bodies.

Key words: Stratigraphy, structural geology, metasediments, metavolcanics, Chitral.

G/21. Gaetani, M., Nicora, A., Angiolini, L. & Le Fort, P., 1993. Geological traverse from Chitral to Karambar (E Hindu Kush to W Karakoram): Preliminary geological results. Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 20-21.

In the easternmost Hindu Kush, Hindu Raj and W Karakoram, the following units may be recognized from south to north:

The Axial Batholith forms two distinct branches in this region. They are separated by a band of metasediments already described east of this zone as the Darkot Group, of Permian age *pro parte*. Possible Mesozoic fossils have been obtained. The Yarkhun river only cuts through the northern branch where two types of granitoid have been recognized: (i) a dark amphibole-biotite granodiorite to biotite, rich in mafic enclaves, often foliated, resembling the Hunza granodiorite of mid-Cretaceous age, (ii) a porphyritic biotite $\pm$ amphibolite granite, often strongly deformed, more abundant to the north of the section, where it intrudes into the metasedimentary formations with a diffuse contact. This second type, resembling the subalkaline mid-Cretaceous Darkot pass granite, is intimately associated with the first, a situation similar in some way to that of the Karambar section (see Debon & Khan Abstract).

North of the Axial Batholith mostly sedimentary rocks crop out, usually arranged in three stacks, thrust southwards. The crystalline basement of the middle stack has been discovered. It is made up of medium-grained biotite granite, largely eroded in a glacial basin, due to its very strong alteration and brittle deformation. To the south, the granite intrudes the dark metapelites of Chikar. The sedimentary succession is directly transgressive on the granite with conglomerates and siltites, in which Early Ordovician acritarchs have been detected (N. Tongiorgi, Pisa). The succession continues upwards with a terrigenous unit, hundreds m-thick, with rare dolomitic intercalations in which Talent et al. (1981) found Middle-Upper Ordovician conodonts. The first significant carbonate unit consists of about 150m of yellow well-bedded dolomites, with peritidal depositional characters. Supposed age: Devonian. A mixed terrigenous carbonate unit, locally extremely rich in corals, brachiopods and bryozoans follows. Field identification: Middle Devonian and Frasnian. Upwards about 100 m of grey wackestone-crinoidal packstones follow, with solitary corals. Supposed age: Carboniferous. The lower part of the Permian is terrigenous and it is correlatable with the Gircha Formation of the Hunza region. Then a mixed carbonate-terrigenous succession, several hundreds m-thick follows, locally crowded with brachiopods, corals, bryozoans, conodonts, gastropods, bivalves and especially fusulinids. For details refers to Angiolifli et al. (Poster Section). After an erosional surface, with local incursions and a thin terrigenous unit, a huge peritidal dolomitic formation, 700 m thick follows. The paleontological control is poor and we suppose it represents the Upper Permian and may be the Triassic up to the Early Jurassic. We have no information about most of the Mesozoic. The southernmost thrust slice may have at its top the Reshun Conglomerate with Orbitolina-bearing pebbles.

A system of sinistral strike-slip faults, SW-NE oriented, the Tirich Mir Fault, brings in contact gray pale dolomites, with low metamorphic grade. Phosphates of Devonian and Triassic fossils have been found. Most significant are mafic metatuffs and various detrital volcanogenic levels, dark red to dark green, interbedded with the sediments.

With faulted contact, the huge, several km-thick Wakhan Slates follows. They are intruded by granitoid bodies made up in general of biotite-amphibole porphyritic granite. A single granitoid pluton (Chatteboj), with a strong contact aureole, was found also intruded in the unit 2). All these granitoid bodies could pertain either to the northern granitoid belt running from Tirich Mir to Khunjerab, in which Cretaceous ages have been obtained, or to the Batura group of Eocene age.

G/22. Gaetani, M., Nicora, A., Cirilli, S., Atudorei, V. & Lucia, A., 1999. The P/T boundary in Karakorum revisited. *Terra Nostra* 99 (Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany), 48-49.

The stratigraphic succession including the P/T boundary in Karakorum, Pakistan, may occur in two different settings: A) Carbonate platform; B) Pelagic, poorly oxygenated basin.

In Central Western Karakorum, within the carbonate platform of the Ailak Formation, the stratigraphic control is very poor and no details can be obtained. Instead, in the Eastern Karakorum, a pelagic succession spanning the interval from the Kundil Formation (Late Murgabian-Midian=Wordian according to Yin et al., 1997) to the Borom Formation (Olenekian-Ladinian) make possible to analyse the P/T boundary to some details. Unfortunately, the strongly tectonised setting hampered in the field a correct recognition of the stratigraphic sequence and hence the interpretation published in Gaetani et al. (1995) is here reconsidered. The type section, measured by MG and LA, is here reconsidered as far as conodont are concerned (AN). Palynostratigraphy (SC) and stable isotope stratigraphy (VA) are added. Particularly, the second hithozone has been reinterpreted and is now considered a tectonic slice of the underlying Kundil Fm., within tight isochinal folding. The search for radiolarians (P. De Wever, Paris) was unsuccessful.

The Wirokhun Fm. results now entirely made of 1 dark-grey marls and slates, with only occasional limestone intercalations. Due to the lithology and the thermal deformation (CAI of conodonts = 5.5-6; TAI of sporomorphs = 5-7, approximately corresponding to Ro of vitinite reflectance 1.35-5), most of the 60 samples collected (including

100 kg for conodonts) were barren. The Permian/Triassic boundary lies near the base of the Wirokhun Fm., being the sample KK1 12 the last Permian datum with *Neogondolella* ex gr. *Changxingensis* and *N. subcarinata*. In sample KK 115, (3.20 m above) the palynomorph assemblage contains *Cyclogranisporites varius*, *Polypodiisporites mutabilis*, *Polypodiisporites* sp., *Verrucosisporites* sp., *Densipollenites indicus*, *Calamospora* sp., *Dictyotrilletes* sp., *Lundbladisporella brevicula*, *Lundbladisporella* sp., *Eucommiidites* sp., *Thymospora lpsviciensis*, *Foveotrilletes* sp. The concurrent presence of a few Permian and dominating earliest Triassic palynomorphs, suggests that the very base of Triassic is here present. This interpretation is supported by sample KK127 (2 m above) in which a conodont assemblage characterised by transitional forms *Hindeodus latidentatus* - *H. parvus*, *H. praeparvus* and primitive *Neogondolella carinata* along with *Neogondolellids* cf. the *tulongensis-taylorae* group, was identified.

A fully Triassic palynomorph assemblage of Induan age is recorded in the following KK124 (6.8 m above) with *Cyclogranisporites varius*, *C. arenosus*, *Kraeuselisporites* sp., *Calamospora* sp., *Inaperturopollenites* sp., *Dictyotrilletes bireticulatus*, *Dictyotrilletes* sp., *Verrucosisporites* sp., *Densosporites* sp., *Baltisphaeridium* sp., *Grandispora jansonii*, *Prothoaploxypinus panaki*, *Thymospora ipsiviciensis*, *Lundbladisporella brevicula*, *Lundbladisporella* sp. This age assignment is reinforced by the following KK126 (1 m above) which contains *H. parvus* with more evolute morphotype and *Neogondolella carinata*. To be noted also the presence of fungal remains in the KK 124, which become abundant 2 m above (KK 129).

No significant data are further preserved in the next 10 m of the section. We suggest that this part is the tight core of an isoclinal syncline and the cherty limestone of the sample KK 149 and KK 150 represents the top of the Kundil Fm. Sample KK 150 interestingly contains a Changxingian fauna with *Hindeodus typicalis*, *Neogondolella* cf. *subcarinata* and *N. cf. changxingensis*. In sample KK 158 *Hiranognathus* cf. *unicostatus* along with several *Neogondolellids* is also present.

The carbon isotope profile displays a marked, gradual decrease in values from values higher than +2‰ recorded at the top of the Kundil Formation, to values as low as -4‰ which characterize the base of the Wirokhun Formation. Such low values are typically recorded in Lower Triassic carbonates and support the age assignment suggested by the palynomorph data. Moreover, the above-mentioned negative shift may correspond to the well-documented drop in values that marks the Permian-Triassic boundary worldwide. The relatively high $\delta^{13}C$ values (around +2‰) recorded in samples KK 150 to KK 159 support the interpretation that Upper Permian strata may be present in this part of the section (as a tectonic slice). $\delta^{13}C$ values from carbonates belonging to the Borom Formation show little variability upsection with an average value of -2.5‰. The strata examined for this study underwent severe thermal alteration and the primary carbon isotopic composition may be distorted; however, the general trends suggest correlations in agreement with the biostratigraphic data.

A reconnaissance has been made from Pasu (Upper Hunza) to Shimshal and then up to Shimshal Pass. The rocks cropping out are mostly sedimentary, with feeble to low metamorphic imprint on the southern side of the Shimshal valley, reaching the maximum metamorphic deformation around Dut. On the right side of the valley, from Shimshal up to just NE of the Mai Dur River, the Permian to Cretaceous succession of the Sost Unit (sensu Gaetani et al., 1990) has been crossed. The Jurassic gray sandstone unit is here widely exposed. All the succession is disrupted by the strike-slip system of the Misgar Fault. Details of the structural analysis of this belt are reported in Zanchi's abstract (this Workshop).

With tectonic contact, granitoid bodies follow, intruding slightly metamorphosed slates (Misgar Slate) and carbonates. The granitoid plutons belong to the important intrusive belt developed northwards of the Karakoram Axial Batholith, which comprises amongst others Mintaka, Kunjerab, Gyraf, and Sughet plutons. They characterize the northern edge of the Karakoram Range, being separated by a sedimentary belt from the Axial Batholith complex.

The ophiolitic mélange is defined as an olistostromal and tectonic mixture of ophiolitic material and sediments of oceanic origin with exotic blocks, reflecting areas which have subsequently disappeared. Being intimately related to

ophiolitic belts they indicate important suturelines connected to plate boundaries. Ophiolitic mélanges occur mostly where continental type plates are subducted with obduction of oceanic material. These fact are discussed on examples from the Middle East and the Himalayas, where the mélanges are particularly well exposed.

G/35. Gansser, A., 1980a. The peri-Indian suture zone: Geology of the Alpine chains born of the Tethys. 26th International Geological Congress, Paris, 5, 140-148.

The 5.000 km long Peri-Indian Suture Zone is divided into the North Himalayan - the Arakan Yoma – and the Quetta belt. It consists of ophiolites with basic volcanics. Ultramafics and associated ophiolitic mélanges which suggest originally steep but narrow oceanic basins. The Himalayan belt is followed northwards by the 2.500 km long Transhimalayan batholith which originated from a mostly oceanic crust and is different from the Himalayan and Karakorum batholiths. On its south side, the batholith is transgressed by the paleogene Kailas molasse. All these elements are interrupted by younger north south directed cross highs and fault zones. In the Arakan Yoma and Quetta belts the ophiolitic associations are similar but the geological frame has partly changed.

G/36. Gansser, A., 1980b. The significance of the Himalayan suture zone. Tectonophysics 62, 37-52.

The 2500 km long Himalayan Suture Zone is discussed within the widest structural frame, with new results obtained from a study of the Landsat pictures. The platform sediments from the Tethys or Tibetan Himalaya, north of the Main Central Thrust, Change northwards into a belt of Flysch sediments beginning in the Triassic and reaching the Paleocene. The belt is mixed with oceanic crust material such as volcanics, mélanges and ultrabasic slabs, and is strongly tectonized: the Suture Zone. It is followed to the north by a conspicuous belt of Kailas Molasse, of Paleogene age and transgressing the late Cretaceous Transhimalayan plutons. They consist of five bodies, predominantly tonalitic, separated by structural anomalies that also cut the Suture Zone. The plutons are structurally controlled and related to the Himalayan Suture (Subduction belt?). They are followed to the north by the south Tibetan Nyenchen Tangla belt, bordered by large fault zones and characterized by frequent Paleogene acid volcanics. The Central Tibetan Chang Thang area is structurally most complex, contains some ultrabasic rocks related to large fault zones, and exposes a large subrecent basaltic volcanism with no structural control but reminiscent of a “hot spot”. The northern Kun Lun — Astin Tagh Paleozoic orogenic belt displays 200 km of rejuvenated fault zones, some older mantle fragments and subrecent volcanism.

This structural aspect of Tibet, with internal older Suture Zones, younging southwards, contrasts with the Indian plate south of the Main Himalayan Suture. This Suture Zone is the only constant structural element all along the Alpine-Himalayan belt.

G/37. Gansser, A., 1980c. The division between Himalaya and Karakoram. Geological Bulletin, University of Peshawar 13, 9-22.

The 5000 km long Peri-Indian Suture Zone has doubled in the western Himalaya and the northern branch forms the division between the Himalaya and the Karakorum. The northward directed Nanga Parbat-Haramosh crystalline spur controls structure and petrology of both the Suture Zone. It divides the over 2000 km long Trans-Himalayan batholith into the eastern Ladakh and the western Swat Batholith. Geology and petrology of the Karakorum north of the Northern Suture Zone strongly contrast with the Himalaya to the south of it.

Key words: Orogeny, Himalayas.

G/40. Gansser, A., 1991. Facts and theories on the Himalayas. *Eclogae Geologi Helvetia*, 84, 33-59.

During the classical exploration in the 19th and early 20th centuries the ratio between facts and theories was 1:0.5. Plate tectonics changed it 1:3 and with geophysics, geochemistry and structural analysis the ratio became 1:5.

The backbone of the High Himalayas is a crystalline core, involving the Lesser Himalayas in the W. Exposed are Precambrian structures and metamorphism, overprinted by a Himalayan phase, its intensity still highly disputed. Cambrian non-orogenic granites cut discordantly rocks with preserved Precambrian structures. New age from 2000 to 900 may confirm this fact. Himalayan PT has not cancelled all the Precambrian elements and thrusting along the MCT has transported some relictic structures. The MCT forms a shuppen zone or can expose a sharp contact (Bhutan). Sediments of the Lesser Himalayas are now dated Late Precambrian to Cambrian, including most of the tillites. No real basement is yet known. Disputed is the fact of reversed metamorphism towards the MCT and above. The hot overthrust theory is contradicted by Jurassic palynomorphs just below the thrust. The Himalayan metamorphic overprint ends with the intrusion of leukogranites. They stress the 5000my intrusive gap from the Cambrian granites, a fact repeated in the North Himalayan crystalline, diapiric domes; a gap filled with nonorogenic Tethyan sediments. These follow above the crystallines with Late Precambrian argillaceous sediments where the high-grade metamorphism gradually decreases to anchi-phase in the Cambrian. Locally the crystalline/sediment contact can be downfaulted, negligible in the Garhwal Himalayas where basal sediments are over 5000m thick. The lesser Himalayas have a similar facies of Late Precambrian, (Dalings, Simla Slates). They suggest a more distal facies of the widespread Vindhyan, covering the northern Indian Shield.

Theories over facts increase when we approach the Indo/Yarlung suture (IYS), the obducted remnants of a large or small Tethyan ocean, outlining the collision between India and Tibet. Its timing, proven by intra-trappean Asian faunas of 67 my predates all previous assumptions, though collision was not synchronous and started earlier in the W Himalayas. The regional outline is surprisingly constant, but the details vary considerably: W Ladakh exposes 3 vertical ophiolitic melange belts. Eastwards they are capped by a large (40-km) ultramafic body, which retains a normal cover of gabbros and volcanics. Further E it is transported 50-km northwards to the tripple-junction at Tashigong, the most important but least known spot along the IYS. From here starts the Shyok suture and borders the Karakoram to the S as a deep fracture or a subduction. In a post-collision phase ophiolite nappes were thrust southwards. Remnants are seen in the Spongtag nappe (40-km thrust), the Amlang-La nappe (80-km) and Shigatse nappe (30-km). Similar nappes are even known along the suture on the West Side of the Indian shield (Quetta branch) with 30 to 50-km thrusts towards the E. In all nappes ophiolitic mélanges, frequently with exotic blocks, form the base and ultramafic bodies, often with primary textures, the top. Most of the nappes have been emplaced within the Lower Eocene.

North of the IYS follow the Andean-type Transhimalayan plutons, subdivided into Gangdese, Kailas, Ladakh and Swat plutons, the latter already W of the western syntaxis within the Kohistan complex, where facts and theories

show an abnormal high ratio. The Transhimalayan plutons, ranging from 100-40 my, the older ones often with a more basic composition, border the complex Tibetan continental margin, from which they have been more or less contaminated. This is documented by many xenoliths from the Tibetan "basement". However, in the western Ladakh pluton, between the Shyok suture and the IYS, NS aligned xenoliths seem to resemble the basement of the Nanga Parbat spur.

Subsequent to the intrusions the Transhimalayas were strongly uplifted and eroded, producing an Oligocene molasse, well preserved in the central Transhimalaya with 4000-m of clastic rocks, still nearly horizontal bedded and from which the spectacular Kailas has been carved, the most sacred mountain in Asia. All the greater rivers in the wider Himalayas originate from the Kailas region cut through the highest uplifts in the Himalayas and deposit their sediments in the Indus and Bengal fans, the largest submarine deltas known.

G/42. Gardezi, A.H., 1970a. Note on the Geology of the area around Nathiagali, District Hazara, West Pakistan. Geological Bulletin, Punjab University 7, 71-78.

The geological investigation around Nathiagali, District Hazara, West Pakistan, was initiated during the summer of 1963 in order to understand (a) the lithostructural features of the Hazara Slate Formation, (b) the nature and inter-relationships of calcareous bands that occur within the Hazara Slate Formation, (c) the nature of the base of post-Hazara slate rock sequence and (d) the tectonic style. During the subsequent years, as the emphasis shifted to other geological problems and to other areas as well, detailed and more extensive investigations were postponed. However, in the following paragraphs are summarised the few conclusions that were arrived at during the preliminary survey.

Key words: Geology, Nathiagali, Hazara.

G/44. Gardezi, A.H. & Ghazanfar, M., 1965. A change of facies at the base of the Jurassic in District Hazara, West Pakistan. Geological Bulletin, Punjab University 5, 53-56.

During his mapping of Hazara District, Middle- miss (1896, p. 124, 125) observed the presence of some "yellow shales" below the so-called Trias limestone near Tarnawal, which he goes on to say might represent the upper part of his Infra-Trias formation. He, however, was not able to confirm their age.

Independent observations were made, in another locality, by Marks and Muhammad Ali (1961, p. 50), who noted the presence of some "brownish to greenish siltstones and shales apparently conformably overlying the cherty limestone of the Infra-Trias". These authors further observed that "higher on the western slopes of Sarbun Dhaka the same formation is developed as haematite breccias associated with red-spotted, yellow sandstones".

The junior writer had an opportunity to study the geological and structural position of the so-called yellow shales during the summer of 1964. He found them to form a distinct rock unit and in his M.Sc. Fieldwork Report referred to them as the Hazira shales, after the village Hazira. In the following year, a more detailed study was undertaken in collaboration with A. H. Gardezi. This work produced some very interesting structural and stratigraphical results, which have led to a useful clarification and elaboration of the observations already made. Their stratigraphic position and field relationships are now better understood than before. The results of this field-work are now summarised and should be considered in conjunction with the map.

The Hazira Formation consists mainly of dirty grey and yellowish brown, calcareous, shaly siltstones, containing earthy concretions and attaining a maximum thickness of some 1,000 ft. It conformably overlies the Abbottabad

formation and is itself overlain by the basal arenites of the Jurassic, which often form a thin band of whitish ironstained orthoquartzite. The yellowish brown colour of the Hazira formation is replaced by a red tinge at places, as at Banda Pir Khan where it also contains a few quartzite bands. Towards its base, the Hazira Formation is generally glauconitic; this is clearly noticeable in the hand specimens.

The following details of the Hazira Formation are given:-

(a) It replaces the Haematite formation in stratigraphic sequence.

(b) Its lower boundary is gradational.

(c) Wherever its upper boundary is preserved, it is followed by a thin band of iron-stained ortho-quartzite (belonging to the Maira Formation of Davies and Gardezi, 1965. p.), which is present at the base of the Jurassic limestone throughout Hazara. Whether the Abbottabad Formation and Haematite formation intervene between the Jurassic and the Hazara slates or not, this band of ortho- quartzite is never missing and, therefore, it must form the lower boundary of the Jurassic. Its presence in no way means the presence of the Haematite formation, even in a reduced form.

The boundary relationships and stratigraphic position, as mentioned above, make a strong case for believing that the Hazira Formation is at least partly equivalent to, and represents a facies change of the Haematite formation.

(d) In spite of the great difference in lithology, the close proximity of the two facies remained puzzling. Therefore, a detailed mapping of the relevant area was undertaken. It has led to the discovery of a major thrust-fault which may be called the Lagarban Fault. This fault, starting from near the Kunhar river in the northeast continues southwards to beyond Abbottabad. The Lagarban Fault has provided translation to such an extent as to eliminate the transitional zone between the two facies, except near Kihal, Abbottabad, where at the base of the Hazira Formation a part of the Haematite formation is developed in the form of haematitic quartzite and quartzite breccias.

(e) Since its lower boundary is gradational and since it lies below the orthoquartzite of the Maira Formation the Hazira Formation should succeed or represent the uppermost part of the so-called Abbottabad Formation. Its counterpart, the Haematite formation should also represent the same with, of course, some slight breaks in sedimentation represented by the volcanic flows. This stratigraphic conclusion is also supported by the way in which the Jurassic overlaps the Hazira and Abbottabad Formations lying below it. In part of the area, there is also evidence of their overstep by the Jurassic on to the Hazara slates. Further support for this regrouping comes from the observation of the cyclic deposition of the Abbottabad Formation itself. Such a grouping would, however, be in contrast with that presented by Marks and Muhammad Ali (1961, p. 50) and should lead to the renaming of the Abbottabad Formation as the Abbottabad Group, which would include the Abbottabad Formation of Marks and Muhammad Ali and the Haematite formation or the Hazira Formation, the last two being equivalent to and interchangeable with each other.

(f) Near Jaster the lower part of the Jurassic limestone formation is very well developed and is underlain by the calcareous fossiliferous shales of the Maira Formation (Upper Liassic). These shales are lithologically quite different from the Hazira shales and have at their base the iron- stained orthoquartzite which always overlies the latter.

(g) No fossils have so far been recorded from the Hazira Formation and it can only be said that it is probably Pre-Jurassic and lies at the top of Middlemiss, "Infra-Trias", or of the Abbottabad Formation of Marks and Muhammad Ali (1962, p. 56) which has been assumed to be of Permo- Carboniferous age.

G/50. Garzanti, E., Critelli, S. & Ingersoll, R.V., 1996. Paleogeographic and paleotectonic evolution of the Himalayan Range as reflected by detrital modes of Tertiary sandstones and modern sands (Indus transect, India and Pakistan). Geological Society of America Bulletin 108, 631-642.

Detrital modes of sandstones derived from the Himalayan suture belt record the history of the mountain range since initial collision between India and Asia, which began in latest Paleocene time. Tertiary clastic wedges deposited in fore-arc, foreland, and remnant-ocean basins, and exposed along the Indus transect from northernmost India to the Arabian Sea, represent the best opportunity to study sedimentary responses to successive tectonic events during continental collision. Quartzose "continental-block" and feldspatholithic "magmatic-arc" sandstones were deposited, respectively, on the passive Indian (Tethys Himalayan succession) and active Asian (Indus Group) continental margins during Late Cretaceous–Paleocene time. Closure of the Neotethys was marked by sudden arrival of volcanic and ophiolitic detritus on the passive continental margin of the Indian plate during deposition of sediments dated at foraminiferal zones P6 (Pakistan) to P8 (India). Starting in early Eocene time (deposition of Chulung La Formation and Murree Supergroup), volcanic and ophiolitic to metasedimentary detritus was accumulated in rapidly subsiding "piggy-back" and foreland basins. Homogeneous petrographic composition within the Eocene–lower Miocene Murree Supergroup, with only slight progressive increase of detrital feldspars, suggests erosion of largely supracrustal rocks involved in thrusting in the north.

In middle Miocene time, marked enrichment in medium- to high-grade metamorphic detritus in foreland sandstones (Siwalik Group) reflects rapid uplift of a warm wedge of Indian crust, which was carried southward along the Main Central thrust. This major paleogeographic change was recorded also by quartzolitic remnant-ocean turbidites, which were fed great distances along transverse fracture zones and later accreted in the coastal Makran subduction complex (Panjgur association and Makran Group). Recycled-orogen detritus derived from the elevated Himalayan chain is still accumulating today in the Indus fan. Enrichment in feldspars with respect to ancient sandstones reflects deep erosion levels into mid-crustal rocks along the core of the growing orogen.

G/56. Gauhar, S.H., 1992. Plate tectonics, crustal evolution, and metallogeny of Pakistan. Geological Survey of Pakistan. Information Release 525, 27p.

A study of the metallogenic zonation of different regions of Pakistan shows a close genetic and temporal relationship with various aspects of crustal dynamics and plate boundary features such as subduction, continental collision, rifting, and emplacement of ophiolites. In the perspective of delineating their exploration potential and priorities, these zones have been further classified into different 'metallotect' belts by combining the plate tectonic environment of each separately discernible geological region with its characteristic metallogenic imprints. Thus besides serving the general purpose of a review article of the state-of-art on the accumulated knowledge about the evolution of crust in this part of the world, the present paper also attempts to give a brief yet unified synthesis on the mineral potential of Pakistan as interpreted in terms of the current concepts of metallogenesis and plate tectonics. Based on mineral prognosis and plate tectonic interpretations, a number of new target areas have been identified for initiating scientific exploration. Some of the more important of these prospects include those of gold, copper, and other base metals in shield protrusions and shield derived sediments in the Punjab and Sin; copper & tin, in the hot spot brine and rift - related Paleozoic rocks in the Salt Range, Punjab; barite fluorite associated lead-zinc-silver deposits in shelf sediments in parts of Baluchistan and NWFP; porphyry type deposits of copper-gold-molybdenum and massive sulphides of copper-lead-zinc in the Chagai and Kohistan regions; epithermal gold in clay altered volcanic rocks in Chagai; lithium in pegmatites in Chitral and adjoining areas; chromite in northern ophiolites; copper and manganese in the Waziristan ophiolitic melanges; and tin & tungsten in Chagai porphyrites and in the granitoids and their contact Paleozoic carbonate rocks in NWFP and the Northern Areas.

Isotopic analyses of gneisses and anatectic granites from the Nanga Parbat-Haramosh Massif (Pakistan Himalaya), a zone of pronounced thermal activity and recent high-grade metamorphism in the Indian Plate, reveal information about the conditions of granite genesis and the nature of Sr exchange in high-grade gneisses and granites. $^{87}\text{Sr}/^{86}\text{Sr}$ ratios for both gneisses and granites are extremely high and heterogeneous (0.7721-1.0642), indicating that both granites and gneisses have an ancient metasedimentary crustal source. Whole rock Rb-Sr data for gneisses scatter around a reference isochron with an age of 1.8 Ga. Although the Nanga Parbat leucogranites have similar $^{87}\text{Sr}/^{86}\text{Sr}$ ratios to the surrounding gneisses, their Nd isotopic compositions ($\epsilon_{\text{Nd}} = -23$ to -25) are higher than those of the gneisses and migmatites ($\epsilon_{\text{Nd}} = -26$ to -29), indicating that the granites' source is not the presently exposed level of gneisses. This result is consistent with other studies that suggest these granites formed as a result of vapor-absent

melting during the recent, rapid uplift of Nanga Parbat. Biotite and feldspar mineral separate Rb-Sr data for six gneisses and one granite have near-horizontal or negative slopes (and ages) on a Rb-Sr isotopic evolution diagram. This behavior is best explained by: (1) a recent «5 Ma) local homogenization of Sr isotopes during the young metamorphism; and (2) after peak metamorphism, Sr isotope exchange occurred between biotite and carbonate minerals after feldspar became closed to Sr exchange. This exchange took place within the last 2 my and was mediated by metamorphic or magmatic fluids which augmented Sr exchange with carbonate/calcsilicate lenses and/or deposited secondary calcite veins in the granites and gneisses. This proposed Sr exchange between silicates and carbonates could have significant implications for the interpretation of the seawater Sr curve because it enables carbonate dissolution to contribute radiogenic Sr to the dissolved load in streams.

The Salt Range and its Trans-Indus extension bridges the reentrant between the outer ranges of the northwestern Himalaya and the Sulaiman Mountain arc. Upper Proterozoic to Recent successions occur in the range, which makes up the southern thrust front of the orogen. There are two regional features of particular interest. The first is the occurrence of thick saliferous deposits of Eocambrian age, overlying Precambrian basement in the Potwar Plateau and thrust southward in the Salt Range over the alluvial Cenozoic.

Thick, saliferous deposits also occur within the Eocene sequence of Kohat. These in-competent formations played a significant role in determining structure. The second feature is the presence of four major unconformities: between the marine Eocambrian to Cambrian sequence and the glacial, Lower Permian conglomerates, and below the Paleocene, the Miocene, and the late Pliocene-Pleistocene formations.

Metamorphic rocks, linking with the Precambrian crystalline basement of north-western India, crop out only in the Kirana Hills some 80 km south of the Salt Range. Within the Salt Range and related areas, unmetamorphosed sedimentary rocks compose the exposed succession, mainly shallow-water marine, until mid-Tertiary time, and lacustrine and fluvial from Miocene time onward.

Prior to Quaternary time, only epeirogenic forces affected the region, accompanied occasionally by local warping. In contrast, during Quaternary time, the effects of the Himalayan orogeny extended southward. Accentuated by movement within the Eocambrian saliferous formation, the Salt Range developed as a complex anticlinorium, emplaced southward along a major thrust, which has recently been determined by seismic reflection measurements to involve a decollement of at least 20 km. Complex fold and fault structures resulted elsewhere within the region.

G/87. George, M.T., 1993. Structural and Thermal Constraints on the Tectonic Evolution of the North-Western Margin of the Nanga Parbat-Haramosh Massif (Pakistan). Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 31-32.

In the Haramosh region of northern Pakistan, the Kohistan island arc is separated from the Indian crust of the Nanga Parbat-Haramosh massif (NPHM) by a 2.5 km-wide, steeply inclined ductile shear zone containing intercalated lithologies derived from both terranes. A combined structural, geochemical and geochronological study across this zone has helped to constrain the thermal and tectonic evolution of the region.

The youngest stage of magmatism within the eastern part of the Kohistan batholith is characterized by biotite granite sheets (Confluence granites) emplaced at 50-30 Ma and younger muscovite granite sheets (Patti granites) at ~26Ma. These are geochemically distinct, with the Confluence granites comprising a range of granitic compositions with high Sr and Ba abundances and the Parri granites comprising granite sheets enriched in Rb. Undeformed granites in both suites have ($^{87}\text{Sr}/^{86}\text{Sr}$)_i in the range (1.7045-0.7054 and $\epsilon\text{Nd}(\text{T})$ of +0.1 to +2.7, suggesting that both groups may be derived from juvenile arc sources.

The Kohistan granite sheets can be traced into the shear zone at Sassi, where they are generally intensely deformed and mylonitized, although locally the sheets cross-cut shear fabrics and intrude intercalations of Indian crust material. Whilst none of the sheets appear to have intruded far into the NPHM, these relationships indicate that the Kohistan granite sheets postdate the initial collision of the northern Kohistan terrane with the Indian continent. The isotopic evidence from the undeformed granite sheets suggests that significant underthrusting of northern Kohistan by the Indian continental crust may not have occurred until after 26 Ma. Within the shear zone, deformed granite sheets show a marked increase in ($^{87}\text{Sr}/^{86}\text{Sr}$)₁ (0.7075-0.7784), with decreased $\epsilon\text{Nd}(\text{T})$ (-13 to -26). These trends are thought to be due to a combination of sub-solidus fluid infiltration and assimilation of crustal material, with fluids or material derived from the adjacent, isotopically evolved NPHM crust.

Structural data were collected from a 24-km long section along the western margin of the NPHM. The main shear fabrics within the belt are at greenschist grade and rework the earlier amphibolite-grade metamorphic assemblages. Kinematic indicators demonstrate an east-side up movement sense, with a strong component of dextral-slip. Since the foliation dips moderately to steeply west, the shear zone has a normal fault geometry, characterized by a north-westerly motion of the Kohistan arc relative to the NPHM.

The timing of movements within the shear zone have been constrained using mica geochronology on deformed lithologies within the zone. Rb-Sr muscovite-WR ages lie in the range 12-28 Ma, and reflect variable post-metamorphic cooling through the 5000C closure temperature. Rb-Sr biotite-WR and biotite-feldspar ages are 11 and 24 Ma, and have locally been reset to 6 Ma, probably during the retrograde shearing within the zone. Interestingly, leucogranites and their metamorphic country-rocks within the adjacent part of the NPHM have Rb-Sr ages of 2.8-7.7 Ma (muscovite) and 1.4-3.4 Ma (biotite), related to recent uplift and Leucogranite intrusion within this part of the NPHM. The absence of such young mica ages within the shear zone bordering the Kohistan arc indicates that in the Haramosh area, the major, recent uplift of the NPHM was not accommodated along the western margin of the NPHM, as occurred further south. The disparity in mica ages between the shear zone and the NPHM, and the lack of any consistent age variation within the NPHM, may indicate a relatively passive uplift of this part of the massif.

G/89. George, M.T., 1995b. Implication of Rb-Sr Mica Ages from the North Western Flank of the Nanga Parbat-Haramosh Massif. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

In the western Himalaya, formation of the Nanga Parbat-Haramosh Massif (NPHM) in late-Himalayan times led to the rapid exhumation of upper-amphibolite grade orthogneisses and paragneisses of the Indian continent. Monazite U-Pb ages suggest that these lithologies were locally still at metamorphic temperatures as late as 4-11 Ma(1). To the west, Indian continental rocks are separated from rocks of the upper part of the Kohistan island arc by a ductile shear zone which appears to have accommodated much of the relative uplift of the NPHM. Near Raikhot in the south (Fig. 1), fabrics within the shear zone indicate that Indian continental rocks have been thrust towards the north-west, over the Kohistan arc. Between Sassi and Darchan in the north, the shear zone dips moderately to steeply towards the west and contains lithologies derived from both the Indian continent and the Kohistan island arc. Greenschist-grade fabrics indicate dextral oblique-slip, with an extensional, west-side-down movement sense.

A detailed geochronological traverse across the shear zone in the Sassi-Darchan area has recently confirmed that exhumation-related cooling has occurred both more rapidly and more recently in the NPHM compared with the Kohistan arc. In this contribution, Rb-Sr mineral data are presented from lithologies collected from the shear zone itself, in an attempt to resolve the timing of cooling and deformation along the flanks of the NPHM in relation to present tectonic models. The well-constrained regional cooling history allows an assessment to be made of the relative importance of shear strain, mineral assemblage and grain-size in controlling cooling ages through variation in closure temperature. Mica ages obtained from several mylonitic granite sheets are similar to ages obtained from both their proximal and distal wall-rocks, and do not reflect cooling following granite intrusion. Mica ages from both igneous and metamorphic lithologies are therefore considered together. All mica ages were calculated by regression to the whole-rock.

Biotite ages mostly lie in the range 5.5-10.8 Ma. However, two amphibolites have yielded ages of 16.7 and 23.7 Ma. The majority of muscovite ages lie in the range 9.5-21 .0. However, four pelitic lithologies from Sassi yield anomalously old muscovite ages of 26, 49, 64 and 293 Ma. In addition, two samples collected from the core of the NPHM in the Astor gorge, 40 km to the south (Fig. 1), have yielded muscovite ages of 36.4 and 21.9 Ma.

The majority of biotite ages lie between those earlier obtained from proximal parts of the NPHM (2-3 Ma) and the Kohistan island arc (13-17 Ma), and they therefore probably reflect simple cooling through ~300 °C, rather than late-stage recrystallisation during shearing. The transtensional movements mentioned above occurred at >300 °C, and these movements therefore accommodated uplift of the NPHM prior to 6 Ma. Only brittle movements were occurring in the shear zone during the late-stage exhumation of the northern part of the NPHM.

Several muscovite ages are anomalously old, and indicate that resetting of muscovite during Himalayan processes was locally incomplete, whilst coexisting biotite, intergrown with the muscovite, was fully reset due to the lower closure temperature of biotite relative to muscovite. A cluster of muscovite ages lies in the range 17-21 Ma, and probably reflects cooling of many shear zone samples through ~500 °C in this period. The youngest muscovite ages obtained from metamorphic samples are 9.5 and 11.9 Ma, respectively. Such a wide range in muscovite ages (21.0-9.5 Ma) may reflect the following:

Maintenance of temperature gradients (>200 °C) due to differential shearing during slow cooling, with the result that different imbricates followed different cooling histories.

Closure temperature variations (>200 °C) due to varying fluid content, grain size or mineral assemblage, with the result that different samples yield different mica ages despite cooling along the same pathway.

Isotopic resetting of the majority of biotite samples, and some of the muscovite samples, due to leucogranite intrusion, sub-solidus fluid activity, or deformation occurring at ~6 Ma, at least 11 Ma after the regional 500 °C isotherm had reached the surface.

The latter hypothesis is considered to be unlikely, since it would also have to account for even younger muscovite ages (4-8 Ma) obtained from samples collected from right across the NPHM. Furthermore, the majority of biotite ages are younger than the youngest muscovite age determined, an observation which suggests that the ages are dominantly controlled by diffusion during cooling rather than resetting during shearing. No correlation can be found between either lithology and grain-size and mica age, and therefore there is no evidence for significant variation in closure temperature existing between the studied samples, although it should be remembered that the grain-size is probably not equivalent to the effective diffusion distance.

In summary, this study shows that:

Closely-spaced lithologies that have been sheared along the north-western flank of the NPHM yield variable mineral cooling ages due to real variations in cooling histories followed by proximal sample, possibly combined with variations in closure temperatures. Relatively old (and variable) ages have also been obtained from the core of the NPHM further to the south, indicating that lithologies lying within the NPHM structure have also been strongly affected by differential cooling since Himalayan collision. Muscovite may not be fully isotopically homogenized during upper amphibolite-grade metamorphism. Temperatures in the Sassi-Darchan shear zone probably remained close to 500°C for 11 Ma, whilst cooling through 300°C occurred in the period 5.5–10.8 Ma. Uplift of the northern part of the NPHM was accommodated by brittle movements occurring along the western margin.

Key words: Geochronology, Rb-Sr mica ages, NPHM.

G/90. George, M.T. & Barlett, J., 1996. Rejuvenation of Rb-Sr mica ages during shearing on the northwestern margin of the Nanga Parbat-Haramosh massif. *Tectonophysics* 260, 167–185.

The shear zone bordering the western margin of the Nanga Parbat-Haramosh massif (NPHM) separates terranes with distinct but well-documented cooling histories. This study was undertaken in order to examine isotopic behaviour and if possible to date deformation or cooling within the contact zone itself. Rb/Sr muscovite and biotite ages and petrographic descriptions are presented for a range of metamorphic lithologies and granite sheets which have been affected to varying degrees by greenschist-facies extensional crenulation. This deformation has been kinematically linked to the differential uplift of the NPHM. Ages for metamorphic lithologies and granite sheets are similar and are considered together. Determined muscovite ages mostly lie in the range 9–22 Ma, whilst the majority of biotite ages lie in the range 2–11 Ma. Mica ages from the shear zone are significantly more variable than ages determined for unsheared lithologies from outside the shear zone. Even closely spaced samples yield variable mica ages, and in some cases there is a significant difference between muscovite and biotite ages determined for the same sample. Muscovite ages yield a bimodal distribution, with groups of ages in the range 17–21 Ma and 8–12 Ma. The older group is thought to reflect the original, purely thermostatic cooling of lithologies through the muscovite closure temperature, prior to formation of the NPHM structure. In contrast, the younger group of muscovite ages reflects variable degrees of isotopic resetting during shearing at temperatures below the muscovite closure temperature, associated with the relative uplift of the NPHM. The majority of biotite ages also reflect partial to complete resetting during shearing. However, biotite samples from structurally competent amphibolite horizons preserve older (>16 Ma) ages, indicating that there was locally a strong lithological or fluid control on the degree of resetting. The flanks of the NPHM cooled through the muscovite closure temperature significantly earlier than the deeper structural levels presently exposed within the core of the NPHM. Greenschist-grade deformation was occurring within the shear zone at the same time that deeper levels of Indian crust were passing through the muscovite closure temperature, suggesting that the shearing reflects the relatively passive extensional movement of rocks sliding off the flank of the actively growing Nanga Parbat structure. The results highlight the isotopic complexities of long-lived shear zones present in orogenic belts, but show that useful radiometric age information may be obtained if the regional tectonic history is well understood and if the samples for dating come from well-constrained structural settings.

Key words: Geochronology, Rb-Sr mica ages, NPHM.

G/91. George, M.T., Harris, N.W.B. & Butler, R.W.H., 1993. The tectonic implications of contrasting granite magmatism between the Kohistan Island Arc and the Nanga Parbat-Haramosh massif. In: Treloar, P.J. & Searle, M.P. (Eds.), *Himalayan Tectonics*. Geological Society, London, Special Publications 74, 173–191.

In northern Pakistan, an integrated structural and geochemical study across the contact between the Cretaceous-Tertiary Kohistan island arc and Indian crust of the Nanga Parbat-Haramosh massif (NPHM) has identified strongly contrasting source regions contributing to post-50 Ma magmatism, which constrains the tectonic evolution of the region. Nd-model ages of Tertiary intrusives increase dramatically across the contact from c. 700 Ma in the Kohistan terrane to c. 2500 Ma in the NPHM.

Following collision between the Indian continent and the Kohistan island arc terrane at c. 50 Ma, biotite granite sheets (Confluence granites) were emplaced into the Kohistan batholith at 50–30 Ma, followed by muscovite granite sheets (Parri granites) at c. 26 Ma. These are geochemically distinct, with the Confluence granites comprising a range of granitic compositions with high Sr and Ba abundances and the Parri granites forming granite sheets enriched in Rb. Undeformed granites in both suites have ($^{87}\text{Sr}/^{86}\text{Sr}$)_i in the range 0.7045–0.7054 and $\epsilon\text{Nd}(\text{T})$ of +0.1

to +2.7, suggesting that both groups may be derived from juvenile arc sources. Detailed structural studies verify that the Kohistan granite sheets postdate the initial collision of the Kohistan terrane with the Indian continent, but are pre- or syntectonic with respect to continued underthrusting of the Indian continent below the Kohistan arc. These results, together with isotopic evidence from the undeformed granite sheets, suggest that significant underthrusting of northern Kohistan by the Indian continental crust could not have occurred until after 26 Ma.

Along the western margin of the NPHM, deformed granite sheets show a marked increase in $(^{87}\text{Sr}/^{86}\text{Sr})_i$ (0.7075–0.7784), with decreased $\epsilon\text{Nd}(T)$ (–13 to –26). These trends are thought to be due to a combination of sub-solidus fluid infiltration and assimilation of crustal material, with fluids or material derived from the adjacent, isotopically evolved NPHM crust.

The NPHM (Indian continent) has been intruded by a series of tourmaline leucogranite dykes and plutons at 2–12 Ma. These intrusives have trace-element signatures consistent with generation by vapour-absent melting of a pelitic source. Sr-Nd isotope systematics indicate derivation from metasediments such as are currently exposed in the basement rocks of the massif, although melting at the present exposure level is generally precluded by subsolidus metamorphic grades in the country rock. Extreme heterogeneities in radiogenic Sr ($(^{87}\text{Sr}/^{86}\text{Sr})_i > 0.9$) are observed in leucogranite dykes from the Liachar thrust zone, probably indicating subsolidus fluid infiltration. In general the NPHM leucogranites result from rapid exhumation of metasediments characterised by unusually high heat productivity.

Key words: Geochronology, Tectonics, Magmatism, NPHM, MMT.

G/92. George, M.T., Harris, N.W.B. & Keynes, M., 1992. Granite Magmatism and Thermochronology across the Main Mantle Thrust, NW Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 32.

In NW Pakistan, the Kohistan Arc is separated from the west margin of the Nanga Parbat Massif (NPM) by a major ductile shear zone. Interpretation of assemblages and structures from either side of this suture suggest contrasting thermal and magmatic histories that help constrain the regional tectonic evolution.

Metamorphic assemblages from the arc record lower amphibolite facies conditions of 500–600°C and 5–7 Kb. Garnets from the arc show strong compositional zoning with X_{Ca} increasing and X_{Mg}/X_{Mg+Fe} decreasing towards the rims, suggesting garnet growth during increasing pressure but decreasing temperature. In contrast, the Precambrian ortho and paragneisses of the NPM lie in the upper amphibolite facies (kyanite grade) and show peak conditions of metamorphism of 600–700°C and 7–8 Kb. Most garnets are unzoned. Mineral growth cannot be directly correlated with thrust tectonics associated with the Main Mantle Thrust.

Lithologies from both terranes are imbricated in a steeply inclined ductile shear zone which operated at lower amphibolite facies conditions. Mineral stretching lineations on the foliation plunge steeply to the NW and shear-sense indicators suggest a dextral-normal movement, presumably related to the post-tectonic uplift of the NPM. This movement has steepened and overprinted earlier fabrics related to underthrusting of the Indian plate beneath the arc. The youngest magmatic rocks in the arc are cross-cutting granite sheets with a poorly constrained age of 20–50 Ma (1). These sheets can be divided into early biotite granites, which are cross-cut by younger muscovite-garnet-sheets, each type characterized by a distinct trace element and isotope geochemistry. Since both suites are strongly deformed in the shear zone, these granite sheets place an important constraint on the age of shearing. The timing of deformation is being further constrained by ongoing laser Ar-Ar microstructural studies of hornblende within the zone.

The NPM basement is intruded by dykes and sheets of leucogranite. A substantial two-mica body (the Jutial leucogranite) cross-cuts the regional fabric of the NPM and is being studied in more detail. Trace element and highly radiogenic ^{87}Sr – ^{86}Sr (0.874–0.891) indicate an origin by crustal melting of NPM basement rocks. Elsewhere in the NPM, the cross-cutting musc-tourm.(±bi) leucogranite sheets, dated at 2.3–7 Ma (2), show a comparable but more scattered trace element and isotopic composition ($^{87}\text{Sr}/^{86}\text{Sr}$ 10.806–1.061) and probably share the same source.

NPM basement rocks have wide-ranging $(^{87}\text{Sr}/^{86}\text{Sr})_i$ of 0.786–0.963, and variable trace element compositions. The metamorphic grade of these suggest that melting occurred at deeper levels in the NPM than those currently exposed. The heterogeneous isotopic compositions are a common feature of Himalayan leucogranites and reflect a variable source, poor magma mixing or late fluid circulation. In addition to its unusually radiogenic Sr-isotope composition, the Jutial granite contains high concentrations of Th (22 ± 9 ppm) compared to other Himalayan leucogranites, a feature which may have contributed to the thermal budget that caused crustal melting.

The thermochronology of the granites in both the arc and the NPM relative to their country rocks is being investigated by both Rb-Sr dating of micas and laser Ar-Ar dating of micas and amphiboles, in order to constrain the time of granite emplacement and the post-magmatic thermal and tectonic evolution of the region.

G/93. George, M.T., & Reddy, S.M., 1994. Differential unroofing and inherited radiogenic strontium in the Western Himalaya. *Mineralogical Magazine*, 58A, 325-326.

In the western Himalaya, the Nanga Parbat- Haramosh massif (NPHM; Indian continental crust) has been differentially exhumed relative to the adjacent Kohistan island arc terrane (Zeitler 1985). This study aims to constrain the detailed cooling history of the region by using both Rb-Sr and laser probe $^{40}\text{Ar}/^{39}\text{Ar}$ dating of muscovite and biotite from closely-spaced samples. Such a study should also help to evaluate the resolution of mineral ages in determining cooling rates in regions of rapid exhumation. Samples dated include granite sheets and their metamorphic country rocks, and come from the NPHM, the Kohistan arc, and from the intervening steeply dipping, high-grade shear zone.

Key words: Exhumation, NPHM, Kohistan island arc, Chronology.

G/94. George, M.T., Reddy, S.M. & Harris, N.W.B., 1995. Isotopic constraints on the cooling history of the Nanga Parbat-Haramosh massif and Kohistan Arc, Western Himalaya. *Tectonic* 14, 237-252.

Nineteen $^{40}\text{Ar}/^{39}\text{Ar}$ and 22 Rb-Sr mineral ages are presented for metamorphic rocks and granites collected from the northern part of the Nanga Parbat-Haramosh Massif (NPHM) and adjacent parts of the Kohistan arc, western Himalaya. The majority of these ages are interpreted as exhumation-related cooling ages, and they therefore place important constraints on the exhumation history of the region. The $^{40}\text{Ar}/^{39}\text{Ar}$ and Rb-Sr mica cooling ages for areas of the NPHM to the north of the Indus River lie in the range 2–8 Ma and are similar to previously published ages from the Indus gorge itself. Cooling histories for these areas show little systematic variation from east to west, suggesting that the basement may have been exhumed as a relatively rigid block, after the main stages of folding. Mica ages increase dramatically from the NPHM westward into the Kohistan arc, where ages lie in the range 13–30 Ma. The contrast in both cooling ages and the age differential between mineral pairs between the two terranes indicates rapid cooling of the NPHM in the last 10 m.y. compared with the Kohistan arc. The relationship between rates of cooling and exhumation is poorly constrained in regions of rapid uplift, where the characteristics of the evolving geotherm are not well understood. However, the results are consistent with an anomalously rapid exhumation history of the NPHM during the last 10 m.y. compared with the adjacent Kohistan arc. The interpretation of some of the ages documented in this study is problematical. Two biotite samples from contrasting lithologies within the NPHM have yielded higher $^{87}\text{Sr}/^{86}\text{Sr}$ ratios than the corresponding whole rocks, but the cause of this isotopic disequilibrium remains unclear. Other biotite samples from the region have consistently yielded younger Rb-Sr ages than $^{40}\text{Ar}/^{39}\text{Ar}$ ages, which may be a reflection of either preferential leaching of ^{87}Sr during fluid infiltration on a regional scale or the presence of excess argon. Alternatively, the relative ages indicate slightly lower closure temperature for strontium diffusion in biotite than for argon diffusion in biotite where samples have undergone rapid cooling.

G/96. Ghani, A. & Nasreen, S., 1990. Ultramafic decorative stones of N.W.F.P. and adjoining areas. Abstracts, First SEGMITE Conference on Industrial Minerals, Peshawar, p.7.

Decorative stones of ultramafic composition in different shades of green occur in various parts of the province and adjacent areas such as Malakand and Mohmand agencies [also Waziristan]. These include rodingite and serpentine.

Internationally, such ultramafic stones are replacing marble (the most widely used decorative stones) due to better colour, hardness, lower porosity, etc.

Key words: Decorative stones, serpentinite, Malakand, Mohmand, Alpuri.

Good quality talc occurs in the Juragh area of district Swat. The deposits lie in the western part of the suture (Lesser Himalayas, exposed in Pakistan) of the Indo-Pak plate in tectonic interaction with Eurasia in the north. The deposits are developed by secondary processes undertaken by the action of hydrothermal solutions on metamorphosed calcareous sediments and impure marbles as well as retrogression during the Himalayan Orogeny. The talc is suitable for utilization in a range of industries, including sensitive ones like automobile, pharmaceuticals, electroceramics and glazes etc.

Yasin Group of metasedimentary rocks lies on the northern extremity of Kohistan Island Arc. F1 (minor folds), F2 (upright fold), F3 (intrafolial and kink folds), F4 (minor folds) and F5 (crenulation observed in oriented hand specimens) are the type of folds that can be studied in addition of slickensides, veins, dykes, foliation, lineation and shear zones. Average trend of dominant axial plane foliation of F2 folds is WNW and the inclination is almost vertical. Veins of different age and origin had been of substantial help in this study. The most recent deposit travertine probably relates to a major fault.

The southern belt of Paleozoic strata of Attock-Cherat Range comprising of limestone, argillite and quartzite, constitutes a major overturned south-verging fold. The southern limb of this fold is truncated by north dipping Hissartang thrust, which is the part of late, Tertiary imbricate thrust system in this area. This fault has emplaced the Paleozoic rocks of Attock-Cherat Range over the Mesozoic sequence of Kala-Chitta Range. From the town Nizampur in the east, the Hissartang fault runs at the foot of Attock-Cherat Range but near the Indus River it swings northeast and a low-angle Hissartang backthrust appears. The tectonically emplaced patches of Jurassic limestone over the Paleozoic rocks of Attock-Cherat Range are quite common east of Indus. The emplacement of Jurassic limestone over the Paleozoic rocks is the result of back thrusting of Hissartang thrust. The north dipping listric normal faults marks the late extensional phase in the area.

Key Words: Structure, tectonics, Paleozoic, Attock-Cherat Range.

G/106. Ghauri, A.A.K., Rehman, O. & Rehman, S., 1983. A new structural model of the southern slopes of Kohat pass, District Kohat, NWFP, Pakistan. Geological Bulletin, University of Peshawar 16, 97-104.

The Darra Adam Khel area has been affected by at least three phases of deformation from Cretaceous onwards. The central block was elevated by an early Cenozoic revolution and has since remained a positive area. Miocene rocks were deposited in linear depressions towards north and south of the block. A central problem in this area is north-verging folds that are anomalous to the regional structural pattern.

The chain of repetitions of Samana Suk and Chichali Formation towards the southern part of the area are neither due to tight folding nor repeated fault slicing, as is generally believed. Instead, there are relatively small, open and somewhat overturned folds developed within the southernmost limb of the main fold, during the last deformational episode, with Chichali Formation being preserved in the synclinal troughs only.

G/110. Ghazanfer, M., Baig, S. & Chaudhry, M.N., 1983. Geology of Tithwal Kel area Neelum valley, Azad Jammu and Kashmir. *Kashmir Journal of Geology* 1, 1-10.

More than three hundred and eighty five square km area between Tithwal and Kel in the Neelum Valley on the right bank of river Neelum has been mapped for the first time. However, of the section between Doarian and Kel only a reconnaissance sketch was prepared. A detailed description and a preliminary petrography of rock unit between Tithwal and Kel is presented. The rocks between Tithwal and Loat comprise a psammatic-pelitic sequence which resemble the Tanol Formation as found further north in Neelum Valley, north of Jared in Kaghan and elsewhere in the region. The rocks found in the vicinity of Authmuqam have also been considered as part of same psammite pelitic sequence and not Dogra Slates as proposed by Wadia (1928). The extensive pelitic-calcareous sequence found north of Loat has been named as Sharda Group. We suggest the term Sharda Group should be replace the term Salkhala Formation as type of rocks described in literature as Salkhala Formation are nowhere to be found around Salkhala village. Three different granite batholiths have been described. The two southern one Jura and Neelum granites are possibly Tertiary while the Kel granite in the north is Palaeozoic or older. The whole sequence of country rock has been regionally metamorphosed. Very broadly speaking the grade of metamorphism increases from south to north (biotite grade at Authmuqam and kyanite grade at Gamot). Two major structures have been detected. The major synclinal structure in the south has been called Salkhala syncline and the major anticlinal structure in the north has been called as the Kel anticline. The Neelum granite appears to be post-tectonic while the Kel granite is pre-tectonic.

Detailed mapping and field relationships of the rocks in Paras-Jared-Sharan area in Kaghan Valley have revealed the presence of an ophiolite-arc derived metasedimentary suit of Palaeozoic age. The ophiolite-sequence is represented by basic lavas of Panjal Trap abundant between the villages of Malakand and Shinu on the Kaghan valley roadside. North and east of the ophiolite sequence a sedimentary-volcanic sequence is represented by agglomeratic slates and arc derived metasediments. The likely age of this sequence of Hazara-Kashmir Syntaxis is between Devonian and Triassic. The sequence continues around the syntaxis, the eastern limb extending over the Kaghan ridge across Neelum Valley and beyond and the western limb turning south of Nadi Bungalow to Balakot and further south and southwest.

G/114. Ghazanfar, M. & Chaudhry, M.N., 1985b. Geology of Bhunja-Batakundi area, Kaghan Valley, District Mansehra, Pakistan. *Geological Bulletin, Punjab University* 20, 76-105.

The part of Kaghan Valley between Mahandari and Batakundi has been geologically surveyed and mapped, at 1:17,000 for the first time. Besides a detailed field description of rock units, brief description of structure and comments on metamorphism, stratigraphic correlation and geomorphology are included. The rocks range from limestones, greenstones, tillites. Pelites, calcareous pelites to psammities in the biotite to silliminite grade. Some locally produced granites and a beautifully developed migmatite unit are also present. Stratigraphically the sequence becomes older towards north. A tentative correlation of the rock units has been attempted with Panjal series, Tanol Formation, Hazara slates and Precambrian Sharda Group (Salkhalas) successively to the north. Major structures consist of a number of asymmetric and at places, overturned folds separated in the form of blocks by high angle north dipping thrusts. Graphite, gypsum and marble are potential economic deposits.
