G/115. Ghazanfar, M. & Chaudhry, M.N., 1986. Reporting MCT in northwest Himalaya, Pakistan. *Geological Bulletin, Punjab University* 21, 10-18.

Work in Neelum valley, Azad Kashmir and Kaghan valley has now made it possible to locate the Main Central Thrust (MCT) in northwest Himalaya. Geological mapping and investigations in the two valleys indicate that the MCT extends in a NE-SW direction between Luat in Neelum valley and Batal (south of Naran) in Kaghan valley crossing the Kaghan watershed near Thod Bhaik. There is a marked difference in the tectonic style, stratigraphy and metamorphism north and south of this line. This difference compares well with that reported from India. This discovery of MCT in Pakistan now, for the first time, enables us to compare and tentatively extend the tectonic zones of Central Himalaya in India into northwest Himalaya in Pakistan.

Key words: Structure, Maps, MCT, Himalaya.

G/117. Ghazanfar, M. & Chaudhry, M.N., 1996a. The Tethys Himalaya of Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 49-50.

Of the four major tectonic subdivisions of the Himalaya, the two northern ones, the Higher Himalaya Crystalline (HHC) and the Tethyan Himalaya, were neither identified nor delineated in Northwest Himalaya of Pakistan until quit recently. The demarcation of MCT in Pakistan and Azad Kashmir (Ghazanfar & Chaudhry, 1986) finally settled the character and boundary of the HHC in Pakistan. This work aims at defining and setting limits and presenting a map of the Tethyan Himalaya in Pakistan.

To the south of Indus Suture in Pakistan a belt of low grade sediments extends all along from Babusar Pass in the east to Swat in the west of these sediments have been largely ignored in the tectonic setting of the NW Himalaya. These were first mapped and described from near Babusar and later westwards to Ledi grade rocks of Banna, Allai, and Swat. In Swat low grade rocks have been described from a number of locations including Sassoi, Karora and Mingora. The presence of these rocks at the head of the high grade HHC terrain below the MMT has been variously explained as a back thrust slice of the Cambrian Abbottabad Formation which occurs far to the south (Coward et al., 1988) or as retrogressed part of the high grade upper Kaghan metasediments which were considered Permo-Triassic (Greco et al. 1989; Spencer, 1993).

These workers thus considered the high grade gneisses of the Burawai Group of the Higher Himalaya of Upper Kaghan as the Tethys Himalaya. Such a suggestion remains highly debatable. The huge Burawai group everywhere in Kaghan and Swat is in the kyanite-sillimanite grade and is an integral part of the HHC. Field observations disprove both the back thrust as well as the retrogression hypothesis.

As opposed to this Chaudhry and Ghazanfar (1992) suggested that the only Tethyan sequence were the low grade metasediments exposed along the MMT north of the HHC. Low grade sediments below MMT were first described from Upper Kaghan by Chaudhry and Ghazanfar in 1987 where they were named as the calcareous Bachh Formation and the graphitic Richpar Formation.

Low grade metasediments are also exposed further west south of the MMT in Banna, Besham and Swat areas. The sequence is best developed in Banna, Allai area east of Besham. Preliminary mapping reveals it can be subdivided into a lower graphitic phyllite (Chiran Formation) an upper thin bedded limestone/ marble (Banna Formation) and an intervening unit comprising intercalations (Palang Formation). The whole sequence is nearly one km thick.

Further west in Swat the low sediments are represented mainly by graphitic pelites which have been called Dargai Formation (Saidu Formation). Structurally they form synclinal inliers with a faulted base.

Geological mapping has revealed that the much attenuated sequence of Upper Kaghan more or less physically continues into the Banna area. Although the units are very thin in Upper Kaghan their continuation from Babusar through Lohyalul and Ledi to Dila is remarkable.

In the Karora area of Besham the lithologies are similar to Banna area except that this is the only area where the unit instead of being faulted at the base is underlain by a boulder bed which rest on the high grade slab of HHC.

In the Kashmir Basin the Tethyan sequence discontinuously continues across the HHC to the south. A somewhat similar situation is present in Lower Swat where the Tethyan sequence occurs as synclinal inliers in the high grade terrain and possibly correlates southwards with the low grade basal rocks of the Peshawar Basin.

Although fossils are likely to be present no fossils have been reported anywhere in Pakistan from this suite far and their age is mainly a matter of correlation. Near Besham the Karora Group rocks have been cut some granite bodies which were dated Precambrian by Baig (1990).

G/118. Ghazanfar, M. & Chaudhry, M.N., 1996b. Structure and Tectonic style in Sedimentary Lesser Himalaya, south Hazara, Northern Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 51-52.

The Attock Hazara Fold and Thrust Belt, AHFTB, is mainly a shelf sedimentary sequence extending in east-west direction for some 250 kilometers from Garhi Habibullah in the northeast to Parachinar in the west.

A thick sedimentary sequence ranging in age from Cambrian to Neogene and overlying the slightly metamorphosed Hazara slate is present in the form of arcuate megasynclinalorium which closes into the Hazara Kashmir Syntaxis in the northeast near Garhi Habibullah and complicates to the west. To the north it is separated from an extensive zone of igneous and metamorphic rocks by the Panjal Fault. This is the Main Boundary Thrust, MBT, coming from east in India. The real throw of MBT in Pakistan is distributed along a number of parallel faults passing through this belt, the chief among these being the Nathia Gali Thrust, NGT. The AHFTB is essentially a westward continuation of the parautochthonous fold belt of Pir Panjal Himalaya over the Hazara Kashmir Syntaxis. Important stratigraphic differences in the belt exist from place to place. The stratigraphic sequences of Kashmir, Hazara and Muzaffarabad constitute three different stratigraphic provinces, which juxtapose in the area of Balakot. The AHFTB constitutes the southern sedimentary fringe of the mainly metamorphosed Lesser Himalaya. West of the HKS the metasediments of Mansehra-Oghi area and the Peshawar Basin lie the north of AHFTB. This study pertains to the Abbottabad-Murree section of northeast AHFTB.

Three major phases of deformation are clearly discernible. The first phase D1 is pre-Himalayan when the Hazara slates were metamorphosed. These Precambrian slates are now overlain by a thick shelf sedimentary Phanerozoic

sequence with an angular unconformity at the base. From the metamorphosed clasts of Hazara Formation in the basal Tannaki boulder bed of the overlying Cambrian Abbottabad Formation. This orogeny has been dated Precambrian (Baig et al., 1987; Chaudhry, 1964; Chaudhry et al. 1989). During the Himalayan orogeny the entire sequence underwent two major phases of brittle deformation. The main phase Himalayan deformation, D2, is now represented by the NE-SW outcrop trends of structures. These megafolds are generally overturned and isoclinal and interrupted by numerous dip slip and oblique slip faults. The vergence of these structures is enigmatic. Apart from the southeast vergence major blocks show northwest vergence of both folds and faults. The southeast vergence is clearly explainable as being in line with the Himalayan direction of transport in this area. The northwest vergence, however, has been explained as later overturning and back thrusting (Coward et al. 1988; Ghazanfar et al. 1990) pertaining to a later phase. Large scale geological mapping of this section (this study), however, indicates box folding and fan folding during D2. A number of normal faults were formed following relaxation of stress. The final Himalayan phase of deformation D3 relates to the formation of Hazara Kashmir Syntaxis, HKS, and a major re-entrant of the Northwest Himalaya. The NE-SE trend of syntaxial phase of folds is at right angles to the NE-SW trends of D2 structures. These folds are generally intraformational and only faintly seen on the map scale where they generally appear as broad flexures and broad bends. Many of these folds are SW vergent and are not accompanied by related faults.

G/119. Ghazanfar, M., Chaudhry, M.N. & Hussain, M.S., 1991. Geology and petrotectonics of southeast Kohistan, Northwest Himalaya, Pakistan. *Kashmir Journal of Geology* 8 & 9, 67-97.

About 2200 km² of southeast Kohistan has been geologically mapped and the stratigraphy of the area established. A possible sequence of events has been listed. Detailed field relations and lithologic descriptions of many units have been reported for the first time. The predominantly plutonic arc set represents a relatively older much-eroded terrane where volcanic cover stands largely removed. The relatively smaller volcano-hypabyssal suite appears to be the latest magmatic event. Most of the amphibolite mass, tholeiitic greenstones and ultramafics represent obducted masses and shreds of oceanic affinities. The hanging wall sole rocks of MMT as well as foot wall rocks along minor syntaxis do contain deeper level obducted slices and shreds of eclogites and high-pressure granulites.

The Chilas norite complex is sandwiched between northern and southern arc masses. The field and petrographic data suggest that the Chilas norite complex appear to have been formed under a spreading center. The MMT suture zone ultramafics are divided into part cumulate and part mantle tectonic. The carbonaceous-argillaceous, argillaceous and calc-pelitic phyllites and associated low-grade carbonates represent Tethyan shelf sediments, sandwiched between the Higher Himalaya and southern suture ophiolites.

Structurally the area is characterized by a number of northwest dipping high-angle imbricate thrusts, which converge into and are terminated by the Raikot fault in the east. Polyphase folding is seen in the Kamila amphibolites while the norites appear to have been folded into tight isoclinal antiform.

Detailed geologic mapping of Kuza Gali - Dunga Gali - Ayubia area has been carried out at a scale 1:9560. Lithostratigraphy, structure and regional geology of the area has been discussed and described in relation to the larger tectonic framework. Stratigraphically the area shows exposures of rock units from Middle Jurassic to Eocene and belongs to the so-called Kohat-Potwar Basin. The overall structure is an anticlinorium bounded by the two synclinoria to its north and south. The whole being a small section of the Attock Hazara fold and Thrust belt of Pakistan.

This paper is a first time attempt at systematizing the stratigraphy between the Main Boundary Thrust (MBT) and the southern Suture zone (SSZ) as exposed in Kaghan valley. The sequence in the Kaghan valley between Para and Naran is mainly inverted and becomes successively older towards the north. From south to north the rocks may be subdivided into three main groups: 1) the Kashmir sequence, Mid-Paleozoic to Miocene, which represents, by and large, tectono-stratigraphy of the Pir Panjal (Kashmir) to the east; (2) the Kaghan Group, possibly Late Proterozoic, which occurs between Mahandri and Naran; and 3) the Sharda Group, possibly Archean to Mid-Proterozoic, which occurs north of Naran and represents a continuation of the Higher Himalaya to the east. The Kaghan valley section also traverses important tectonic scars, including from south to north the Murree Fault, the Panjal Fault, the Main Central Thrust (MCT) and the Main Mantle Thrust (MMT).

G/127. Ghazanfar, M., Chaudhry, M.N. & Spencer, D.A., 1995. The geological character and problems of Lesser Himalaya in Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

With the delineation of the Main Central Thrust (MCT) in the Northwest Himalaya of Azad Kashmir and Pakistan, the Lesser Himalaya slab can now be defined. The Lesser Himalaya of Pakistan and Kashmir is divided into a northern metamorphic zone and a southern sedimentary zone. The northern metamorphic zone is represented by the mutually analogous Kashmir Basin in the east and the Peshawar Basin in the west separated by Kaghan and Northern Hazara in between. Whilst the Lesser Himalaya of Kashmir and Peshawar basins are characterized by simple fold structures, the intervening Kaghan and Northern Hazara are marked by schuppen structures. The Kashmir and Peshawar basins are limited to the south by the sedimentary zones of Pir Panjal in the east and the Attock Hazara Fold and Thrust Belt in the west. Both these sedimentary belts are again marked by numerous closely spaced ramp faults. In the area of Balakot these two zones along with the sedimentary sequences of Muzaffarabad comprise three stratigraphic provinces on the boundary of Hazara and Kashmir. Southeast Hazara is characterised by a four phase sequence of deformation. The first phase is Pan-African while the other three phases are Himalayan in age. The earliest Himalayan phase of deformation is marked by south verging folds and thrusts, the second by north verging structures and finally the third by open north-south cross folds related to the formation of HKS. Evidence of pre-Himalayan metamorphism is now well documented in the Lesser Himalaya of Pakistan. The pre-Himalayan phases start in the Proterozoic and end in the Hercynian. The Tanol-Tanawal controversy, regarding the age and correlation of these formations in Kashmir and Hazara, can now be finally settled. The Tanawals of Kashmir are Devonian to Carboniferous while the Tanols of Hazara are Precambrian in age and are older than the Hazara slate to which they have always been considered younger.

Key words: Geology, metamorphism, MCT, Himalaya.

G/128. Ghazanfar, M., Chaudhry, M.N. & Spencer, D.A., 1999. The geological character and problems of the Lesser Himalaya in NE Pakistan. Geological Bulletin, Punjab University 33 & 34, 9-42.

With the delineation of the Main Central Thrust in the Northwest Himalaya of Azad Kashmir and Pakistan, the Lesser Himalayan slab stands defined. The Lesser Himalaya of Pakistan and Kashmir are divided into a Northern Metamorphic Zone and a Southern Sedimentary Zone. The Northern Metamorphic Zone is overlain by the Peshawar Basin in the west of Pakistan and also includes Northern Hazara and the middle parts of Kaghan and Neelum valleys to the east.

Whilst the Kashmir and Peshawar Basins are characterized by a Tethyan stratigraphic sequence deformed by simple folding, the intervening middle Kaghan and Northern Hazara areas are highly deformed schuppen structures on the limbs of the Hazara-Kashmir Syntaxis. The Kashmir and Peshawar Basins are limited to the south by the sedimentary zones of the Pir Panjal in the east and the Attock-Hazara Fold-and-Thrust Belt in the west. Both these sedimentary belts are marked by numerous closely spaced ramp faults. The Attock-Hazara Fold-and-Thrust Belt is marked by a polyphase sequence of deformation. At least one phase is Precambrian. The occurrence of Pre-Himalayan/Pre-Cambrian metamorphism in the Lesser Himalaya is now well established. The Himalayan overprint is missing or at best limited. The Tanol-Tanawal controversy regarding age and correlation of these formations in Kashmir and Hazara is discussed and it is here suggested that among the Pre-cambrian formations the Tanawals of Hazara are in fact older than the Hazara slates.

G/129. Ghazanfar, M., Chaudhry, M.N., Spencer, D.A., Hussain, S.S. & Dawood, H., 1999. The nature and problems of the Tethyan Himalaya in Pakistan and western Kashmir. Geological Bulletin, Punjab University 33 & 34, 43-69.

This paper aims to define, describe and discuss the occurrence of the tectonic subdivision of the Tethyan Himalaya in northern Pakistan and western Kashmir. With the demarcation of the Main Central Thrust in the Neelum and Kaghan valleys (western Kashmir and Pakistan), the Higher Himalaya and the Lesser Himalaya have now been differentiated in these areas. In the NW Himalaya, two domains of the Tethyan sedimentary rocks have been

recognised, both north and south of the Main Central Thrust. To the south, the Lesser Himalaya in Pakistan and Kashmir is overlain by a sedimentary sequence of Tethyan affinity. The relationship of this Southern Tethyan Sequence, incorporated as part of the Lesser Himalaya, is interpreted to be analogous to that of the cover sediments in Kashmir and the autochthonous fold belt of Pir Panjal. To the north of the Higher Himalaya and directly underneath of the Indus Suture, the 'Northern Tethyan Sequence' possibly consists of low grade sediments which are found in Upper Kaghan, Banna, Karapa and Lower Swat. These sediments can be interpreted to be analogous to the Tethyan Himalaya. Other interpretations of these sediments (i.e., their suture zone affiliation) are also discussed. Finally, the high grade metasedimentary cover of Higher Himalaya is also regarded as being the equivalent of the Tethyan Himalaya in the 'Northern Tethyan Sequence'. The role and significance of these Tethyan sequences, in the subdivision terminology of the Himalaya, is assessed with the other known subdivisions of the Pakistani Himalaya and western Kashmir.

G/130. Ghazanfar, M., Chaudhry, M.N., Zaka, K.J. & Baig, M.S., 1986. The geology and structure of Balakot area, District Mansehra, Pakistan. Geological Bulletin, University of Punjab 21, 30-49.

Nearly 65-km² area in the vicinity of Balakot has been mapped at 1:10,000. The stratigraphy and major structures are described and discussed. The stratigraphy of Balakot brings out three separate stratigraphic sequences of rocks east and west of the river Kunhar. A new stratigraphic interpretation of the metamorphics is presented. The small but interesting Bamphora structure is explained. The Muzaffarabad fault is correlated with the Riasi fault and with the Great boundary fault, passing through Potwar. Jhelum fault is the youngest major structure, which has displaced the western limb of the Hazara-Kashmir Syntaxis.

G/133. Ghaznavi, M.I., & Karim, T., 1978a. A note on phosphorite deposits of Lagharban and Kalu-di-Bandi areas, Hazara District, NWFP, Pakistan. Geological Survey of Pakistan, Information Release 103, 31p.

Phosphorite deposits have been discovered in Kalu-di-Bandi and Lagharban areas (toposheet. 43 F/7) of Hazara district. The phosphorite is found in the upper cherty dolomitic part of Abbottabad Formation. The phosphate beds are present along both the western and eastern limbs of an overturned syncline.

The phosphorite zone found in the western limb is more promising because of its quantity. It is lenticular in shape with average thickness of 18 feet and lateral extension 8500 feet. The P₂₀₅ percentage varies from 24 to 31%. The reserves of this zone upto 500 feet dip depth are about 5.00 million tons.

The eastern limb deposit is not as extensive as that of western limb. The phosphate zone has 14 feet average thickness and the lateral extension is about 3500 feet. The P₂₀₅ percentage of this zone is very good and varies from 30 to 38%. The reserves of this zone are about 2.00 million tons.

The total probable estimated reserves of Kalu -di-Bandi area are about 7.00 million tons upto dip depth of 500 feet.

G/134. Ghaznavi, M.I., & Karim, T., 1978b. Phosphorite deposits of Dalola–Daulatmar area, Hazara District, NWFP. Pakistan. Geological Survey of Pakistan, Information Release 104, 31p.

The phosphorite deposits have been discovered in Dalola-Daulatmar areas (toposheet No.43F/7) of Hazara district. The phosphorite is found only in the middle silty beds of Galdanian Formation. Three different phosphorite zones in the same stratigraphic horizon have been discovered in this area. The zone No 1 is 5580 feet long and has 28 feet average thickness. The zone No 2 is 2700 feet long with 48 feet average thickness. While the third zone No 3 is further divided into A and B with 3630 feet and 2300 feet respective lengths. The average thickness of former is 29 feet and of later 18 feet. The P205 percentage varies from zone to zone and within the same zone. The best and richest zone is No 2 and the poorest is zone No 3. The P205 percentage of phosphorite deposits of this area varies from 8 to 39%. On the whole the phosphate is low grade and needs beneficiation to upgrade. The total probable estimated phosphorite reserves of this area are about 9 million tons upto a dip depth of 300 feet.

The area around Abbottabad contains commercial grade phosphate in several localities. The stratigraphy of the phosphate-bearing units is of great interest. This report documents the position of a major unconformity which can be used to improve stratigraphic correlation and which may shed some light on the genesis of the phosphate beds. The phosphate deposits are contained in stratigraphic sequence comprising the Abbottabad formation, a cherty dolomite; the Hazira formation, a complex unit, mostly silt stone; and the Samana Suk limestone, which is of Jurassic age.

The Shangla Par-Alpurai Area is composed mainly of schist and phyllites containing volcanics at some horizons. These rocks were originally deposited in eugeosynclinal conditions or argillaceous sediments and have subsequently been metamorphosed to schists and Phyllis. These rocks are probably Cambrian in age. They have been intruded by the ophiolites, which have now been metamorphosed to amphibolites. These are the southern amphiboles which are ortho in character. Subsequently the area has been strongly folded and intruded by Basi granite and then by the ultramafic body. This body was originally a complex peridotite-pyroxenite-amphibole-pyroxene etc. rock which has been altered first to serpentinite and then further metasomatised at places to talc-carbonate rock. The area lies on the Northwestern Limb of the syntaxis and therefore, the prominent strike is NW+SW. Almost all major contacts are faulted. The folding pattern is isoclinal.

The project area covers about 307 square kilometers, located between Reshian and Jura to the ESE and NE of Muzaffarabad, Azad Kashmir. The work has involved geological mapping of the area on a scale of 1:25,000. In this thesis an attempt has been made to introduce the detailed geology of the area. Bulk geological sequence of the area consists of sedimentary, volcanic, metamorphic and granitic rocks. The area is tectonically, highly disturbed being involved in Himalayan orogeny. Major and minor structures of the area are described with the help of figures and maps. For Petrographic analysis sixty thin sections were studied microscopically. Tectonic setting and stratigraphy of the area are described briefly. Economic rocks and minerals found in the area have been described in detail to some extent.

Key words: Structure, geology, Azad Kashmir.

The area lies in the Pir Panjal Range of the lesser Himalaya, a pre Cambrian to late Paleozoic sequence of the Northern margin of Gondwana is imbricated by NE dipping thrust faults. The major thrust faults from south to north are the Murree thrust and the Panjal thrust. The former emplaces the late Paleozoic Panjal formation on to the Oligocene to Miocene molasses of the Murree formation. The Panjal thrust emplaces the Precambrian tanol formation and early Paleozoic granitoids on to the Panjal formation. Petrography of the rocks is given and comments are made on regional metamorphism,

G/143. Gill, W.D., 1951. The tectonics of the Sub-Himalayan fault zone in the northern Potwar region and in the Kangra district of Punjab. Quarterly Journal Geological Society of London 107, 112-121.

The paper defines three major zones of deformation across the Nimadric (Tertiary freshwater) geosyncline between the foreland and the autochthonous folded belt in the North-West Himalaya:-

- (1) A zone of open folding, affected to a varying degree by fold-faulting.
- (2) A fault zone, displaying a number of reversed faults of steep northerly hade and great lateral extent with open folds between them in the west and, in places, gently dipping monoclines in the east.
- (3) A zone with closely spaced strike-faults and severely compressed folds, referred to in the Potwar area as the isoclinal zone, terminating at the main boundary fault which forms the general northern limit of Nimadric rocks.

This succession of structural zones has a superficial resemblance to progressive deformation of the Jura type towards the nappe zone, and previous workers have regarded the tectonic pattern as reflecting tangential pressures from the north.

The author seeks to demonstrate that such an interpretation is denied by the evidence of the structures themselves. Two areas are chosen to illustrate in adequate detail the tectonics of all three zones, and in particular the crucial fault zone. In the west, the Jhamat-Khushalgar area of western Potwar typifies the fault zone of the area between the Indus and the Jhelum rivers. In this area there is clear evidence of the steep hade of the great strike-faults at the surface, and also important evidence of their continued steep hade in depth from the results of boreholes drilled by the Attock Oil Company. Analysis of the relationship of the faults to the fold structures leads to the conclusion that

the faults have no genetic relationship to the fold axes. They are considered to be fractures due to shearing stresses principally with a vertical orientation, whilst the folding reflects the subsidiary compressive force. The Nadaun Dun area of Kangra district is some 200 miles to the southeast of the Potwar area, but lies across similar structural zones and typifies the relationships of the anticlinal zone and the fault zone in the region east of the Jhelum River. In this area the Gumber fault is seen to present all the features of the great strike-faults of the fault zone in the Potwar and is an upthrust structure produced by quasi-vertical movement. A feature not present in the Potwar is the marked contrast between the gently dipping monocline to the north of the fault and the strongly folded country to the south, providing a clearer distinction between the influence of tangential and vertical forces. It appears that the fault movement provided a block-line against which tangential forces from the south were directed. Important evidence of tangential pressure from the south is provided by the Barsa fault, which typifies the most common form of fold-fault in the anticlinal zone throughout the region. Gravity collapse structures are recorded in the form of severely overturned "flaps" of sandstone on the south side of the Sola Singhi ridge.

G/144. Gill, W.D., 1952. The stratigraphy of the Siwalik series northern Potwar, Punjab, Pakistan. *Quarterly Journal of the Geological Society of London* 107, 375-394.

Detailed mapping of the Jhamat area in the west and of the Soan syncline in the east forms the basis of revision of the stratigraphy of the Siwalik Series in the northern Potwar region. The succession is here affected by facies changes of regional significance: -

1. Near the Indus River the uppermost 3000 feet of the Middle Siwalik sequence (Upper Nagri and Dhok Pathan stages) contain thick beds of conglomerate which die out eastwards and south-eastwards into sandstones and clays. Farther eastwards, across the Soan syncline, a clay facies develops at progressively lower horizons in the Nagri Stage, replacing a considerable portion of the massive sandstones of the type area. The facies change is accompanied by a reduction in thickness. The facies variation in the Middle Siwalik rocks is indicative of a channel environment in the west at Jhamat, clearly coinciding with the line of the present Indus River and grading eastwards into deposits of "flood plain" type.

2. The Lower Siwalik rocks show a development of coarser facies in the opposite direction to that noted in the Middle Siwalik. At the eastern end of the Soan syncline the lowest 1500 feet of the Chinji Stage, which in the west is almost entirely of clay-shale facies, contain thick beds of hard sandstone and the sequence is very similar to that of the underlying Kamli Stage.

In the Soan area, the complete Siwalik succession from the Kamli Stage to the Pinjor Stage (Villafranchian) is free from any marked unconformities but is overlain with strong unconformity by post-Siwalik Pleistocene beds—the Lei Conglomerates. This interpretation differs greatly from that of de Terra (1936, 1939), who placed the first great unconformity of the area at the base of the Tatrot Stage. The revision explains Pilgrim's reluctance to include the Villafranchian in the Pleistocene, since in the Indian Siwalik belt this stage forms the highest member of a conformable succession which was intensely folded and subjected to peneplanation before the next deposition took place. The decision at the International Congress in 1948 to adopt the Villafranchian as the base of the Pleistocene places the Siwalik phase of Himalayan orogenesis within the Pleistocene System.

G/146. Gingerich, P.D., 1977. A small collection of fossil vertebrates from the middle Eocene Kuldana and Kohat Formations of Punjab (Pakistan). *Contributions from the Museum of Paleontology, University of Michigan* 24(18), 190-203.

1975 the author made a new collection of fossil vertebrates from the Middle Eocene Kuldana and Kohat Formations in the Kala Chitta mountains of the Punjab Province in Pakistan. Vertebrates were found at twelve localities in the

vicinity of Lammidhan and Chharat. All of the identifiable mammals came from Lammidhan. Two additional mammal specimens from Lammidhan in the British Museum (Natural History) are also described and illustrated for the first time. It is suggested that Gandakasia may be a primitive cetacean rather than a mesonychid condylarth. The new artiodactyl genus Lammidhanina is proposed for the anthracothere species 'Anthracobune' wardi Pilgrim, 1940. Discovery of a small concentration of mammal specimens at one locality suggests that there is very good potential for the discovery of additional middle Eocene mammals in the Kuldana Formation and its lateral equivalents.

Key words: Vertebrates, Eocene, Kuldana Formation, Kohat Formation.

G/147. Gingerich, P.D. & Gunnell, G.F., 1995. Rates of evolution in Paleocene mammals of the Clarks Fork Basin of Wyoming, and a comparison with the Neogene Siwalik lineages of Pakistan. *Palaeogeography, Palaeoclimatology, Palaeoecology* 115, 227-247.

Rates of size change are quantified in 19 species-level evolutionary lineages of Clarks Fork Basin Paleocene and early Eocene mammals. Intrinsic rates of change in Clarks Fork Basin lineages range from about $10^{-0.1}$ to $10^{-3.4}$ haldanes (standard deviations per generation), with a median rate of about $10^{-1.1}$ haldanes. These values are in the usual range of intrinsic rates commonly seen in other settings. Temporal scaling slopes indicate that seven of the 19 Clarks Fork Basin lineages were stable over time (37%), five were stable with a random component (26%), four were indistinguishable from random (21%), two were directional with a random component (11%), and one lineage cannot be classified. Clarks Fork Basin mammalian species have mean durations of about 0.95 m.y. and median durations of about 0.76 m.y. Intrinsic rates of size change are similar to those for Miocene Siwalik mammals, but the average species duration is less than one-half the average for Siwalik mammals.

G/148. Gingerich, P.D., Raza, S.M., Arif, M., Anwar, M. & Zhou, X., 1994. New whale from the Eocene of Pakistan and the origin of cetacean swimming. *Nature*, 368, 844-847.

Modern whales (order Cetacea) are marine mammals that evolved from a land-mammal ancestor, probably a cursorial Palaeocene–Eocene mesonychid. Living whales are streamlined, lack external hind limbs, and all swim by dorsoventral oscillation of a heavily muscled tail. A streamlined rigid body minimizes resistance, while thrust is provided by a lunate horizontal fluke attached to the tail at a narrow base or pedicle. We describe here a new 46–47-million-year-old archaeocete intermediate between land mammals and later whales. It has short cervical vertebrae, a reduced femur, and the flexible sacrum, robust tail and high neural spines on lumbar and caudal vertebrae required for dorsoventral oscillation of a heavily muscled tail. This is the oldest fossil whale described from deep-sea shelf deposits, and it shows that tail swimming evolved early in the history of cetaceans.

Key words: Palaeontology, marine mammals, Eocene.

G/149. Gingerich, P.D. & Russell, D.E., 1981. *Pakicetus inachus*, a new archaeocete (Mammalia, Cetacea) from the early-middle Eocene Kuldana Formation of Kohat (Pakistan). *Contributions from the Museum of Paleontology, University of Michigan*, 25, 235-246.

A new genus and species of primitive protocetid whale, *Pakicetus inachus*, is described from the early-middle Eocene Kuldana Formation at Chorlakkhi, Kohat District, North-West Frontier Province, Pakistan. The holotype is a nearly perfectly preserved posterior portion of a cranium. *Pakicetus* is distinctive among whales in retaining an extremely primitive auditory region. The auditory bulla articulates with the squamosal, basioccipital, and paroccipital in addition to a normal cetacean articulation with the posterior process of the petrotic. The cochlear part of the petrotic articulates with both the squamosal and the basioccipital. Three genera of early-middle Eocene whales are now known from Pakistan. *Pakicetus* is intermediate in size between *Ichthyolestes* and *Gandakasia*, and it resembles both to some degree in dental morphology. "*Protocetus*" *atocki* from Ganda Kas is here referred to *Pakicetus*.

Key words: Paleontology, mammals, Eocene, Kuldana Formation, Kohat.

G/150. Gingerich, P.D. & Russell, D.E., 1990. Dentition of Early Eocene *Pakicetus* (Mammalia, Cetacean). *Contrib. Museum of Paleontology, University of Michigan*, 28(1), 1-20.

Thirty deciduous and permanent teeth of *Pakicetus inachus* are described from Chorlakkhi in Pakistan. Geological sequence stratigraphy indicates that *Pakicetus* is latest early Eocene (latest Ypresian) in age. Incisors of *Pakicetus* are simple high-crowned sharply-pointed teeth. The upper canine may have been double-rooted. Lower canines vary in size and may have been dimorphic. Premolars have simple narrow crowns with coarse serrations on some anterior and posterior crests. Upper molars retain three roots and distinct protocones. Lower molars have simple pyramidal trigonids and narrow trenchant talonids. These teeth are combined in a model based on the type braincase-basiscranium showing that all represent a single species. *Pakicetus inachus* may prove to be a junior synonym of *P. attocki* when the latter is better known, but restudy of contemporary *Ichthyolestes* and *Gandakasia* confirms that these genera are distinct. The three early Eocene genera are placed in a new subfamily Pakicetinae of the Archaeocete family Protocetidae. Teeth of *Pakicetus* have several distinctively archaeocete characteristics. Upper and lower cheek teeth have wear facets on apices of pointed cusps indicating that the lower jaw was retracted when food was punctured. Buccal phase shearing and lingual phase grinding wear facets are also mesent. Deciduous teeth at Chorlakkhi indicate that juveniles and adults were present in approximately equal proportions, suggesting that juveniles, like adults, spent a significant amount of time on land.

G/151. Gingerich, P.D., Russell, D.E., Hurtenberger, J.L., Shah, S.M.I., Hassan, M., Rose, K.D. & Ardrey, R.H., 1979. Reconnaissance survey and vertebrate paleontology of some Paleocene and Eocene formations in Pakistan: Contribution Museum of Paleontology, The University of Michigan, 25(5), 105-116.

In 1977 we spent approximately two months in the field in Pakistan studying three geological formations to assess their potential to yield identifiable fossil mammals. The middle Eocene Domanda Formation was examined at six localities spanning a 100 km distance along the east side of the Sulairnan Range in southwestern Punjab. This formation yielded abundant fish remains, including skulls and skeletons, and some reptilian bone. Mammalian remains included a poorly preserved skull fragment and postcranial elements of cetaceans. Land mammals may also be represented, but they are too poorly preserved to be useful for study. The Domanda Formation appears to be entirely a shallow water marine formation, with little potential to yield land mammals unless localized deltaic facies can be found.

The Paleocene Bara Formation was examined at five localities in the Lakhi Range in Sind. This formation yielded only fragmentary remains of crocodilians and turtles, but the middle part of the formation appears to be fluvial in origin, and with further work it could eventually yield mammals. The early-middle Eocene Kuldana Formation was examined at six localities in Kohat District, North-West Frontier Province. All of these localities yielded reptilian and mammalian bone and tooth fragments, and one locality near Chorlakkhi village yielded a diverse assemblage of mammals. The vertebrate fauna of the Kuldana Formation is becoming increasingly well known in Punjab and Jammu-Kashmir on the east side of the river Indus, and our work indicates that good collections can also be made west of the Indus as much as 100 km west of previously known localities.

G/152. Gingerich, P.D., Russell, D.E., Singogneau-Russell, D. & Hartenberger, J.L., 1979. *Chorlakkia Hassani*, A new middle Eocene Dichobunid (Mammalia Artiodactyla) from the Kuladana Formation of Kohat (Pakistan). Contributions to the Museum of Paleontology, The University of Michigan 25 (6), 117-124.

A new genus and species of artiodactyl, *Chorlakkia Hassani*, is described from the middle Eocene Kuldana Formation in the Kohat District of Pakistan. This is the smallest artiodactyl described from the Paleogene of Asia, and it is one of the smallest artiodactyls yet known. The familial position of *Chorlakkia* is somewhat uncertain, but it appears to belong to the family Dichobunidae (s.l.).

Key words: Vertebrates, Eocene, Kuldana Formation, Kohat.

G/153. Gingerich, P.D. & Sahni, A., 1979. *Indraloris* and *Sivaladapis*: Miocene adapid primates from the Siwaliks of India and Pakistan. Nature 279, 415-416.

The primate family Adapidae underwent a major radiation during the Eocene in Europe and North America. Asian and African Eocene mammalian faunas are still poorly known, but there is sufficient evidence to indicate at least a modest radiation of Eocene adapids in Asia and probably also in Africa. Apart from possible lemuriform and anthropoid primate derivatives, the family Adapidae was thought to have become extinct at the end of the Eocene (middle Tongrian, approximately 37 Myr). We present here new evidence which indicates that at least two genera of adapid primates, *Indraloris* and *Sivaladapis* (gen. nov.), survived into the late Miocene of India and Pakistan. These genera are little advanced over Eocene Adapidae in terms of dental adaptations and are apparently south Asian relicts of a much earlier radiation.

G/155. Glennie, E.A., 1956. Gravity data and crustal warping in Northwest Pakistan and adjacent parts of India. *Royal Astronomical Society, Monthly Notices, Geophysics Supplement* 7(4), 162-175.

Gravity data are used to investigate the geological structure of an area of about 160000 square miles in the light of the crustal warping hypothesis. The region is in N.W. Pakistan and India, and includes the whole of the alluvial plains of Sind and Punjab, the Salt Range and the Potwar Plateau.

A new gravity anomaly is introduced and used by an original method, which leads automatically to the detailed contouring of the basement rock below the region, the basement being assumed to be the upper surface of the Earth's crust. The standard crustal section employed is a two-layer crust with a total thickness of thirty kilometres but a table permits direct comparison with other sections of a six-layer crust, two of which have increased thickness.

The basement contours show a ridge about 300 miles long separating the Indus Basin from the Lahore Basin. It is hidden by alluvium except for a few outcrops near its northern end. This ridge has apparently suffered sub-aerial erosion under typical S.W. monsoon conditions, extending in places to a depth of over 3000 feet below sea level. This modification of the basement requires a revision of the contours over the ridge, and two contoured charts show firstly the simple crustal upwarp underlying the ridge and secondly the eroded surface of the basement. A deep valley with its bottom far below sea level cuts through the ridge connecting the Indus and Lahore Basins. In Sind a similar valley leads from the direction of the sea to the Indus Basin, but here interpretation is uncertain.

It is concluded that the hypothesis yields results giving depths to the basement of the right order in deeply downwarped areas, but in upwarped areas the possibility of erosion, or other concealing factors, leads to uncertainty of interpretation unless the area is wide enough to include a complete section of the upwarp.

G/160. Gohar, A., 1999. Concrete feasibility for the limestone of the Kohat formation, District Kohat. M.Phil. Thesis, University of Peshawar, 99p.

Limestone is a valuable raw material, which is widely used in the chemical and construction industries throughout the world. With huge deposits of limestone in Pakistan, it is immensely used as concrete aggregates. The Eocene limestone of the Kohat Formation is generally exposed in the Kohat, Hangu and Bannu districts. It is cream to gray in color, hard, compact, well-bedded and fossiliferous. The limestone of Kohat Formation has been evaluated mineralogically, chemically and physically, for its use as concrete aggregates during present study.

Mineralogically, the studied limestone is dominantly calcite with abundant fossil shells. Fine-grained quartz, chalcedony, clay, dolomite and opaque phases are present in minor amount. The limestone generally has fine to medium-grained granular mosaic with bioturbated microfossils. Deleterious minerals to concrete are generally foliated in the argillaceous variety of the studied limestone.

Chemically, the studied limestone (by weight) is classified as high-calcium limestone, with CaCO_3 between 81.23 and 98.93%. The SiO_2 varies from 0.50 to 13.90 wt %, Al_2O_3 from 0.47 to 0.74 wt %, Fe_2O_3 from 0.05 to 0.30 wt %, CaO from 46.07 to 57.03 wt %, Na_2O from 0.35 to 0.45 wt % and K_2O from 0.01 to 0.05 wt %. MnO and MgO are up to 0.25 and 2.69 wt %, respectively. The average chemical compositions of various cements manufactured in N.W.F.P. are within the ASTM limits. The alkali-silica reactivity graph for the limestone aggregates based upon ASTM C 289-90 also verify the petrographic observations. Physical properties (i.e., soundness, water absorption, Los Angeles abrasion and specific gravity) are generally in accordance with the ASTM standards for aggregates to be used in concrete. The studied limestone of the Kohat Formation except its argillaceous variety found in the eastern part of the study area, is generally free of dolomitization and has no other deleterious substances as far as the durability of concrete is concerned. This Eocene limestone of the Kohat Formation is therefore, recommended for its use as concrete aggregates.

G/162. Gohar, S.H.U., 1985-87. Lithostructural mapping and geology of Bara Gali-Kunola Area, District Abbottabad, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 95p.

This report gives an account of geological studies and lithostructural mapping carried out in Kuldana-Bara Gali area. The prescribed area lies on both side of the road leading from Murree to Abbottabad. It is a mountaneous region with fairly high relief.

Lithostructural mapping of approximately 20 sq.Km was carried out. The stratigraphic succession ranges from Hazara Formation (pre-Cambrian) to Kuldana Formation (Eocene) with absence of Cambrian to Jurassic rocks. The lithology is mainly limestone, sandstone and shale. Extensive sampling was carried out and micro structural studies along with petrography of the various rock units under the microscope from thin section of certain rock samples was also carried out in the laboratory. A geological map is prepared on a scale of 1:7060 and two cross section (AA' and BB') were also drawn in order to interpret the regional structure and tectonic history of the area. This report also included the brief study of the rock units exposed in the project area. Major structures (folds and faults) lies in the project area are also discussed. Finally there is a general discussion about the source rocks, reservoir rocks (Hydrocarbons) and the economic importance of the rock units present in the project area.

G/165. Gormov, A.V. & Zeb, Z., 1992. On the mineralogy of pink topazes from Katlang deposit (Pakistan). (Russian with English abstract). Zapiski Vsesoyuznogo Mineralogicheskogo Obshchestva 121, 72-79.

In addition to the relatively recent discovery of significant amount of emerald, aquamarine, and ruby, Pakistan has also begun to produce fine gem quality pink topaz. In a small hillock of recrystallized limestone north of Katlang, narrow calcite veins encase pink topaz crystals up to 3 cm long accompanied by larger amounts of reddish brown, tan and colourless topaz crystals. More than 70000 ct of gem quality pink topaz has been reported to date. The refractive indices, optic axial angle, unit-cell dimensions, and density of the topaz are influenced by a partial replacement of fluorine by hydroxyl ions. The color is due to trace elements – principally chromium (Cr^{3+}). Treatment experiments reveal that the color of the brown, tan, and colorless topaz from this source may be improved by irradiation and heat.

Key words: Mineral deposits, topaz, gemstone, Mardan.

G/166. Gornitz, V. & Seeber, L., 1981. Morphotectonic analysis of the Hazara arc region of the Himalayas, North Pakistan and North West India. Tectonophysics 74, 263-282.

In the Hazara arc region of northern Pakistan, some of the active basements structures buried below a thick, detached sedimentary layer are inferred from the distribution of lineaments and the drainage patterns, as viewed in Landsat satellite imagery and from river profiles.

A prominent set of NW-trending lineaments seen on satellite imagery, coincides approximately with the southwest or updip side of the Indus—Kohistan seismic zone (IKSZ) —the most active basement structure of the region, even though this structure is buried beneath and decoupled from a 12 km thick sedimentary layer. The IKSZ has been interpreted as an extension of the Himalayan Basement Thrust, and is also associated with a prominent topographic “step”.

Knickpoints on major rivers in the region lie on or north of the IKSZ. All Indus River tributaries, examined north of the IKSZ, show prominent knickpoints, while two tributaries draining south of the IKSZ have no knickpoints. These

results suggest ongoing uplift above and north of the IKSZ, and are consistent with the tectonic model obtained from the seismic data. Another prominent lineament set is detected along the north—south section of the Indus River. This set is probably related to the Indus River horst—anticline and associated reentrant. One of the two highest lineament concentrations occurs at the intersection between the NW-trending IKSZ lineament and the N-trending Indus River lineament. The other is along the west bank of the Indus Valley, 25 km north of Tarbela Dam. A topographic ridge (Swabi—Nowshera ridge) appears to be forming along the west side of the Indus River, in the Peshawar Basin. The rising ridge is ponding the Kabul River upstream of Nowshera, where the drainage is braided.

The geomorphology of the Hunza valley, Karakoram Mountains, Pakistan. In: Miller, K.J. (Eds.), *The International Karakoram Project 2*, 359-410. Cambridge University Press.

The Hunza Valley in northern Pakistan shows greater relative relief than any other place on Earth. It cuts through the diverse structural and lithological elements of the Karakoram Mountains. At low altitudes it flows through an area of aridity and of desert vegetation. The slopes in the area are highly unstable, weathering by salt and frost is active, glaciers are active and large, discharge is highly seasonal, channels are subject to marked changes, and sediment and solute loads are high. The overall denudation rate is approximately 5000 t km⁻² yr⁻¹.

G/180. Greco, A., 1986. Geological Investigation in the Reshian Area (Jhelum valley, State of Azad Jammu and Kashmir). *Kashmir Journal of Geology* 4, 51-66.

Petrographical and structural geology investigations have been carried out in the Panjal Volcanics, Triassic Limestone, and Salkhala Series exposed in the Reshian area. The study of the microstructures shows a complex relationship between deformation and metamorphism. The highest metamorphic grade-greenschist in the volcanics and amphibolitic in the Salkhala- has been reached before the main deformation phase. Retrograde mineral paragenesis is pre- to synkinematic. Only in the upper part of the investigated area the highest metamorphic conditions seem to persist during the deformation. Shear was the most important. Due to the thrusting of the Salkhala over the Panjal and over the Murree Formation a penetrative, continuous schistosity has been developed. Its trend is sub-parallel to the bedding and the thrust planes, and it is accompanied by an intense stretching lineation, showing the NE-SW direction of tectonic transport. In a later phase the crenulation cleavage, which cuts the previous structures, has been developed in the less competent rocks. All these events agree with the tectonic model elaborated by Bossari et al. (1984).

A map is presented which summarizes the work of the ETH Himalayan Group in the Kaghan Valley and adjacent areas of the NW Himalaya in Pakistan. The stratigraphical, structural and metamorphic features of the lithologies belonging to a virtually complete section through the Indian plate are described. Evidence is presented which shows a stratigraphic range in ages from the Precambrian Salkhala Formation to the Eocene Murree Formation which have been metamorphosed at various metamorphic grades ranging from very low grades/unmetamorphosed to eclogite facies. An inverse metamorphism, associated with the Main Central Thrust is also described. A large-scale tectonic

subdivision of the area into the classical Sub-, Lesser and Higher Himalayan elements can be correlated with the Kashmir Himalaya to the east. A tectonic model is presented which suggests that an anticlockwise rotation of the transport direction caused the refolding and stacking of the nappe piles in the Paleogene.

My original intention was to spend some time shooting in the Hanle district of Ladakh and then go on to Phobrang and cross into Chinese Turkistan by way of the Aksai Chin. With this object I left Srinagar on the 12th April, and when passing through Leh arranged with Bishop Peter of the Moravian Mission to send my porters and supplies for the Changchenmo-Aksai-Chin crossing, to Phobrang. On arrival at the latter place I received word that my passport for Central Asia had not arrived, and it looked possible that I might not get one at all. I therefore went off to shoot round Dakpo Karpo and the Changchenmo; on my return again to Phobrang I learnt by wire that the passport had been despatched from Nanking on the 29th May and I judged that it should reach Leh by the 5th July at the latest. I now decided to return to Leh and travel by the shorter and quicker route by the Karakoram pass. I left Leh on the 23rd June, having given instructions for the passport to be forwarded to me by special runner, and spent some time mapping the Chong Kumdan glacier and the Shyok lake. Having completed this work I pushed on to Daulat-Beg-oldi, close to the Karakoram pass, but after waiting some time for the passport, my supplies began to run short, and, though I tried to persuade my caravanbashi to go on to Suget for more, he refused to do so and I was forced to return. This short paper therefore is merely a brief summary of my observations of the Chong Kumdan glacier-dam. It was on the 28th June that I left Takshai, the last village in the Nubra valley. Up till that date no one had crossed the Saser pass that year and the inhabitants of Nubra stated that it was still deep in snow and unfit for pony-transport. I had three permanent porters with me and collected six more at Takshai (pay Re. 1/- a day). In the Thulan-buti defile I met the first of the Yarkandi caravans. Their news was not very hopeful; they had stayed at Saser Brangsa, north of the pass, till their food was almost exhausted, and had then tried to force it, with the result that they had had to abandon their baggage on the pass after losing two ponies and three asses. I therefore left my own animals at Skyangpo-che and moved up towards the pass with my coolies only, halting that evening at the first of the lakes. I intended to start at 5 a.m. the next morning, cross the pass and reach Saser Brangsa that day, but at midnight, when I looked out, the snow was frozen hard and the moon full, so that I felt it was an ideal opportunity to cross. I went over to the porters, but they were not for it, saying that it was too cold and that in their local boots they would get frostbitten, but that they would start at five. At five the next morning it was snowing hard and we were forced to remain there all day. It was again snowing at 5 a.m. on the 3rd July, but an hour later the sky looked better, the snow had stopped and the porters agreed to make a move. Fortunately for us the sun hardly came out all day and the eight miles to Saser Brangsa were covered in eight hours. On the 4th July I moved the camp up the Shyok valley to the Kichik Kumdan glacier, from the terminal moraine of which I could see the snout of the Chong Kumdan glacier lying across the valley like a bar of silver. There was very little water in the Shyok, and at the Saser Brangsa ford it was only about a foot deep. On the 5th I went up to the Chong Kumdan. The point from which the best view can be obtained is about a thousand feet above the main valley bottom on the right bank of the Shyok. From here the Shyok lake can be seen stretching away to the north, beyond the three miles of glittering ice-pinnacles of the Chong Kumdan glacier almost immediately below. The panorama published with this paper gives some idea of the magnificence of the spectacle. The lake at that time was ten miles long and varied from a mile to a mile and a half wide. Later when I went round and camped at the north end of it, I found that its level was rising at a rate of from six to seven inches a day. Above the surface-level on the hillsides at the edge of the lake were to be seen previous marks caused by water-erosion. In July the lake was from thirty-five to forty feet below the highest erosion-mark from which fact I concluded that by the beginning of the winter of 1931 the surface would be at its high-water level. As regards percolation through the ice-barrier, three hundred yards downstream of the snout of the glacier the Shyok river-bed was dry. On the 5th July there was very little water coming off the Chong Kumdan, and though on the 6th there was more, there was still less here than was issuing from the Kichik Kumdan glacier.

The Chong Kumdan glacier descends from a broad trough in the mountains. Standing at the snout it is up the Chong Kumdan valley and not up the main Shyok valley that one looks. The Chong Kumdan glacier and lake, in fact, form the upper branches of a "Y", the tail of which is the Shyok valley below the snout. Unless this is realized, the map, which shows a "T" lying on its side, is misleading. At the time of my visit the width of glacier against which the waters of the lake were resting was about 1500 yards, the same as that of the valley bottom immediately below the snout. The ice of Chong Kumdan, or left branch of the "Y", extended for a distance of 1100 yards below the point where the eastern edge of the lake met the ice.

The height of the ice at the snout was about ninety feet; where it was holding up the lake it might be as much as two hundred. Here it was a mass of pinnacles and it was difficult to judge the height. These pinnacles extend for a distance of three miles up the glacier and are due, I think, to the effect of the warm dry wind blowing up the main valley. They and their attendant ice-walls make climbing on the glacier difficult and crampons, ice-axe and rope are essential. I did not come across any bad crevasses, but the surface was badly cracked, and there would have been danger of an accident with laden or inexperienced men. The height of the pinnacles was from sixty to eighty feet. Once the sun reached the glacier surface, stones and ice started to fall; for this reason it was unsafe to be on the glacier after eight o'clock. A curious feature of the Chong Kumdan glacier was the complete absence of dead lateral moraine. The valley out of which the glacier emerges has steep cliffs on either side or the glacier ice reached right up to these cliffs. The terminal moraine consisted of a small pile of stones, out of all proportion to the size of the glacier. The channel cut in the ice by the escaping waters in 1929 could be clearly seen and acted as a central drain for the surface ablation of the glacier. Should the lake overtop the glacier, its waters would use this channel and probably open it up so rapidly that a flood would follow. If the barrier actually breaks, it seems to me probable that it will do so in August 1932, this being the month that it has usually burst before. With the water up to the high-water level and the old scar in the glacier, with the almost complete absence of percolation, I consider that the lake is almost certain to overtop the barrier or burst it in 1932. Should anyone think of going up to the ice-barrier in 1932, I would suggest that, after halting at Saser Brangsa, they move up the right bank of the Shyok to just short of Kichik Kumdan, using porters only from Saser Brangsa onwards. The next camp should be pitched near the snout and the party should start the next morning very early, pass the two side glaciers on the right bank of the Chong Kumdan, and cross the main glacier just above where it is joined by the lake. Should there be a break, in all probability this route will be above it and will remain. On the north side of the glacier a camp could be pitched on the spur on the west edge of the lake, just above the point where the lake meets the ice. This would save the long detour by the Depsang plains. Also, the two metal boats left by Gunn in 1929 at the mouth of the Chip-chap have now been removed. I ought perhaps to warn people against attempting to climb the cliffs on the left bank of the Shyok just below the glacier. Though it is possible to do so and to reach the lake by this route, the chimneys that have to be traversed form dangerous stone-shoots. I would also recommend that any party moving on the glacier itself should be clear of it by 8 a.m., when the sun may get on to it and render it dangerous from falling ice and stones.

Note by the Editor. Thanks to the courtesy of Captain Gregory and Messrs. Ludlow and Gunn, we have now some forty photographs of this glacier, taken from various points during the last four years. Much as I should like to do so, it is not possible to publish all these, though a careful examination makes clear some very interesting conclusions. In addition to the photographs and accounts of these observers, we also have a report by Mr. P. C. Yisser of his observations in July 1930. The photographs taken in 1928 and 1929 from below the snout are very similar. The larger series of 1929 show some definite features that led me then, in spite of Gunn's report, to doubt whether the glacier had begun to retreat, and I then foretold that the channel cut by the lake would heal during the winter of 1929-30, and that another lake would be impounded. These features are very marked when the 1929 photographs are compared with Captain Gregory's beautiful series taken in 1931.

In 1929 the upstream photographs show a vertical, and in places an overhanging, dam face holding the lake. The ice at the edges of the lake showed cracks and the ice-pinnacles emerged almost directly from the water's edge. The ice itself showed intensely white in the photographs, and even from a distance little englacial or medial moraine could be observed. These features may be seen to some extent in the two photographs in the *Himalayan Journal*, vol. ii, opposite pages 38 and 46. A complete series of fourteen photographs by Ludlow emphasizes them.

In 1931 there was a marked change. The lateral pinnacles were much reduced in size and became more degenerate; masses of medial moraine were being carried to the edge of the ice and were falling into the lake. In 1929 the lake edge of the dam had a marked convex bulge into the lake, probably owing to pressure against the rock wall opposite. The 1931 dam showed a straight, almost a concave, edge to the lake. Downstream of the glacier, the 1928 photographs show a protuberant tongue, possibly due to snout-spread, in the centre of the Shyok valley. There is little difference in 1929, both before and after the burst. The edges in both 1928 and 1929 were vertical (slightly more so in 1928 than after the burst in 1929, probably due to seasonal ablation in August). In 1931, as shown in the illustrations in this volume, not only the snout-tongue, but the whole snout-face was breaking up into detached ice-pinnacles very much interspersed with englacial and surface moraine. In pinnacled glaciers such as this, moraine-banks are only left as isolated terminal moraines when the ice-pinnacles are dead. 'Retreat' is most irregular, and, as could be seen in the neighbourhood of the Kichik Kumdan glacier in 1928, much dead ice is left below the living snout. If further proof were required that 'retreat' and degeneration has now set in, it is to be found in the pictures of 1929 and 1931 which give a longitudinal profile of the glacier surface. Ludlow's and Gunn's photographs of 1928 and 1929 show that of the portion of the glacier lying across the Shyok valley, the highest point lay then towards the left bank of the Shyok, which indicates that the ice had been forced up by pressure against the wall. The panorama

looking up the Shyok across the glacier, published in the present volume, shows that the highest point in 1931 was where the glacier enters the Shyok valley. From here the height tailed off towards the left bank, indicating a relief from pressure. This panorama also shows very distinct signs of pinnacle degeneration, particularly towards both edges and the opposing wall.

In 1929 the waters of the lake cut a channel approximately five hundred feet wide. The channel apparently commenced from near the right or western shore of the lake, took a course towards the centre of the glacier and emerged near the left or eastern side of the Shyok valley. In July 1930 the Vissers reported that the channel had completely healed and that there was no sign of it, though traces of the burst were still to be seen below the snout. In the same month, in 1931, though there was still no percolation through the glacier and no water issuing from beneath the ice, the channel had again opened out and acted as a central drain for surface water from the glacier. These facts again point conclusively to a release from pressure.

Estimates of the height of the ice at the snout and of the depth of the water at the dam are difficult to compare. In the snout observations we do not know whether the observations were made at the same spot. Ludlow's estimate in 1928, from some distance away was, "at its snout it could hardly have been less than 200 feet high". Gunn gives the height in August 1929 as "about 500 feet". Visser does not mention it, but in July 1931, Gregory gives it at about 90 feet. A few days before the burst in 1929 Gunn gives the depth of the lake at the dam as about four hundred feet; in July 1930, when the reformed lake had reached a length of three miles, Visser calculated the depth at the dam to be 133 feet; in July 1931, Gregory thought that it might be as much as 200 feet. Too much reliance must not be placed on these figures; it is notoriously difficult to make such estimates. But even assuming that Ludlow was liberal, that Gunn was radical, and that Gregory was conservative, these figures do bear out the conclusions given above from examination of the ice-formation in the photographs.

The two points of human interest are: Will the dam burst catastrophically? And if so, when? The second question may be answered first. There can only be a catastrophe if the dam bursts when the river is at or near normal high summer-level. This is between mid- July and October, inclusive. Damage from scour and isolated accidents from drowning may occur at other periods, but villages and grazing should be above the flood level. The point is: Will the dam hold till then? In my opinion, though there was no percolation in July last year, degeneration had set in to such an extent that in all probability there was a good deal of leakage before the winter. By October I believe the glacier may have been too degenerate for any substantial recuperation during the winter, and that spring and summer ablation in 1932 with normal periodic decline will relieve the lake of much of its water. It is an opinion that I hesitate to put forward, for observations of the little glaciers of other parts of the world are of no value for comparison. Of one thing I feel certain. I still maintain that after 1932, there will be no further danger of a block for over thirty years.

The above Note was sent to Captain Gregory, who comments as follows:

Now that I have had time to examine carefully the state of the glacier snout as shown in Gunn's photographs, I too think that degeneration has set in ; but at the same time, though I do not know very much about the subject, I shall be very astonished if so great a volume of water can be carried away by percolation. It may be of interest to mention the following facts which may affect the percolation question. In 1931 on the 7th and 8th July there was no percolation at the snout when I was there. On the 12th July I crossed the Shyok at Saser Brangsa; the water was then knee-high as against about eight inches on the 4th July, say ten inches higher. On the 17th and 18th July I was at Yapchan when the lake was rising at the rate of six or seven inches a day. On the 22nd I again crossed the Shyok at Saser Brangsa; the water was now -up to the men's hips, say 2 feet 10 inches at midday. The crossings on the 12th and 22nd were made at the same time of day, and the difference of level may have been merely seasonal. When I crossed the Shyok at Khalsar, about 135 miles downstream of the barrier, there was a good deal of water and a Yarkandi had been drowned the day before, but the men at the ferry did not say anything about the water being particularly high. I wonder whether percolation set in just after I left the Chip-chap.

In my opinion the normal seasonal advance and regeneration in the coming winter will almost certainly close the narrow transverse channel that has been cut, and by next spring this should have completely healed. I believe that another lake will almost certainly form next spring, but since the seasonal retreat next summer will now be assisted by periodic retreat, the dam will definitely degenerate in height and strength. It may be that the lake so formed will drain away by percolation, or it may gradually wear away a channel, taking several days to drain (as happened in the last of a similar series with the Khurdopin glacier). If the healing is so complete as to prevent either of these two courses, I believe the dam will break again in August 1931, the month of maximum inflow to the lake, and the month of maximum degeneration of the ice. Under no circumstances can the dam impound a lake in the next few years* of the same magnitude as that liberated in 1929. In my opinion there is no danger of a serious flood for many years to come, while the present danger of a complete block and a minor flood will be over at latest in 1932, after which there will be nothing to worry about till 1969. There will then be 100 year scare-period".—Himalayan

Journal, vol. ii, p. 46. With the exception that I did not foresee a healing so complete that the dam would hold throughout 1931, this forecast has been accurate and I see no reason to modify the prediction for the future. The terminal moraines left by the Chong Kumdan when the pinnacles have melted cover a very wide area, as may be seen in the photographs opposite pp. 200, 202, Chap. xx, vol. ii, of Professor Giotto Dainelli's *Pxri e Qenti del Caracorum* (Firenze : 1924). These photographs were taken in 1914, about thirty years after the previous year of maximum advance. It appears to have been impossible then to determine how much of this moraine was on ice. It is well worth while comparing Dainelli's photographs of this glacier in its degeneracy with those of the last few years taken since its rejuvenation.

G/198. Grujic, D. & Wosnitza, E., 1999. Thermomechanical analogue modelling of Himalayan collision processes. Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 63-64.

To simulate crustal rheological stratification in physical models, it is necessary to take into account the variations in mechanical properties induced by temperature. So far this has been done by using different materials, such as sand and silicone putty, for brittle and ductile behaviour respectively (e.g. Davy and Cobbold, 1991). Major advances have been made in understanding the Himalayan collision processes in this way (e.g. Chemenda et al., 1995). However, the major drawback with such models is that the material points within the model crust retain their physical properties throughout the experiment regardless of their changing position within the crust. The second approach to model the crustal layering is to use a single material with temperature-sensitive viscosity. This design has the advantage to reproduce the mechanical consequences of thermal readjustment during the model run. In our opinion this is the most important direction in improvement of modelling technique for plate tectonic processes. For example, it has been shown that the changing rheology of subducted sediments is an important phenomenon governing the material balance in the subduction zones (e.g. Mancktelow, 1995). This concept has been also applied to the exhumation of the Greater Himalayan Sequence (GHS) in the Bhutan Himalaya by ductile extrusion (Grujic et al., 1996).

Channel flow model

The process of extrusive flow can be approximated quantitatively by channel flow models that have been used to describe subduction zone processes. Such model characterises a thrust system as a viscous material-filled channel lying between two rigid sheets that deform the viscous material between them through induced shear and pressure gradients within the channel. The exact result depends on the geometry of the channel, but the simplest qualitative characteristic of these models is that the velocity field is a hybrid between two end-members (e.g. Turcotte and Schubert, 1982): (1) induced shear applied at the boundaries which produces a uniform vorticity across the channel; and (2) induced pressure gradients which produce a “pipe-flow” effect with highest velocities in the centre of the channel and opposite vorticity at the top and bottom of the channel. In these channel flow models the transition from uniform simple shear to “extrusive flow” is highly sensitive to viscosity and to lateral pressure gradients.

In a parallel-sided channel, the driving force for reverse flow at the top of the channel—the buoyancy of subducted material—is compensated by lithostatic pressure. In situations where the channel walls are non-parallel the (nonlithostatic) pressure gradient might cause high rates of buoyant return flow of the channel fill provided that the

viscosity is low enough (Mancktelow, 1995). In a thrust system such as the Himalayan Main Central Thrust (MCT), a lateral pressure gradient would develop due to building of topography during collisional tectonics. Similarly, major changes in viscosity also accompanied motion on the MeT. Swapp and Hollister (1991) and Davidson et al. (1997) presented evidence of early heating of the GHS followed by rapid high-T decompression. This early heating history may have been aided by heat advection due to the leucogranite intrusions into the GHS (e.g. Hollister et al., 1999). The related temperature increase would result in a drop in viscosity within the “channel” at the same time as the creation of orogenic topography produced a lateral pressure gradient within the channel.

In the GHS the main history of the system apparently records a hybrid process with a major influence of the pipe-flow effect. In particular, the reverse shear sense at the top of the channel is exactly the flow-pattern inferred across the top of the GHS along the South Tibetan Detachment system whereas south-direct ductile thrusting dominates at the base of the GHS belt.

Thermomechanical analogue models

In order to investigate the extrusion processes, in particular the role of rheology in distribution and propagation of deformation, we have constructed a deformation rig specially designed for thermomechanical modelling. We use analogue materials with temperature-sensitive viscosity to properly simulate the change in mechanical properties with depth. By inducing a vertical thermal gradient in the model, by precisely heating the bottom and cooling the top, one can produce a viscosity gradient. As the material points in the model change their depth by deformation they consequently change their material properties. The thermal perturbation is monitored by a series of resistance temperature detectors and by infrared camera. Correlating the thermal with physical field in the model one can deduce its rheological structure. As the differential stress, strain and temperature can be accurately measured during the experiment the onset of the instability can be easily defined. It also means that the rheology of the materials and the bulk rheology of the model can be characterised under exactly the same conditions as hold in the experiments themselves. Using all the informations together the dynamics of the structures formed can be investigated.

Key words: Gems, Emerald, Pakistan.

G/200. Gubelin, E.J., 1981. Geological observations on new Emeralds from Pakistan. Gemology, 7.

Only during the last few years have the gem riches of Pakistan become known to the rest of the world. This article reports on three gem materials currently being mined: emerald, corundum (most importantly, ruby), and spinel. Intensely colored emerald crystals occur in dolomitic talc schists in the Swat Valley. Unusually high optical properties and density serve to distinguish these emeralds from those found elsewhere. Numerous gas-liquid inclusions are also typical. In the Hunza Valley, specimen and gem-quality crystals of corundum and spinel occur in beds of marble enclosed in gneisses and mica schists. The gemological properties of the Pakistan rubies and sapphires vary only slightly within normal limits.

Key words: Gemstones, ruby, emerald.

Emerald is found with quartz and dolomite in the Swat Valley of Pakistan, near Mingora in the area of Hindu-Kush. Stones of a fine colour have a n_D 1.588 and n_W 1.596 with a birefringence of 0.007. Strong bands occur in the

absorption spectrum at 683 and 680 nm with weaker bands at 662, 646, 637, 477.4 and 472.5 nm. The stones appear an orange red through the Chelsea colour filter. Specific gravity is 2.77. Inclusions of calcite and dolomite crystals have been noted, with various patterns of liquid droplets. A table of constants of emerald from various localities is given.

G/205. Gubelin, E.J., 1990. Gemological characteristics of Pakistani emeralds. In: Kazmi, A.H. & Snee, L.W. (ed.), *Emeralds of Pakistan: Geology, Gemology and Genesis*, 75-91. Van Nostrand Reinhold, New York.

The gemmologically ascertainable diagnostic properties of emeralds from Khaltaro, Gujar killi, Makhad, Charbagh and Swat mines 1, 2 (5-8 specimens from each) together with 70 specimens from the Mingora area are given. All of the emeralds have mean constants of E 1.583 and W 1.590, rather high for gem-quality emerald but in agreement with emeralds containing appreciable Fe: D ranges 2.66 – 2.78 with a median of 2.71 g/cm³. There is a broad absorption band in the blue from 420 for E to 430 for W , with an absorption maximum at 427 nm. This absorption band is consistently present in the Pakistani emeralds tested and is an additional means of identification. Primary fluid inclusions are of two types; narrow rectilinear filaments in parallel alignment along and pronged three-phase inclusions reminiscent of those in Columbian emeralds. The second fluid inclusions are also of two kinds, finger print inclusions and flat film-like, two-phase inclusions. Mineral inclusions found are actinolite, chromite, dolomite, enstatite, feldspar, gerdorffite, magnesite, mica and pyrrhoites: 321 colour photographs of the inclusions are presented.

G/206. Gubelin, E.J., Graziani, G. & Kazmi, A.H., 1986. Pink topaz of Pakistan. *Gems and Gemology*, vol. 18, pp. 123–139.

The occurrence of pink topaz in Pakistan was discovered less than 20 years ago. This attractive material has been reported on several occasions in the gemological literature [Afridi et al., 1973; Bank, 1976a and b; Petrov et al.; 1977a, b, and c; Jan, 1979], but details of the deposit itself have only recently become available. In this article, the authors report on their investigation of the geology and mineralogy of the pink topaz deposit near Katlang, and on the chemistry and the gemmologically ascertainable properties of this material. As part of this study, the authors also investigated the other color varieties of topaz found at the deposit and their reaction to treatment.

The topaz is found in one of two hills that rise abruptly from the fertile agricultural plain of the Mardan District in the neighborhood of a small village. This settlement of farmers and the topaz hillock both bear the same name—Ghundao—and are located about 4 Km (2.5 mi.) north of the small town of Katlang (figure 2). The geographic coordinates of the topaz-bearing hill of Ghundao are latitude 34°24'N longitude 72°06'E which places it about 63 km (40 mi.) northeast of Peshawar and about 20 km north of the district capital Mardan "as the crow flies" (approximately 50 km southeast of the Swat Valley emerald deposits; see Gubelin, 1982). The hill is easily reached by automobile. The other hill, which contains no topaz deposits, lies about 1 Km northwest of the Ghundao hill.

The summit of Ghundao, the topaz hill, is approximately 80 m higher than the village, and the two hills are conspicuous features of an otherwise unbroken plain

Key Words: Gemology, topaz, Mardan.

G/209. Guillot, S., Cosca, M., Allemand, P. & Le Fort, P., 1999. Contrasting metamorphic and geochronologic evolution along the Himalayan belt. In: Macfarlane, A., Sorkhabi, R. & Quade, J., (Eds.), *Himalaya and Tibet: Mountain roots to mountain tops*. Geological Society of America Special Papers 328, 117-128.

Systematic different pressure-temperature-time paths are recorded along the internal zone of the Himalayan orogen. High-pressure rocks rapidly exhumed during the Eocene and Oligocene are restricted to the western part of the Himalayan belt. Farther to the east, both in the North Himalayan Crystalline massif and in the High Himalayan Crystalline slab, there are upper amphibolite facies rocks, which were unroofed during the Miocene. In the High Himalayan Crystalline slab, a systematic decrease in mica $40\text{Ar}/49\text{Ar}$ cooling ages can be correlated with the degree of low-pressure anatexis to the east. The observed contrasts in both the metamorphic and geochronologic evolution along the Himalayan belt can be related to the counterclockwise rotation of the Indian plate during the India-Asia collision. Such rotation, together with a shallower dip of the intracontinental subduction plane to the east, would explain the delay in nappe stacking, a warmer thickened upper crust, and the observed decrease in ages from west to east.

G/211. Gul, A., 1983-85. *Geology and petrology of Burawai Area, upper Kaghan valley, District Mansehra, Pakistan*. M.Sc. Thesis, Punjab University, Lahore, 125p.

The project area lies in the upper Kaghan valley on both sides of the river Kunhar and along its adjoining tributaries. The Kaghan valley administratively is a part of the district Mansehra, province of Sarhad, Pakistan. Within the Kaghan valley the area starts at Battakundi in the south and goes upto Babun near Jalkhad in the north and covers about 114 square kilometers (nearly 70 square miles) and is covered by the Survey of Pakistan, toposheet No. 43 F/13, at the scale 1:50,000. The area lies between;

Latitude; $34^{\circ}53'38''$ to $35^{\circ}00'00''$

Longitudes $73^{\circ}45'00''$ to $73^{\circ}58'30''$

Battakundi, Dabukan, Dunga, Bans Bandi, Rakhan, Burawai, Wetar and Seri are the main villages on the roadside, in the project area. This report represents partial fulfilment of the requirements for the M.Sc. Applied Geology Examination at the Institute of Geology, University of the Punjab. The field work for this field

Key Words: Petrology, petrography, Kaghan valley, Mansehra.

G/212. Gul, A., Rehman, S.S. & Hamidullah, S., 2001. Hydrological studies of Panjkora River system and its tributaries Dir District, NWFP, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 64-65.

The North West Frontier Province (NWFP) is primarily drained by the Indus River along with a tributary network of perennial streams including the Kabul, Swat, Chitral, Kunhar, Bara, Kurram, Gambila, Gomal and Haro. Among these, River Panjkora, a snow fed tributary of Swat River which originates from the mountains of Dir Kohistan near Thal and drains Dir District and part of the Malakand Agency. The confluence of Panjkora and Swat rivers lies northwest of Kolangai village near the border of Malakand and Bajaur agencies. The catchments area of this river is mostly forested. This river is important for its high head and great discharge even in winters. Sarhad Hydel Development Organization (SHYDO) has selected a number of sites on this river and its tributaries for high head power production. This study is planned to carry out hydrological investigations of the water samples of Panjkora River for better management. Water samples were collected from eleven sites, Rashai dub/Thal down to Bussaq/Sharbati village and were analyzed for pH, alkalinity, hardness, TDS and suspended sediments concentration. Chemical analysis are under process and there data together with other parameters will be compared with generally accepted water quality standards for the maintenance of human and aquatic life and also for agricultural growth of the region. Various recommendations are suggest for better use of this natural gift, on the basis of data obtained during the current investigations.

G/216. Guraya, M.A. & Khizr, K., 1981. Geology of Swani–Sheringal region, Kohistan, District Dir, North West Frontier Province with special emphasis on Mineralogy and Petrology. M.Sc. Thesis. Institute of Geology, Punjab University, Lahore.

Swani-Sheringal Area is part of Hindu Kush range and is included in Northwest Himalayas. The area is mainly composed of metamorphic rocks of sedimentary origin, with igneous intrusions. The main rock units in the area are calcareous quartzites, chlorite schists, biotite schists and amphibolites. Calcareous quartzites are believed to be the oldest rock unit of the area. Chlorite schists, biotite schistose and amphibolites have formed as a result of progressive regional metamorphism of calcareous quartzites. The contacts of calcareous quartzites with the schistose and the contacts between chlorite and biotite schistose are gradational. Amphibolites are developed as formless patches in the schistose. The area is tectonically highly disturbed being involved in Himalayan Orogeny. The report

presents a detailed geological and petrological investigation of about 40-km² area. A detailed map of the investigated area on a scale of 1:10,000 are presented, along with its cross-section along X-Y line. Succession of Rocks of the area has been worked out. Detailed petrography of all the major units of the area is described.

H/3. Hadi, S., Abbasi, I.A., Khan, M.A. & Shah, M.R., 2000. Structure and stratigraphy of the collision related Main Boundary Zone, Thal area, Western Kohat. Late Abstracts, Third South Asia Geological Congress, Lahore, p.8.

For further details consult the following account.

Key Words: Structure, stratigraphy, MBZ, tectonic mélange, Thal, Hangu.

H/4. Hadi, S., Abbasi, I.A., Khan, M.A. & Shah, M.R., 2001. Tectonostratigraphy along the western collision zone Thal area, western Kohat, NW Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 26-27.

The mélange zone and carbonate sequence exposed around Thal area defines the western most intersection of the Main Boundary Thrust (MBT) and the Kuram Boundary Zone (KBZ) that records the imprints of the western oblique collision of the Indian Plate with Afghan block. The associated deformation due to these structures in the area has bimodal nature. The first phase is syn-ophiolite obduction, which brings the Shahur Tangi-Kahi Group over the Indian shelf sequence as a thrust sheet with large aerial extent, and is contemporary to Paleocene as constrained by the highly brecciated and attenuated Lockhart Formation. The younger phase of deformation associated with Main Boundary Thrust (MBT) and uplift of the Kuram Boundary Zone (KBZ) caused the Indian shelf sequence (Isha Group) to breach out along the high angle south verging structures e.g. Kiliadii-nak & Darsamand structures. This phase is believed to be post-Pliocene as it deforms the young conglomeratic deposits of the molasse sequence.

The Isha Group (Jurassic-Paleocene) is comprised of Sainanasuk/Chiltan, Chichali/Lumshiwal, Kawagarh and Lockhart formations. The Shahur Tangi-Kahi Group represents a sub-CCD flysch olistostromal sequence and is subdivided into Ahni Tangi, Shinki Post and Khajuri Post formations of the Late Cretaceous age. The Eocene rocks are represented by shale/limestone sequence (Panoba Shale & Kohat Limestone) that unconformably overlies the post-ophiolite obduction thrust stack and marks the western extremities of the Eocene Kohat Basin where most of the Eocene rock taper out. Thick molasse sequence of the Kohat foreland basin unconformably overlies the Eocene rocks and is represented by Kamlial, Chinji & Nagri formations.

Key Words: Tectonics, stratigraphy, collision, Thal, Kohat.

H/5. Hafeez, M.A. & Ahmad, S.A., 1992. Status of geological mapping on 1:50,000 scale in Pakistan. Geological Survey of Pakistan, Information Release 535.

H/6. Hallam, A. & Maynard, J.B., 1987. The iron ores and associated sediments of the Chichali Formation (Oxfordian to Valanginian) of the Trans-Indus Salt Range, Pakistan. *Journal of Geological Society*, London 144, 107-114.

A distinctive and widespread belemnite-bearing shale of the Tethyan region is well exposed in the Trans-Indus Salt Range as the Chichali Formation, where it contains two workable ironstone seams. Facies analysis indicates a pronounced deepening in the Upper Oxfordian and Kimmeridgian followed by two regressive cycles marked by a transition from glauconitic-phosphatic shales to glauconitic silts and sands and finally to winnowed and oxidized glauconitic sandy ironstones. The first cycle ends in Berriasian belemnite-rich beds; the second cycle, which has few belemnites, extends into the Valanginian, and is followed by deltaic sediments of the Lumshiwal Formation.

Comparison with other areas indicates that the source area for the clastic components was the Indian Shield to the east and south. The increased clastic supply in the Upper Jurassic-Lower Cretaceous is thought to result from tectonic uplift in this source area rather than from climatic change.

The ironstone beds are distinctive in being pelletal glauconites compared with the oolitic chamosite and goethite so typical of the Jurassic elsewhere. Enrichment of the glauconite to commercial grade was by winnowing and oxidation on the seafloor. The absence of oolitic chamosite and goethite could be related to generally deeper water and an overall Eh in the environment too high to allow iron to migrate in appreciable quantities as Fe²⁺.

Key words: Economic geology, iron ore, sedimentary rocks, Chichali Formation, Trans-Indus Salt Range.

H/8. Hameed, A., 1992-94. Sedimentary petrology/sedimentology of Early Cretaceous Lumshiwal Formation and Early Palaeocene Lockhart limestone and lithostructural mapping of Sirgah area, southern Hazara, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 150p.

A comprehensive study of Geology and structure of Dhamtaur area is represented along with special constraints on the sedimentology of Lumshiwal Formation of Early Cretaceous and Margalla Hill Limestone of Early Eocene. Large scale (1:10000) Geological mapping of a small segment of the Lesser Himalaya in the Dhamtaur area is presented. The lithostratigraphic unit range from upper Paleocene to Pre-Cambrian, Hazara Formation being the oldest. Structurally the area comprises NW-SE trending major anticlinorium. The folds are tight to isoclinal and opposing southeast and North West vergence on the two sides of the core formation. Some anticlines show plunge to the southeast direction. Almost all faults have vergence parallel to the folds developed in the core on the two sides of the main anticlinorium. Most are reverse faults although some may be of the normal type. Faulting appears to be dip-slip to oblique slip and in general involves a maximum displacement of few hundred meters.

A detailed study of sedimentary petrology/sedimentology of Lumshiwal Formation of Early Cretaceous and Lockhart Limestone of Early Paleocene has been carried out. The object was to study the petrography environment of deposition and diagenesis of the above said formations.

The section of Lumshiwal Formation from Jhamiri village between Haripur-Jabrian Road is medium to thick bedded glauconite sandstone. This formation is divided into nineteen microfacies. The microfacies overlying Chichali formation is glauconite, iron oxides and quartz cemented, quartz arenite. The other microfacies are mainly quartz, glauconite and carbonate cemented, and mature to super mature quartz arenites. The maximum development of glauconite is from central to upper part. Upper horizons are selectively cemented with flint.

The Lumshiwal Formation indicates low energy conditions in the subtidal zone. The formation of glauconite itself reveals slow rate of sedimentation and mildly reducing conditions. Diagenetic history indicates the formation of glauconite, secondary quartz, feldspar and flint earlier and ferroan calcite and dolomite at a later stage. The last stage involves the formation of ferroan dolomitization which occurred during final uplift with parts convening into dedolomites.

The section of Lockhart Limestone near Ghumawan is medium to thick bedded. The Lower contact of Lockhart is disconformable with Hangu Formation and upper contact of Lockhart Limestone with Patala Formation is sharp and

conformable. This section is comprise of 25 microfacies and 4 facies ranging from mudstone, wackestone and packstone; have been defined on the basis of field observation and petrographic studies.

The deposition of Lockhart Limestone took place in open marine shallow shelf conditions. Neomorphism of syndepositional micrite has taken place under various conditions during different phases of tectonic activity. Mechanical and chemical compaction are present in the forms of aligned fauna and stylolites. The porosity is generally low. The type of porosities are fracture and vug.

Key words: Iron ore, sediments, Chichali Formation, Salt Range.

H/10. Hamidullah, S., 1984. Asbestos occurrence in Mohmand Agency: Genesis, economics, and related health hazards. Geological Bulletin, University of Peshawar 17, 69-73.

Two new localities of asbestos are reported from Mohmand Agency. It is considered that the asbestos development is associated with shearing and circulation of water and some CO₂ in ultramafic rocks. The asbestos is of considerable economic significance, however, there is strong circumstantial evidence that its related health hazards have already started affecting the local miners.

Key Words: Minerals, asbestos, ultramafics, Mohmand Agency.

H/11. Hamidullah, S., 1991. Chemistry of clinopyroxene from the Deosai volcanics, Baltistan, N. Pakistan. Geological Bulletin, University of Peshawar 24, 161-176.

Seventy analyses of clinopyroxene phenocrysts from the Deosai volcanics were obtained and tested for substitutions and other petrogenetic characters. The data shown an overall core-margin substitution of $x\text{Ca}+x\text{Na}+x\text{Fe}^{3+} + x\text{Al}+x\text{Ti} = x\text{Si}+x\text{Mg}+x\text{Fe}^{2+}+x\text{Mn}$ type in the phenocrysts, with "x" representing the actual amount of a cation entered or replaced, and which can be determined precisely from its variation along with unit variation of Si. The data also indicate crystallization in a temperature range of 1100 – 1200°C, under highly variable pressure, from a basaltic magma of alkaline (but transitional to non-alkaline) characters.

Key Words: Mineralogy, chemistry, pyroxene, Deosai, Baltistan.

H/12. Hamidullah, S., 1994a. Chemistry of hornblendes from the Deosai volcanics, Baltistan, northern Pakistan. Geological Bulletin, University of Peshawar 27, 1-8.

Seventy eight core to margin spot analyses of 8 hornblende phenocrysts from an andesitic basalt of Deosai plateau, Baltistan. N. Pakistan, are presented in the form of means and standard deviations. The data show an igneous parentage for these hornblendes. Chemical variations do not agree with commonly accepted substitutions for igneous hornblendes and an overall core to margin substitution of $[x\text{Fe}^{3+}x^{\text{iv}}\text{Al}+x\text{Ti}+x\text{Mg}+x\text{NaB} = x^{\text{iv}}\text{Al}+x\text{Fe}^{2+}(\pm x\text{Mn})+x\text{Ca}+x\text{Si}+x\text{A-site}]$ type is suggested with the former set of cations higher in cores and the latter in margins. A tentative temperature range of 875-700°C and a PH₂O range of 6-4.2 kb are suggested for the crystallization of these hornblendes. It is also suggested that like clinopyroxene the Deosai hornblendes carry unusual chemical features which may be related to variations in physio-chemical environment of the magmata chamber, and for that reason, possibly, of the source region.

Key Words: Chemistry, hornblende, volcanics, Deosai, Baltistan

H/13. Hamidullah, S., 1994b. The Waziristan complex: some more chemical data and their interpretation. Geological Bulletin, University of Peshawar 27, 69-79.

Tholeiitic and cal-alkaline affinities are reflected by two different rocks from the Waziristan island arc in 22 major element rock analyses. Previously published clinopyroxene analyses are used for comparison. The data confirms the existence of a fossil island arc in Waziristan.

Key Words: Geochemistry, Island arc, Waziristan.

H/14. Hamidullah, S., 2000. Geology and mineral chemistry of the Deosai volcanic, Baltistan, N Pakistan. Abstract Volume, 15th Himalaya-Karakoram-Tibet Workshop, (Chengdu) China, p.416.

The westerly extension of the Dras volcanics in the Deosai plateau of Baltistan, northern Pakistan, lying east of the Nanga Parbat-Haramosh Massif, is comprised of agglomerates and tuffs together with flows consisting of basalt, andesite and some rhyolite. In the field these volcanics are overlying the Ladakh batholith and both these basic and acidic suites of rocks carry the signatures of the Nanga Parbat-related orogeny. The flows appear to have evolved from a basaltic magma, with opaque oxide, clinopyroxene, hornblende and plagioclase, respectively appearing on the liquidus. These have been metamorphosed under greenschist facies conditions and may contain abundant epidote, chlorite and secondary amphibole. Metamorphic impact seems to be stronger in the west, i.e., in the vicinity of Nanga Parbat-Haramosh Massif, than in the east. An $^{40}\text{Ar}/^{39}\text{Ar}$ age of 125.4 ± 6 Ma on hornblende phenocrysts in an andesite is in agreement with the Late Jurassic to Cretaceous age of the Dras volcanics, in India, and indicates that Nanga Parbat related tectonics may have played a part in the growth of lower green schist facies assemblage of the volcanic rocks.

Though the various chemical discrimination plots of the clinopyroxene phenocrysts show them as representing igneous parentage, with crystallization in a temperature range of 1100-1200°C, under highly variable pressure, from a basaltic magma of alkaline (but transitional to non-alkaline) characters, these data however, show substitutions which do not agree with the commonly accepted ones for clinopyroxenes from igneous rocks. Therefore, an overall core-margin $v\text{Ca}+v\text{Va}+v\text{Fe}^{3+}+vt\text{Al}+v\text{Ti} \rightarrow v\text{Si}+v\text{Mg}+v\text{Fe}^{2+}+v\text{Mn}$ type substitution has been suggested for these phenocrysts, with 'v' representing the actual amount of a cations entered or replaced, and which can be determined precisely from its variation along with unit variation of Si. Similarly the hornblende phenocryst chemical data also show igneous characters but with variations which do not agree with commonly accepted substitutions for igneous hornblendes. Therefore an overall core to margin substitution of $[\text{Fe}^{3+}+iv\text{Al}+\text{Ti}+\text{Mg}+\text{NaB} = vi\text{Al}+\text{Fe}^{2+}(\pm\text{Mn})+\text{Ca}+\text{Si}+\text{A-site}]$ type is suggested with the former set of cations higher in cores and the latter in margins. A tentative temperature range of 875-700°C and a PH_2O range of 6-4.2kb are suggested for the crystallization of these hornblendes. It is also suggested that like clinopyroxene the Deosai hornblendes carry unusual chemical features which may be related to variations in physio-chemical environment of the magmatic chamber, and for that reason, possibly of the source region triggered by subduction along the main Mantle Thrust.

Key Words: Geology, mineral chemistry, Deosai, Baltistan.

H/15. Hamidullah, S. & Ahmad, A., 1992. Pseudo-amphibolites in the southern amphibolite belt, Kohistan arc, N. Pakistan. Geological Bulletin, University of Peshawar 25, 73-76.

More evidences strengthening the view of the existence of (a) pseudo-amphibolite forming as a result of reaction between pre-granitic hornblendite or amphibolite and the granitic magma and (b) of certain hornblendites forming as a result of reaction between pre-granitic amphibolite and the granitic magma, in the southern amphibolite belt of the Kohistan island arc, are presented in this paper.

Key Words: Amphibolites, Kohistan, Island arc.

H/16. Hamidullah, S., Bangash, I.H. & Reuber, I., 1990. Petrology of the southern amphibolite belt rocks from Mahak and surrounding area, Kohistan arc, north Pakistan. Geological Bulletin, University of Peshawar 23, 27-43.

The various rock types of Mahak are medium- to coarse -grained amphibolites, hornblendites, hornblende pegmatite, diorites, meta-gabbro, metapyroxenite and quartzo-feldspathic veins and dykes. Amphibolites are most abundant rocks of the area. These are distinguished into epidote amphibolite and plagioclase amphibolite. The major element chemistry of the amphibolites suggests their derivation from a basic igneous parent of tholeiitic character,

but field data also indicate some of them to be hybrids having been developed as a result of reaction between hornblendites and the granitic magma. The true amphibolites contain mineral assemblages indicating amphibolite grade metamorphism followed by the prevalence of epidote amphibolite facies and a minor phase of green schist facies environments. Hornblendites are usually monomineralic. Two types of hornblendite occur, i.e. (a) pre-granitic and the common ones and (b) sys-granitic. Field and laboratory data show that the former types may be representing early cumulate for the basic amphibolites or rocks having been formed in the loci of fluid phases during the amphibolite grade metamorphism. However, field evidence show that the sys-granitic hornblendites are the product of reaction between amphibolites and the granitic magma.

Key Words: Petrology, amphibolites, Mahak, Kohistan Arc.

H/17. Hamidullah, S. & Hussain, I., 1990. Geochemistry and petrology of the southern amphibolite belt rocks from Mahak and surrounding area, Swat, North Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, p.24.

Part of the amphibolite belt rocks around Mahak area in upper Swat has been investigated for petrogenetic interpretation. The petrology of the rocks indicates their production as a result of the combined igneous, metamorphic and metasomatic activity. The major igneous activity was followed by amphibolite facies and green schist facies metamorphism, indicating retrogression. Limited metasomatic and/or igneous activity took place together with or followed by the major metamorphic episode.

Key Words: Petrology, Amphibolites, Mahak, Kohistan Arc.

H/20. Hamidullah, S., Jabeen, N., Bilquees, R. & Jamil, K., 1986. Geology and petrology of the Malakand granite, gneiss and metasedimentary complex. Geological Bulletin, University of Peshawar 19, 61-76.

The Malakand granite intrudes a series of low-grade metasediments and granitic gneisses. It appears to be Calc-alkaline in characters. A temperature range of c. > 875-6500C and PH_2O of c. 5 <5 kb has been suggested for the development of various phases in the granite. The chemical features and age relationship also indicate that the Malakand granite is not genetically related to the alkaline igneous complex of the Peshawar Plain.

Three types of gneisses have been distinguished; a) siliceous gneiss, b) silica-rich granitic gneiss and c) normal granite gneiss. Among these only the normal granitic gneiss seems to be genetically related to the Malakand granite. The metasediments indicate several episodes of regional metamorphism ranging from lower green-schist facies to upper green-schist facies environments. The presence of garnet in schist at the contacts of granite has been related to the thermal effects of the intruding granitic magma.

Key Words: Petrology, granite, gneiss, Malakand.

H/21. Hamidullah, S. & Jan, M.Q., 1986. Preliminary petrochemical study of the Chilas complex, Kohistan island arc, northern Pakistan. Geological Bulletin, Univ. Peshawar 19, 157-182.

The Chilas complex, stretching more than 300 km and reaching 40 km in width, consist predominantly of gabbro-norites with minor pyroxenites, anorthosites and quartz diorites containing labradorites / andesine. Within these are found upto 4 km², seemingly intrusive, masses of dunite-peridotite-troctolite-anorthosite association characterised by the presence of bytownite / anorthite. Sixty four new chemical analyses reflect a genetic relationship among the various rock types. The data suggest crystallization from an arc-related parent magma of calcalkaline character. The oxides vs. D. I. And CMAS plots indicate olivine, orthopyroxene, and plagioclase as the dominant liquidus phases for the development of rocks varying from ultramafic through mafic to intermediate compositions. It is concluded that crystallization occurred possibly at a depth of < 25 km followed by pyroxene granulite facies metamorphism. This was followed by widespread amphibolitisation during uplift. The masses of ultramafic and related rocks appear to be early cumulates that were remobilized and emplaced into the main gabbro-norite association.

H/22. Hamidullah, S., Jan, M.Q. & Khan, Barkatullah, 1992. Petrography of the Deosai volcanics, N, Pakistan. Geological Bulletin, University of Peshawar 25, 17-22.

The western extension of the Dras volcanics in the Deosai plateau is made up of agglomerates and tuffs together with flows comprising basalt, andesite and some rhyolite. The flows appear to have evolved from a basaltic magma, with opaque oxide, clinopyroxene, hornblende and plagioclase, respectively appearing on the liquidus. These have been metamorphosed under greenschist facies conditions and may contain abundant epidote, chlorite and secondary amphibole. An ⁴⁰Ar / ³⁹Ar age of 1125.4 ± 6 Ma on hornblende phenocrysts in an andesite is in agreement with the Late Jurassic to Cretaceous age of the Dras volcanics.

Key Words: Petrography, volcanics, Deosai, Baltistan.

H/27. Hamidullah, S. & Khan, M.J., 1993. Two clinopyroxenes from Upper Swat: Their chemistry and its petrogenetic implications. Geological Bulletin, University of Peshawar 26, 35-43.

Two sets of clinopyroxene analyses, one from the andesites of Utror volcanics and other from a troctolite patch in diorite from Deshai, Upper Swat, are used to ascertain the magmatic affinity and tectonic setting of their host rocks. Both the sets indicate igneous crystallization in island arc-related orogenic environments. Clinopyroxene data from the volcanic rock indicate calcalkaline affinities, while, those from troctolite appear to have grown from tholeiitic magma.

H/28. Hamidullah, S. & Onstot, T.C., 1992. $^{40}\text{Ar}/^{39}\text{Ar}$ evidence for late Cretaceous Formation of the Kohistan Island Arc, NW, Pakistan. Kashmir Journal of Geology 10, 105-122.

Hornblende, biotite and plagioclase separates from Kalam-Dir igneous complex, Kohistan Island Arc, NW Pakistan, have been analyzed by the $^{40}\text{Ar}/^{39}\text{Ar}$ technique. Hornblende from the volcanics and diorite plutons of Gabral (near Kalam) and Dir areas and biotite from tonalite at Matiltan yield dates ranging from 74 to 54 Ma, whereas other biotite and one of the plagioclase separates from the diorite plutons at Gabral yield 44 to 39 Ma plateau dates. Plagioclase from another diorite of Gabral and one from the ultramafic rock unit of Mahodand are contaminated by excess argon.

These date indicate that the Late Cretaceous to Early Eocene period was dominated by calc-alkaline plutonic magmatism (represented by diorites) accompanied by a short span of calc-alkaline volcanism (Kalam-Dir volcanics) at about 70 Ma, in the northern Swat and Dir areas. The ages increase progressively southward. Each major magmatism and/ or volcanism has caused high-grade metamorphism of already crystalline rocks in the south. The culmination of magmatism in the Kalam-Dir area at 54 Ma probably resulted from the collision of the Kohistan Island Arc with India.

The 45-39 Ma dates of the biotite and plagioclase from the diorites of Gabral reflect a middle Miocene to Oligocene metamorphism followed by cooling due to uplift and erosion in the area, and may represent the after-effects (extensional environments) of collision of Kohistan Island Arc with India. Alternatively, they may reflect the collision of the combined Indian and Kohistan Arc plates with that of Eurasia (along the MKT).

Key Words: Geochronology, Ar/Ar dates, Gabral diorite, Utror volcanics, Kohistan island arc.

H/29. Hamidullah, S., Saifullah, M. & Shah, M.T., 1997. Heavy metals concentrations in the soils of Peshawar metropolis. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p.16.

H/31. Hamidullah, S., Saifullah, M. & Shah, M.T., 2000. Heavy metal pollution in soils of Peshawar city, NWFP, Pakistan. Geological Bulletin, University of Peshawar 33, 1-9.

Soil samples from 10 locations in Peshawar city have been analyzed for heavy metals including Cr, Co, Ni, Cu, Zn, Fe and Pb in order to evaluate the impact of heavy metals pollution reported earlier in the air, surface clay and sewerage system of Peshawar city by Hamidullah et al., (1997). It is concluded that heavy metals found in the dust fall of the city 012 the roadsides have so far not reached the soil horizon. The relative enriched Cr in the soils

compared to the heavy metals data of the corresponding air samples, reported earlier, has been attributed to the source material including the rock of the Main Mantle Thrust and Kohistan Island Arc. Higher Fe in these soils has been attributed to the process of soil formation. It has been warned that though heavy metals do not directly percolate into the soil horizon within the city at an alarming rate, these metals make their way from surface through the sewerage system of the city and via Budni Canal to Kabul River which is the feeder of the underground water system in Peshawar Basin. The indirect potential threat of heavy metals pollution to the subsurface strata of the basin does exist and needs to be blocked.

Key Words: Heavy metal, pollution, Peshawar.

H/32. Hamidullah, S. & Shah, M.T. 1993. Textural and minerachemical significance of hornblendes from an andesite at Dir, Kohistan arc, N, Pakistan. Geological Bulletin, University of Peshawar 26, 45-58.

Petrography and minerachemical features of a hornblende andesite from Gira Khwar, northeast of Dir proper, are studied to envisage the crystallization mode of hornblende phenocrysts, in the rock. It is determined that the cores of the hornblende phenocrysts are primary igneous. On the other hand the bluish green rims of these phenocrysts and probably the groundmass hornblende are a product of subsolidus re-equilibrium and or metamorphic recrystallization. The very tips of the hornblende phenocrysts appear to have recrystallized during shearing and cataclasis at a latter stage.

Key Words: Petrography, mineral chemistry, andesite, Dir, Kohistan arc.

H/33. Hamidullah, S., Shah, M.T. & Khan, M.A., 1996. Identification and characterization of the quality of silica sand resources from Munda Gucha, district Mansehra, in glass making. Geological Bulletin, University of Peshawar 29, 59-68.

The silica sand deposit of Munda Gucha area occurring in the quartzose rock of Tannawal Formation, district Mansehra, has been mapped and sampled for identification and characterization of its quality for glass making. Petrographic, geochemical and field studies show that the Munda Gucha silica sand deposit has tremendous potentials as a source of silica sand for glass, steel, soap and ceramic industries. With previous studies suggesting inferred reserves of 70 million metric tones and an average SiO₂ between 90-95 %, the present data has enhanced the average SiO₂ to 95.21%. Samples collected from the snow white zone of Bela Sukian block along Munda Gucha-Jacha road have maximum SiO₂ content of 99.7 % and those from Mohri have 98.84 %, providing to be useful in manufacturing of first quality optical glass. On the basis of grain size (0.3-0.5 mm in diameter) the Munda Gucha silica sand stands the best standard known in Pakistan. It is concluded that the deposit has tremendous potential as source of silica sand for glass, steel, soap and ceramic industries. Simple or very dilute acidic washing is suggested for the removal of tFe₂O₃ because of its occurrence as surfacial iron leaching.

Key Words: Economic geology, Silica sand, Munda Gucha, Mansehra.

H/34. Hamidullah, S., Tariq, S., Saifullah, Khan, M.S., 1999. Environmental studies in and around Peshawar Metropolis with special reference to heavy metals pollution. H/35. Hamidullah, S., Tariq, S. & Shah, M.T., 2001. Soil pollution in the western part of Peshawar basin. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.45.

Nineteen samples from horizon A (0-20 cm depth) and 18 samples from horizon B (20-45cm depth) of the soils from various spots of the western part of Peshawar basin were analysed for major elements, certain trace elements and heavy metals in order to (a) compare these soils with soils from other parts of the world, (b) determine if any

contamination is existing and (c) to identify the source of such a contamination. The data show that SiO_2 , Al_2O_3 and Fe_2O_3 stand normal in these soils. MgO , CaO , Na_2O , K_2O , and P_2O_5 of these soils are however, higher than the limits given for normal soils by the United States Department of Agriculture (USDA, 1957). Similarly, heavy metals including Cu, Pb, Ni and Cr are high in these soils when compared with international limit. The reasons for high concentrations of CaO , Na_2O , K_2O are water logging and salinity arid for high MgO , Cu, Ni and Cr, the availability of source material in the nearby Skhakot Qua ultramafic complex. Similarly, the high concentration of P_2O_5 may also be due to the presence of this element in the P_2O_5 bearing rocks at the northern extremities of the basin at Selai Patai (Malakand - Mohmand junction) or the overuse of phosphate-bearing fertilizers in the agricultural practices. The source of Pb in soils at certain locations may be both i.e. source rocks and industry.

Key Words: Soil pollution, Peshawar.

H/36. Hamidullah, S., Zahid, M. & Majid, M., 1991. Mineralogy and mineral chemistry of the amphibolite belt and Main Mantle Thrust Rocks from Gantar area, Allai Kohistan, north Pakistan. Geological Bulletin, University of Peshawar 24, 133-146.

Petrographic and mineralogical studies are performed for the Kohistan island arc, MMT mélange zone and Indian plate lithologies at Gantar village and in its surroundings, in Allai Kohistan, Hazara. Petrographic studies reveal that locally, the Kohistan island arc lithology is exclusively comprised of amphibolites and epidote amphibolites with certain patches of hornblende pegmatites. The MMT mélange zone includes greenschist and blueschist whereas the Indian plate sequence is made up of a variety of schistose rocks and siliceous marble. Petrography and mineral chemistry indicate that amphibolites have an igneous parentage and have undergone successive metamorphic episodes of amphibolite facies, epidote-amphibolites facies and greenschist facies, in a temperature range of $530 \leq 500^\circ\text{C}$ and a pressure range of $6 \leq 4.5 \text{ kb}$, whereas the MMT mélange zone rocks show signature of amphibolite facies, blueschist facies (7kb) and greenschist facies metamorphic episodes. The hornblende pegmatite patches in amphibolites are interpreted as products of low pressure metasomatism, on the basis of lower viAl content in hornblende as compared to that in amphibolites. Small outcrops of metagabbro and metanorite found in the area are regarded as part of the island arc system, on the basis of their clinopyroxene chemistry. Structural, petrographic and mineral-chemical features indicate a subduction-obduction related petrogenesis for these rocks.

Key words: Mineralogy, chemistry, amphibolite, MMT, Allai Kohistan.

H/38. Hammarstrom, J.M., 1989. Chemistry of emeralds and some associated minerals from Pakistan and Afghanistan; An electron microprobe study. In: Kazmi, A.H. & Snee, L.W. (Eds.), Emeralds of Pakistan: Geology, Gemology and Genesis, 125-150. Van Nostrand Reinhold, New York.

An electron microprobe was used to study a suite of nine emerald samples representing four separate occurrences of gem-quality emeralds from northwestern Pakistan and neighboring Afghanistan. The study was undertaken to characterize the chemistry of the emeralds of the region, to compare the emeralds with emeralds from other locations, and to investigate local variations in composition. The results of the study could help unravel the complex and unusual parageneses of these deposits, and ultimately could aid in refinement of exploration techniques. The study also includes data for (1) green vanadian beryls from the Mohmand emerald district, (2) green chromium-rich tourmalines from the Swat emerald district, and (3) minerals in the carbonate host rock at Mingora. The electron microprobe technique allows nondestructive chemical analysis of discrete spots across a single crystal and is useful in the study of minerals.

This technique can determine transition metals responsible for color and can identify compositional zoning within single grains. The principal disadvantages of the technique are that elements lighter than fluorine (atomic number 9)

cannot be determined and that different oxidation states of elements such as iron cannot be distinguished. Thus, we do not report data for beryllium, a major constituent of emerald; lithium and water, which can occur in emeralds in amounts up to several weight percent; and boron, a major constituent of tourmaline.

H/41. Hamood, O., 1992-93. Tectonics and structure of Timargara-Lal Qila-Wari areas District Dir N.W.F.P. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 265p.

The structural geological mapping of 673 sq. km area of Timargara, Lal Qila and Wari areas District Dir N.W.F.P was conducted along with structural, petrographical economic geological studies. The area lies in the western extremity of Kohistan Island Arc where the Mesozoic amphibolitized ocean floor Kohistan Island arc are sutured to the Shamoza Green schist mélange which is under thrust by gneisses of Indian plate.

The amphibolites exposed in the southern and northern extreme of the mapped area were the parts of a single ocean floor under which the arc was built. These amphibolites were formed by the metamorphism of basic volcanics and pillow lavas of tholeiitic affinities, and subordinate interlayered sediments of argillaceous, arenaceous and carbonate composition. The sediments were deposited on ocean floor along with lavas at mid oceanic ridge (MOR). The concentration of metasediments in the southern exposure is relatively less and thin as compare to northern part of amphibolite where thick piles of these sediments were evident. The amphibolites exposed in the project area are different from Kamila amphibolites which were formed by the metamorphism of basic plutonic rocks. The Kamila amphibolites represent the base of Kohistan Island Arc and are exposed near or, around Nangaparbat syntaxis due to uplifting and uncovering of base rocks. Whereas Dir amphibolites represent the supra crustal material of Kohistan Island Arc under which the arc was built. The southern part of Dir amphibolites are dominantly composed of fresh and altered plagioclase 20 to 38 % (altered to seracite, koalinite, epidote and chlorite) amphibolites hornblende 10 to 61 %, actinolite 15 to 15.5 %, tremolite 1 to 5 %, cummingtonite 1 to 6 % but in shear zones its amount is 17 to 30 %, and athophylitic 1 to 5 % and quartz 2 to 50 %. Carbonate metasedimentary layers with in these amphibolites contain calcite 10 to 25 % and siderite 18 %. Whereas biotite 18 % and garnet 6 % is found in meta argillaceous and arenaceous layers. The northern part of Dir amphibolites are mainly composed of fresh and altered plagioclase 3 to 47 % (altered to seracite, kaolinite, epidote and chlorite), amphibolites (dominantly hornblende 1 to 68 %, actinolite 2 to 52.5 % and quartz 3 to 65 %). The carbonate metasediments in these amphibolites contain 8 to 20 % calcite, whereas biotite is 0.52 to 31 % and garnet is 30 to 33 % (in two samples) in meta argillaceous and arenaceous part of these amphibolites.

From the geochemical studies of Dir amphibolites the major elements which were determined are SiO₂ (38.06 to 64.26 wt%), TiO₂ (0.07 to 1.3), Al₂O₃ (3.34 to 19.54), Fe₂O₃ (5.25 to 12.56), MnO (0.16 to 0.28), MgO (0.84 to 15.50), CaO (5.58 to 20.70), Na₂O (0.03 to 5.0), K₂O (0.17 to 1.44), P₂O₅ (0.01 to 0.20) and Cr₂O₃ (0.01 to 0.41 wt%). The trace elements are Ba (38 to 120 ppm), Ni (42 to 138), Sr (116 to 182), Zr (25 to 66), Y (12 to 20), Nb (10 to 24) and Sc (24 to 31 ppm).

The plutonic rocks exposed in the area consist of norite, gabbro-norite, diorite, tonalite, trondhjemite, granite/adamellite and quartz porphyries/aplites/ pegmatites are intruded in the Dir amphibolites and were exposed due to uplifting and uncovering of amphibolites. But the presence of small and large roof pendant of amphibolite in these plutonic rocks (which previously called xenoliths and screens of amphibolites) evident the presence of amphibolites over there.

The petrographic studies of plutonic rocks show that there is gradational change in mineralogy from norite/gabbro-norite towards diorite. The amount of quartz increases further from diorite (13.40%), tonalite (20%), trondhjemite (51.5%) to granite (54.1%) and adamellite (59.3%).

The amount of major elements determined from chemical analysis varies from norite/gabbro-norite to acidic bodies as SiO_2 (52.78 to 70.54 wt%), Fe_2O_3 (9.62 to 1.53), MgO (6.08 to 0.59), CaO (8.06 to 2.7), Na_2O (3.11 to 3.34), and K_2O (0.51 to 3.82 wt%). Whereas TiO_2 , Al_2O_3 , Cr_2O_3 does not show any remarkable variation. MgO , Fe_2O_3 , CaO and Al_2O_3 decreases with increase of SiO_2 towards tonalite and acidic bodies.

Generally three types of ultramafic rocks are exposed in the mapped area. The first type of ultramafic are highly altered and metamorphosed. These ultramafic rocks are present as exotic blocks in amphibolites. The second type which are present as roof pendant over the surface of some plutonic rocks (i.e. granite adamellite and diorite). These ultramafic were emplaced in oceanic crust (amphibolites) during its development at MOR. The third type of ultramafic which are mostly hornblendites and schelites are exposed both in amphibolites and plutonic rocks, were probably fractionated from the hydrous magma produced due to the partial melting of Indian plate and ascended to higher levels due to buoyancy acquired by their magmas as a result of residual liquid enrichment. Structural studies show that the rocks of Kohistan Island Arc exposed in the area are folded into northward dipping southward verging tight folds in the south (near MMT) which opens up northwards. The amphibolites have undergone at least two phases of isoclinal folding. In the first phase of recumbent or isoclinal folding S_1 axial planar foliation was developed in these rocks. The first phase of deformation is probably related to the subduction of Kohistan Island Arc under Eurasian plate. In the second phase these rocks were again folded. The second phase is probably related to the subduction of Indian plate under Kohistan. The rocks of Kohistan Island Arc have undergone a third phase of deformation which produced in the shear zones and a retrograde metamorphism of chlorite grade along shear zone which is most probably related to the collision of Indian plate with Kohistan Island Arc.

The southern part of Dir amphibolites near MMT mostly trend EW and dips 65° to 80° northwards, which is almost parallel to the trend of MMT. In the central portion of the mapped area, the plutonic rocks trend NE to SW and their dip varies from 40° to 70° NW and SE most of the fold axes in plutonic sequence are parallel to each other which mostly trend NE to SW and plunges from 12° to 50° . The northern part of Dir amphibolites mostly trend NE and dips 15° to 60° SE.

The economic significance of rocks of the project area was also studied. Geotechnical properties of Balambat norite, Panjkora diorite and hornblendite were analyzed and found that these rocks could be used as dimension stones as well as aggregates and building material.

H/42. Haneef, M., Jan, M.Q. & Rabbi, F., 1986. Fracture fills or "sedimentary dykes" in the lake sediments of Jalala, NWFP. A preliminary report. Geological Bulletin, University of Peshawar 19, 151-156.

Quaternary lake sediments of Jalala in Mardan District are intersected by discordant structures which have been described as clastic dykes by Allen (1964). These sediments consist of horizontal, alternate beds of clay, silt and sand with local pockets of erratics. Poor sorting, angular to subangular shapes of the grains, and varied mineralogy indicate short distance of transport. Metasediments, amphibolite and granitoids are among the possible source rocks. Field evidences indicate that episodic tectonic activity produced fracture in the sediments which were filled by the plastic flow of clayey material from the overlying beds.

The geological and the structural mapping of Aghar, Gulpur and Nar areas of about 200 square kilometers was carried on the scale 1: 50,000 using the Toposheet No.43 G/15 of Survey of Pakistan. Then it was enlarged to the present scale 1: 18750. The lithostratigraphic units exposed in the area are mainly sedimentary in nature and range in age from Upper Miocene to Pliocene. These units are the Nagri Formation (Upper Miocene) and the Dhok Pathan Formation (Pliocene) of Siwalik Group of rocks. The Siwaliks are the molasse sediments which were derived from the upthrust mountain ranges of the Himalayas and adjoining foredeep area. The rocks of the area have been deformed during the two phases of deformation named as D1 and D2. D1 deformational event is related to F1 folds. F1 folds are the major anticlines and synclines of the area. These are Barali Anticline, Gulpur Syncline and Nar Anticline. F2 folds are formed during the second phase of deformation D2 due to change in plunge of F1 folds. About fifty rock samples were collected from different localities of the project area out of which twenty samples were selected for the petrographic studies. Tectonically, the Siwaliks lie in Sub-Himalayas and the project area is situated on the southern side of the Himalayan region, where the Siwaliks are deposited in the foreland basin. This foreland basin was formed in association with the collision of the Indian and Eurasian plates.

The Shigar Valley is crossed by a large, southwest-verging reverse fault containing pods of serpentized ultramafic rock; the fault is correlated with the Northern Suture, which separates Paleozoic shelf-type sedimentary rocks of the Asian plate from Cretaceous volcanic rocks of the Ladakh-Kohistan arc. In the Shigar valley, the Asian plate is represented by a series of folded schists and marbles (the Daltumbore Formation) that is faulted southward over metasedimentary rocks and volcanoclastics (the Bauma-Harel Formation) belonging to the volcanic arc. Cretaceous turritellid gastropod fossils were found in the Bauma-Harel Formation. Metamorphism on both sides of the suture

occurred in a regime of high temperature but only low to moderate pressure. Metamorphic isograds are cut by the suture, so metamorphism must have occurred before faulting along the suture. Two main phases of igneous intrusion are exposed in the arc terrane: a pre-tectonic, possibly tholeiitic phase about 100 m.y. old, and a post-tectonic, calc-alkaline to subalkaline phase 40 to 60 m.y. old. The Northern Suture does not have the appearance of a major suture, but the Ladakh-Kohistan Arc seems to have been a separate plate from the Asian continent. The suture probably marks the closure of a small ocean basin in late Cretaceous to early Eocene time.

H/52. Haq, I., 1999. Geology and geochemical investigation of the part of Ushiri valley, Distt. Dir, Northern Pakistan. M.Phil. Thesis, University of Peshawar, 215p.

The study area is lying in the north-western portion of the Kohistan arc terrane. This terrane is bounded by two suture zones of regional extent at its northern and southern sides, believed to be formed by obliteration of ancient oceanic basin. The Kohistan arc consists of a series of east-west trending geological units, which are:

1) Jijal Ultramafic Complex, 2) Kamila Amphibolite, 3) Chilas Complex, 4) Chalt Volcanic Group, 5) Yasin Group and 6) Kohistan Batholith. This arc experienced its first collision at its northern margin with the Karakorum plate at 90-80 Ma, and its second collision at the southern margin during Early Eocene with the Indian plate. Rocks of the area are distinguished into two main lithological units: (1) Amphibolites and (2) Metadiorites/Metagranodiorites. The amphibolites occupy the southern part of the studied area while metadiorite/ granodiorites are exposed in the northern part of the area. Both these rock units have intrusive contact and exhibit local faulting and shearing. The amphibolites also host small patches of gabbro-norites which are less metamorphosed. The amphibolites are generally massive but also exhibit banding at places. These amphibolites are intruded by quartz and quartzofeldspathic veins especially in areas where the shearing and faulting are intense. The amphibolites are also intruded by the metadiorite/granodiorite in the form of small plugs. The metadiorites/granodiorites are medium to coarse-grained, massive in character and have xenoliths of amphibolites. Copper mineralization in the form of disseminated grains of tetrahydrite and chalcopyrite and supergene enriched in the form of malachite and azurite occur within quartz veins in limited areas. Petrographically the amphibolites are mainly composed of hornblende and plagioclase with subordinate amount of quartz and alkali feldspar. Biotite, muscovite, chlorite, epidote, apatite, sphene, rutile, calcite and opaque occur as accessories. The metagabbro-norites contain plagioclase, orthopyroxene and clinopyroxene, as the dominant mineral constituents. Quartz, sphene, apatite, chlorite, epidote and opaque are present as minor constituents. The metadiorite, quartz-diorite and metagranodiorite are dominantly composed of plagioclase with variable proportion of quartz and alkali feldspar. The other minor constituents include biotite, hornblende, muscovite, apatite, sphene, zircon, garnet and opaque. Chemically the amphibolites and metagabbro-norites are comagmatic. Their chemical characteristics favour the igneous parentage (i.e., host gabbro-norite) for the studied amphibolites. Both the amphibolites and gabbro-norites could be related to either Kamila amphibolites belt or Chilas Complex. The major and trace elements study of these rocks suggests that these are of calc-alkaline nature and are formed by the arc magma within the subduction related environment. The chemical characteristics of the granitoid rocks (metadiorite/granodiorite) suggest that these are comagmatic and have close affinity towards the calc-alkaline rocks, developed in island arc type of set up. The mineralogical and geochemical studies of the stream sediments (both pan concentrate and -80 mesh) suggest that the area has no anomalous zone of base and precious metals which could be attributed to the specific mineralization in the area.

H/55. Haq, S.S.B. & Davies, D.M., 1997. Oblique convergence and lobate mountain belts of western Pakistan. Geology 25, 23-26.

The thin-skinned structures of the Pakistani convergent margin have formed as a consequence of the relative motion between India and Eurasia. Most of the resultant motion is being accommodated along or near the current edge of the Eurasian plate: the southwest-northeast striking Chaman fault zone. It has been observed at oblique margins that the total plate motion is resolved into a component parallel to the margin, accommodated through strike-slip faulting, and a component normal to the margin taken up as contraction. However, the orientations of structures along the Pakistani convergent margin in and around the Sulaiman lobe and Sulaiman Range cannot be explained simply by resolving the plate motion vector into components normal and parallel to the plate boundary. Our modeling suggests that the complex juxtaposition of strike-slip faults with thrust faults of various orientations can be explained by the presence of a block centered upon the Katawaz basin that translates along the southwest-northeast structural barrier of the Chaman fault zone, moving with respect to both Eurasia and India. As this relatively rigid block moves northeastward relative to Asia, it causes deformation of the sedimentary cover and is responsible for much of the structural complexity in the Pakistani foreland. Our simple model explains several first-order features of this oblique margin, such as the eastward-facing Sulaiman Range, the strike-slip Kingri fault (located between the Sulaiman lobe and Sulaiman Range), and the reentrant at Sibi. This leads us to conclude that very complex structural and geometric relationships at oblique convergent plate boundaries can result from the accommodation of strain with simple initial geometric constraints.

H/56. Haq, Z., 1990-91. Geology and petrography of Kundal Shahi, Thunian, Thod and Balkand area Neelum valley, District Muzaffarabad (A.K.). M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 92p.

The Project area is located in district Muzaffarabad (A.K), it covers about 200 Sq. Km the part of topographic sheet-No. 43 F/I3 and 43 F /14 published by survey of Pakistan.

Geological map at a scale 1:15000 from Kundal Shahi to Balkand area is presented. The area includes Salkhala Formation/Tanol Formation. On the basis of field observation and Petrographic studies the rock units are interpreted accordingly. The rock units exposed are the metasediments of the Precambrian age with sheet intrusives. These intrusives are from granite to pegmatitic in nature and composition, pelitic to psammitic and furthermore calc silicates are also present in the northern side of area. The metasediments are under normally prograde metamorphism towards north. While some effects of retrogressive metamorphism are also observed. The mineral assemblage lies from green schist to lower amphibolite facies.

H/61. Haque, S.M., 1974. Geology of the Balambat quadrangle (Toposheet No. 38 N/13), District, Dir, West Pakistan. Geological Survey of Pakistan. Information Release No. 81, 34p.

The Balambat quadrangle (38 N/13) covers about 250 square miles of mountainous terrain in Dir state in the north western part of West Pakistan.

The quadrangle is underlain by metamorphic and igneous rocks, comprising four main rock types, i) quartz-feldspar-biotite schist with interlayers of metamorphosed limestone, ii) amphibolite, iii) rocks of diorite group and iv) series of pegmatite-aplite dykes cutting the amphibolite and the diorite group rocks.

The amphibolite is well foliated and has quartzite and gneissic interlayers and inclusions of granitic rocks. It is conformable and gradational with the quartz-feldspar-biotite schists. The diorite group of rocks intrusive into the amphibolite consists of varieties of diorite and granodiorite and hornblendite. Bulk of this group has been metamorphosed. The amphibolite has been folded into a major syncline trending east-northeast. Foliation and mineral lineation form very characteristic structural features of the rocks. Foliation is well developed in the schist and the amphibolite, and weakly developed in the diorite.

Few folds, observed, are small and partially exposed. They are similar folds moderately open to tightly appressed and appear to belong to a single fold system. Microfolds and ptygmatic folds, which commonly characterize the amphibolite, have presumably resulted from the effect of metamorphic flowage. Very few faults have been observed. They are in part parallel with foliation, which are shear faults, and in part transverse to the foliation.

A structural analysis by plotting the recorded foliation, and lineation has been attempted. The results in general confirm the field observation and lead to the following conclusion.

1. The quadrangle area is occupied by a large syncline trending ENE-WSW.
2. The preexisting structure has not been substantially affected by particular deformation producing
3. In a large part the folds are more or less isoclinal
4. In part of the area the folds are reclined type.

Showings of pyrite chalcopyrite and bornite? As disseminated in quartz-feldspar dykes and at a place beryl in a pegmatite dyke were noted. Small occurrences of kaoline resulting from weathering of feldspar rich portions of pegmatite are common in some parts. No pattern of mineralization could be established.

Key Words: Geology, Balambat.

H/62. Harding, R.R. & Wall, F., 1987. Blue spinel from Hunza valley, Pakistan. Journal of Gemmology 20, 403-405.

The spectral features of the blue spinel from Hunza valley are described. The crystals occur as single or twinned octahedral. The mean of nine probe analyses is SiO₂ 0.05, TiO₂ 0.18, Al₂O₃ 69.3, Cr₂O₃ 0.73, V₂O₃ 0.05, FeO 3.75, MnO <0.05, MgO 24.6, ZnO 0.35, CaO < 0.05, NiO < 0.05, = 99.01. The presence of Ti and Cr in addition to Fe is probably responsible for the colour.

H/66. Hasan, B. & Khan, S.A., 1986. Possible impact of plate tectonics on Basha Dam Site. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, 26-27.

The Basha Damsite is proposed on the Indus River 314 km upstream of Tarbela and 40 km downstream of the town of Chilas. It will be a 660 feet (200m) high Dam, constructed of earth and rock with a central core and concrete cut off to bedrock. It will store 7.3 MAF (9.3 km³) of water and would generate 2400 MW of power. Rocks exposed at site are predominantly igneous complex, comprised mostly of Norite with subordinate Peridotite and Hornblendite.

The Main Mantle Thrust, which forms the Northern boundary of Indian Plate, is located at a distance of about 30 Km to the south of Basha Dam Site and dips towards Basha. The Northern Megashear passes East to West at the Southern boundary of Eurasian plate. The plate tectonics and associated structures could possibly affect the design of the dam seriously. In the present state of the art the seismic factors are evaluated for maximum credible earthquake (MCE) and operation basis earthquake (OBE). The structure which could create great hazards to human life on their failure are designed on the MCE, while others are designed for OBE. For this purpose it is pertinent to evaluate all the major fault of the area including the plate tectonics.

The Indus river occupies a broad valley between Raikot and the dams site which is filled with sediments upto a considerable depth. Faults could also be present under the alluvium, Raikot fault on which several hot springs are present, is located in the upstream area of the reservoir. The Raikot fault and possible buried faults could get activated under Basha reservoir water load and seepage water penetrating into the fault planes and induce higher seismicity.

Any storage project on the main stem of Indus cannot be constructed unless all the aspects having bearing on the safety of the dam are evaluated. For this purpose it has to be ascertained that no major event of catastrophic nature will occur during the life of the project or if so, correct provisions are made in the design. The paper details broadly the possible effect of the plate tectonics and associated geologic features on the proposed dam-site.

Marine phosphorite deposits of Cambrian age are located in the NW of Pakistan on the flanks of the structurally complex Hazara-Kashmir syntaxis. Phosphorite deposits are developed at two horizons within the bedded cherty dolomite of the Abbottabad formation and a horizon within the shale and siltstone of the overlying Hazira formation.

The phosphorite is partly siliceous, generally granular, but also dense and laminated, and dark in colour. The Phosphate content ranges 10-30% P₂O₅ and reserves of phosphate rock are estimated at 22.9 million tones. The deposits will be difficult to mine because of extensive faulting and folding.

The investigated area lies in the toposheet No.43 F/4, 30 km west of Abbottabad town. The work was undertaken for studying and firming up the phosphorite deposits in the area. Phosphorite is developed in the basal beds of Hazira and upper most part of Abbottabad Formation. The lateral extension of phosphorite is about 750 meters with a variable thickness of 2-3 meters. The total probable reserves of low to medium grade are estimated at 4050 million metric tonnes with P₂O₅ ranging from 7 to 25 percent.

H/81. Hashmat, Z., 1970-72. Geology of Manarai Band area (Upper Swat). Institute of Geology, Punjab University, Lahore, M.Sc. Thesis, 57p.

Rocks of Manarai Banda area comprise metamorphic rocks making buttress of Himalayas. They are known to extend to form Dir and extend to Kalam.

Three different rock types are exposed within 50 miles² of area mapped.

Amphibolites have been metamorphosed to amphibolite grade; hornblende, epidote and in some garnet are very common. The group has a thrust faulted contact with the rocks of lower Swat-Buner schistose group. Ultramafic body is formed by the complete alteration of Peridotite bodies occurring in the surrounding area. The area is of some economic importance because of the occurrence of magnetite and corundum.

H/85. Hassan, B., 1984. Geo-technical problems for Kohala tunnelling. Abstracts, First Geological Congress, Lahore, 40-42.

The Jhelum River runs in a gorge throughout its journey in Azad Kashmir territory. It flows in North/Westerly direction while entering the area and follows the same direction upto Domel where it takes a very sharp turn to the South and continues in rapids towards Mangla where it debouches into the plains. Enroute it is joined by the waters of the Neelum and Kunhar. The river, in the upper arm of bend has a steep gradient of about 31 feet per mile which flattens to 13 feet per mile along its lower reach. Depending upon the respective locations on either side of the syntaxial bend a drop of 200 feet to 950 feet can be created and utilized for power generation, by linking both arms through 2 miles to 11 miles long transmountain tunnels.

As a result of preliminary design studies, four different alignments for topographic survey and geological investigations work were picked up. Further studies and field investigations narrowed to the most attractive choice for Barrage and Tunnel alignment near Dhani Village.

The scheme recently investigated envisages a low height diversion dam of 72 feet, about 9 miles Upstream of Muzaffarabad. The water would be diverted through two six mile long 24 feet finished diameter tunnels outfalling into Jhelum river, 13 miles downstream of Muzaffarabad. Natural drop of above 570 feet would thus be available and utilized to install 500 MW capacity. The project configuration also offers the possibility of integration with the upstream Neelum/Jhelum, diversion hydel project, which would substantially increase its power potential.

Regional Geological Framework

The project area occupies the axial zone of the "North Western Syntaxis". River Jhelum also takes almost 90° turn at Muzaffarabad shown by the change in its course from westerly direction upstream of Muzaffarabad to the south (downstream of Muzaffarabad). There are two more or less parallel thrust faults that warp around the syntaxis. These have been named as Punjab thrust and the Jhelum/ Murree faults. The syntaxis contains the youngest rocks

i.e. Murree formation in its core, successively older rock warp around the periphery. South of Muzaffarabad the Jhelum/Murree fault, passes at a short distance from Kohala power house area but has a steep dip ($70^{\circ} - 80^{\circ}$) towards east. The fault strikes N $30-50^{\circ}$ East. The area lying within the sharp bend of river Jhelum is a big synclinal structure with an anticlinal structure within it. This highly complex geology might have considerable influence on various engineering structures, particularly in the power tunnels area.

Geological Features along Tunnels Alignment; About 6 mile long, two tunnels are proposed for Kohala power generation. It is very difficult and expensive to do any sub-surface investigations in these tunnel alignments due to high relief and rough terrain. Hence only strip surface geological mapping has been conducted. It is difficult to project the geology at the tunnel level from the strip surface geological maps due to complex geology of the area. On the basis of the strip and regional geological mapping, it is interpreted that the major rock units of sandstone and shale will be encountered during the excavation of the tunnels. The physical & structural characteristics of sandstone and shale along tunnels have been inferred from the extensive drilling done, on nearby other projects in Murree formation. Number of adits have been done on similar rock units at Abassian Dam site. A number of rock mechanical in situ tests were also conducted in the adits, which would help in evaluating the design parameters for the proposed tunnels. However, it is very difficult to assess the proportion of the sandstone and shale which shall be encountered and its structural characteristics along the tunnel alignment. The study of aerial photographs and surface geological feature, it has been evaluated that tunnel alignment area is highly folded and faulted. Due to tight folding and faulting, it is difficult to predict the geological features of the area at tunnel elevation. Due to high rainfall, Snow cover in part of that area and the geological structure acute ground water problem is expected during tunnel excavation.

Anticipated Geological Problems

It is anticipated that foundation rock, particularly the sandstone shall be highly jointed and fractured due to tight folding in the area. Proper precaution and controlled blasting would have to be undertaken to reduce the excessive breakage during the excavation particularly in the jointed sandstone. It may also be necessary that the shale whenever excavated be immediately provided with supported and protective cover to protect against surface weathering. Acute ground water problem may be encountered during the excavation of the tunnel. As sandstone has interbeds of shale, the tunnel inlet and outlet areas should be excavated with care to avoid any possible slips along the weaker planes. The above problems will be explained during presentation of the paper with the help of maps/charts/photographs to elicit useful discussions.

Key Words: Engineering geology, Jhelum River, Kohala, Azad Kashmir.

H/86. Hassan, C.S., 1981-83. Geology and Petrology of Lower Yasin Valley Gilgit Agency. M.Sc. Thesis, Punjab University, Lahore, 85p.

This field report described the results of geological studies in area, extending Sher Qila to Gahkuch, in Lower Yasin Valley, Gilgit Agency. The enlargement from toposheet was prepared. On this map different units are shown as granite, diorite, amphibolite and paragneiss. The mineralogical description and petrographic analysis of these rock units are reported in detail. The petrogenesis of these rock units has been discussed as well.

The granite is considered to be a part of Karakoram axial granite, which is emplaced as partially fused and mobile mass rich in alkali feldspar during synthetic phase of orogeny. The diorite is probably tholeiitic basaltic magma injected into the pre-existing rocks, which were partially melted and assimilated. Decrease of calcic contents produced granodiorite during cooling. Green stone is product of regional metamorphism of basic igneous rocks.

Intense tectonic disturbance is evident from the frequent occurrences of strained and crushing effect on minerals. The area shows evidence of extensive mountain glaciation in the quaternary and glacial deposits are common. The economic mineral potential of the area is also discussed.

Key Words: Petrology, petrography, granites, diorites, Yasin valley, Gilgit.

H/87. Hassan, M., 1977. Oil and gas prospects of the basins of Pakistan. Geological Bulletin, Punjab University 14, 91-94.

The history of petroleum investigations in Pakistan is very old and can be traced back to the middle of 19th century. However, oil in commercial quantities was found in 1914 at Khaur, by the Attock oil company. Since then, several companies have carried out extensive survey of the country and exhaustive information on petroleum geology has been accumulated, though most of this work is not open to the public. Some of the works available are those of

Rahman (1963), Movshovitch (1968) Sokolov (1971) and others. Classification of areas of Pakistan into oil and gas and possible oil and gas basins has been worked out by these authors. Before proceeding further it will be plausible to understand the term "basin" and the sense in which it is being used in the present work. Olenin (1977) defines oil and gas basin as a geological body within the limits of a large element of the stratisphere which is structurally immersed as a whole relative to its limiting elements. Thickness, form and composition of the sediments forming this body and its hydrogeological characteristics guarantee in its generation and accumulating of dispersed hydrocarbons and conservation of pools of oil and gas.

H/90. Hassan, S., 1990-92. Geological mapping and evaluation of geotechnical and deformability, characteristics of building materials, Neelum valley, Azad Kashmir. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 62p.

Granitic gneisses, schists, Hazara slates, dolomite, marble, Panjal volcanics, Margalla Hill limestone exposed in various parts of Neelum valley Azad Kashmir have been investigated for geotechnical properties, chemical and petrographic characters to evaluate these rocks as building material. The physical properties like compressive strength, crushing strength, soundness, absorption, porosity and specific gravity observed in the rock samples of various localities have been found within the range of ASTM specification with few exceptions.

A modified classification has also been proposed on the basis of porosity and absorption percentages. Various grades of building materials have been made for economic exploitation of the rocks taking into consideration the accessibility, cheap labour and geographical control of the area. It is suggested that the marbles are presently being used as roadstone is not rational. The Panjal volcanics are still to be investigated as building material or roadstones, the gneisses are good decorative stones. The dolomites can be rationally exploited for steel manufacture. The rational use of limestones is in cement industry.

Key Words: Mapping, building material, Neelum valley, Azad Kashmir.

H/91. Hattori, K. & Shirahase, T., 1998. Platinum group element signatures of ultramafic-mafic rocks of the Kohistan block: evidence for crustal cumulate origin. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 76-77.

The Kohistan block in northern Pakistan near the India-China border is bounded by the Main Karakoram Thrust to the Eurasian continent and by the Main Mantle Thrust to the Indian continent, The east-trending, crescent-shaped block is interpreted to be a 100 Ma island arc within the Tethys ocean, which was accreted and uplifted during the Himalayan orogeny. The block consists of four units; ultramafic Jijal complex, Kamila amphibolite, gabbroic Chilas complex and volcanic rocks of Chalt complex in ascending order to the north. The Chalt complex is predominantly basaltic-andesitic volcanic rocks with intercalated sedimentary rocks. The Chilas complex consists of gabbro, gabbro-norite, norite and minor troctolite and dunite. The igneous rocks in the complexes show low concentrations of high field strength elements (HFSE) compared to large ion lithophile elements (LILE) indicating arc origin [1]. High ϵ_{Nd} (100 Ma; +5 to +6) and mildly low initial $^{87}\text{Sr}/^{86}\text{Sr}$ (≈ 0.70400 at 100 Ma; [2]) suggest derivation from a depleted mantle wedge. The Jijal complex consists of dunite, pyroxenite and websterite. The lithology and the

relationship with other units have suggested an origin as cumulates of arc magmas. However, there has been no geochemical evidence to support this interpretation because the incompatible elements that might have been useful for petrogenetic study have low contents in the ultramafic rocks. Also, alteration-metamorphism may have modified their trace element compositions. Thus the usual geochemical tools are not likely to be useful for identifying the origin of the ultramafic rocks. Ultramafic rocks, however, contain significant concentrations of platinum group elements (PGE; ruthenium, palladium, osmium, iridium, platinum, rhodium), which are diagnostic for the origins of the rocks.

Here, we report the concentrations of Re and PGE for the ultramafic and mafic rocks from the Kohistan block.

The concentration of PGE in Kohistan rocks are highly fractionated with low Os, Ru and Ir and high Pt, Pd and Re. Gabbroic rocks contain very low Ir-type PGE (Ir, Ru, and Os): less than 10 ppt Os and 50 ppt Ir. Even ultramafic rocks of the Jijal complex with high MgO (<30 wt.%) and Ni (<800 ppm) contain low Os (<0.13 ppb), Ir (<0.79 ppb) and Ru (<0.9 ppb). They are much lower than mantle rocks, which contain ~4 ppb Os, ~3 ppb Ir, and ~5 ppb Ru. The patterns of PGE, which are normalized to primitive mantle composition, show a deep concave shape: moderately high Ni, deep lows at Os, Ir and Ru and steep positive slope towards Pt (<0.5 times PM), Pd (<3 times PM) and Re. The total PGE contents show a broad correlation with the concentrations of Sr. Because Sr is an incompatible lithophile element, the correlation with siderophile and chalcophile PGE indicates a low sulphur concentration in the parental magmas. The results indicate that the ultramafic rocks in the Kohistan block are indeed cumulates of arc magmas, which formed by partial melting of a depleted mantle, under sulphur-unsaturated condition. The parental magmas did not reach sulphur saturation during cumulate crystallization. The PGE concentrations and patterns from the Kohistan ultramafic rocks are identical to websterite and dunite from the cumulates of the Jurassic Talkeetna arc in Southern Alaska [3]. Similar patterns of PGE and covariation with other lithophile elements from the two arcs appear to suggest that arc magmas are generally sulphur unsaturated during the partial melting in the mantle source and during crystallization in the lower crust.

To evaluate the Os isotope ratios of the arc magma, $^{187}\text{Os}/^{186}\text{Os}$ ratios were determined. They range from 1.19 to 1.55 ($^{187}\text{Os}/^{186}\text{Os} = 0.143\text{--}0.187$). The values are low, although higher than the depleted mantle value, $^{187}\text{Os}/^{186}\text{Os} = \sim 1$ ($^{187}\text{Os}/^{186}\text{Os} = \sim 0.120$). Although the precise initial ratios are difficult to determine due to probable mobility of Re, the data suggest that the subduction-related mantle metasomatism was accompanied by little enrichment of radiogenic Os.

H/92. Hayase, I., 1965. Age determination of a Karakorum rock. In: Matsushita, S & Huzita, K. (eds.), *Geology of the Karakoram and Hindukush. Results of the Kyoto University Scientific Expedition to the Karakoram and Hindukush, 1955*, Vol. VII, 149-150. Nippon Printing & Publishing Co., Ltd., Japan.

In Dusso area, granitic pegmatites commonly intrude granitic gneisses. This is a study of age determination on the whole rock sample of a pegmatite by Rb/Sr method and on its muscovite by K/Ar method. The Rb/Sr date is distinctly older (28 Ma) than the K/Ar date (4 Ma).

H/93. Hayat, A.M.S., 1968. *Geology of Balakot and Dadar Area*. M.Sc. Thesis, Punjab University, Lahore, 83p.

An attempt has been made to map the area in detail and as such, apart from drawing isogrades in different metamorphic units, their grades and types of metamorphism have been studied thoroughly. Contacts have been traced, followed and plotted in the case of the sedimentaries and their environmental conditions, correlation and age have been discussed and, structure pointed out. Granite, which occupies about one third of the area concerned, has been assigned a magmatic origin, due to certain definite field evidences (explained under granite). Great emphasis has been placed on structure, as the area lies at the tip of the Syntaxial bend, one of the greatest controversies of all times (Geological). Five stereographic projections have been provided in order to show the types of stresses prevailing in the area, clarified further by the two geological sections attached to the map and a special structural map included. Fifty thin sections have been studied under microscope, of which thirteen have been included in the report. Four faunas have also been described.

H/96. Hayden, H.H., 1898. On the geology of Tirah and the Bazar Valley. Geological Survey of India, Memoirs 28(1), 96-117.

This paper is compiled from notes made by me while attached to the Tirah Expeditionary Force, during the months of October to December, 1897. The area examined consists of parts of the country lying between the Samana range and the southern slopes of the Area examined portions of Khaibar) Chura and the Bazar Valley. Of this area, the geology was in part known from the survey made by Mr. Griesbach¹ in Previous observers. 1891, yet there still remained a considerable portion the geology of which could only be conjectured, and although the nature of the late expedition was such as to preclude the possibility of an exhaustive examination of the still unmapped country, yet the route followed by the troops crossing the strike of the strata at right angles-opportunity was afforded for an examination of almost the entire sequence of beds between the Samana range and the southern slopes of the Safed Koh. I propose to divide this paper into two sections: the first dealing with the country south of the Safed Koh and its eastern extension, the Surghar range, and the second dealing with the area lying north of those ranges. I.--The Area South of the Safed Koh. Orographically this area consists of four main mountain ranges parallel to one another and running almost due Orography. These ranges are separated by longitudinal troughs, but locally connected with one another by spurs trend 1 Vide his paper on "The Geology of the Safed Koh." Rec. G. S. I., Vol. XXV, p. 59. In the same paper will be found a list of the most important literature bearing on the subject.

H/99. Hayden, H.H., 1914. Notes on the geology of Chitral. Records geological Survey of India, 65, P.271-.

Hayden made the first important geological traverse through northern Pakistan. He followed the route through Chitral, over darkot pass, down the Yasin valley, east to Gilgit, then north along the Hunza River valley. This traverse, though hurried, gave two cross-sections approximately normal to the regional trend. His notes contain valuable descriptions and correlation including those of the darkot group, Chalt volcanics, Yasin group, and the granitic batholiths.

H/100. Hayden, H.H., 1916. Notes on the geology of Chitral, Gilgit and the Pamirs. Geological Survey of India, Records 45(4), 271-335.

Hayden performed reconnaissance survey of the area from Mastuj, via Darkot, Yasin, Gupis, Gilgit, Hunza onward, to Pamir. The traverse, though hurried, gave two cross-sections approximately normal to the regional trend. He provided valuable information on the region, and established the geological concept of the areas of Western Karakoram and Eastern Hindu Kush. One of his contributions in this work was the discovery of Cretaceous molluscan and coral fossils at Yasin “in the cliffs behind the Rest House on the right bank of the river...” in 1914. He also made a sketch of the stratigraphic succession there. He found fossiliferous shaly limestone containing large number of Fusulinae and Bryozoa near Darband that appeared to be underlain by massive limestones and shales, often calcareous. Although not studied in situ because of bad weather, he correctly inferred that the hills on either side of the glacier at Darkot were granitic.

H/103. Head, J.J., 1995. Two new trionychids (Reptilia: Testudines) from the Miocene of Pakistan: evolution of Aspideretini. Journal of Vertebrate Paleontology, 15 (supplement 3), 33A.

Two skulls from the middle and late Miocene Chinje Formation of the Siwaliks deposits of the Potwar Plateau, Pakistan, represent two new species of trionychid turtle. The first specimen is a member of the tribe Aspideretini, based on several morphological characteristics: the basisphenoid is medially constricted and the quadrate is separated by the trigeminal foramen by contact between the pterygoid and the prootic. The specimen is dated at 14 MYA, and is the oldest known member of Aspideretini. The second specimen is a member of the tribe Ulutrionychini, and is the most complete skull known for the tribe. This assignment is based on: shortened facial region with downturned prefrontals and weakened maxillary-prefrontal contact. Medial constriction of the basisphenoid in this specimen is shared with Aspideretini. The specimen is dated at 12 MYA, and is the youngest member of the tribe.

This new material supports the hypothesis that Aspideretini are derived from Ulutrionychini. In addition, the presence of an ulutrionychid in younger strata than an aspideretid suggests that Ulutrionychini persisted for a minimum of 2 MYA after the derivation of Aspideretini.

H/104. Head, J.J., 1997. Reptile palaeontology of Dhok Pathan Formation, Siwalik Group, Pakistan: Preliminary results. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, 58-62.

Mammalian paleontology of the Siwalik Group of Pakistan has been heavily studied in regards to taphonomy, paleoecology, and phylogenetics, however, reptile fossils from the Siwaliks have received much less attention. The majority of reptile studies have been taxonomic depositions (e.g. Lydekker, 1885), and brief paleoclimatic reconstructions based on reptile occurrences from the Siwaliks of Nepal (West et al., 1991). Presented here are the preliminary results of what is intended to be an extensive survey of the Siwaliks herpetofaunas, emphasizing changes in ecology and phylogenetics through time.

Reptile fossils were surface collected at 31 localities throughout the middle and upper Dhok Pathan Formation in the Padhri-Hasnot region during March, 1996. These localities comprise a timespan of approximately 7.92-6.3 Ma (J.C. Barry, pers. comm.). Reptile taphonomy of these localities is similar to conditions described for mammals from the Dhok Pathan Formation (Badgley et al, 1995), with the exception of skeletal element frequencies; turtles are predominantly represented by shells, and snakes exclusively by vertebrae. These differences are due to the unique morphologies of the reptile groups. No complete specimens were recovered, and articulation of skeletal elements was nearly absent with the exception of several snake vertebrae and a partial trionychid turtle carapace. The incomplete nature of the specimens, combined with difficulties in phylogenetic assignment of represented taxa (e.g. Gardner and Russell, 1994) prevents species-level assignments at this time.

Due to both their scarcity in preservation and difficulties in phylogenetic determinations, squamate fossils are only briefly discussed here. Remains were recovered from only five localities, with the majority of remains recovered from a single locality, Yale 935, which contained vertebrae of possibly two partially complete snake specimens. Snakes are the most abundant squamate remains, and several specimens are nearly identical to, *Acrochordus*, a taxon known only from the Siwaliks and modern Indonesia/Australia (West et al., 1991). Lizards are poorly represented, with only several vertebrae from locality Yale 457, questionably referable as varanoid.

Historically, there have been at least five named crocodilian species from the Siwaliks: *Crocodylus palaeindicus*, *C. sivalensis*, *C. bugtiensis*, *Gavialis hysudricus*, and *Rhamphosuchus crassidens* (Lydekker, 1885; C. Brochu, pers. comm.). Remains from the Padhri Hasnot region consist of *Crocodylus* sp., *Gavialis* sp., and single tooth, possibly referable to *Rhamphosuchus*. (West et al., 1993) tentatively described *Tomistoma* sp. from the Siwaliks of Nepal, however, no definitive evidence of this taxon was recovered from the Dhok Pathan Formation. Size ranges of crocodilians include extremely small (tooth crown height .75 cm: neonate/juvenile) to extremely large (tooth crown height 4.2 cm: *Rhamphosuchus*?), with no apparent pattern of size increase or decrease through time. Turtle remains are the most abundant reptile fossils. All recovered specimens can be grouped into two main lineages, Trionychoidea (aquatic turtles) and Testudinoidea (semi-aquatic and terrestrial turtles). There is no definite evidence of pleurodiran turtles. Trionychoids are the most common reptile fossils, and their diversity includes carretocheyids and both cyclanorbine and trionychine trionychids. Carretocheyid specimens are diagnosed on the basis of punctate shell sculpturing; lack of acute sulci combined with the presence of peripheral bones; and the extension of sculpturing to the internal surfaces of the shell (Meylan, 1987; W. Bartels, pers. comm.). Among trionychids, the presence of cyclanorbinines is indicated by partial epiplastra, similar to the extant Asian species *Lissemys punctata* (Meylan, 1987). Trionychines are diagnosed by fragmentary plastra. At least one trionychine specimen may be referable to a specific genus; a partial carapace from locality Yale 933 retains a preneural element, a characteristic of the genus *Aspideretes* (Meylan, 1987). The taxonomic utility of this characteristic has been argued as being undiagnostic (Meylan, 1987; Gardner and Russell, 1994), however, the tentative assignment to this genus is corroborated by the endemism of modern aspideretids to Asia, and the occurrence of earlier members of this lineage in the Chinji Formation (Head, 1995). Size ranges for aquatic turtles range from diminutive (carapace length less than 15 cm) to extremely large, with localities, Dartmouth-Peshawar 13 and 28, containing remains of trionychid carapaces longer than 100 cm.

Testudoideans include emydid, batagmine, and testudinid turtles. Emydids are recognized on the basis of low-domed carapaces, lack of extensive shell ornamentation, and the presence of a plastral hinge (Emydid morph "A", Fig. 1) in adult specimens. Six forms of batagrine turtles have been recognized from the Siwaliks of Nepal (West et al., 1991), on the basis of shell fragments. Similar fragments have been recovered from the Dhok Pathan, however, differentiating between testudinids and batagrine remains from the Padhri-Hasnot region is tenuous at best. Among definitive testudinids, the species *Geochelone* is recognized by an epiplastron possessing a prominent cranial buttress. The distribution of this genus in Pakistan and India spans the Oligocene to Plio-Pleistocene of Pakistan to present of India (Auffenberg, 1974). An additional testudine taxon is represented by neural elements possessing extremely high, transverse crests. As with trionychids, emydid specimens recovered at locality Dartmouth-Peshawar 13 are extremely large, with carapace lengths approaching 100 cm. Large size testudinids (greater than 50 cm carapace length) were recovered from localities dated at 7.3 Ma and younger. The presence of these large testudinids indicates a mean cold month temperature of warmer than 20° C (Hutchison, 1982). An increased aridity in the Siwaliks at 7 Ma has been reported, based on Dhok Pathan rodent faunas (Jacobs and Flynn, 1981) and a transition from C3 to C4 photosynthesis (Quade and Cerling, 1995). The expected results of increased aridity on the reptile faunas would consist of an increase in diversity and abundance of taxa adapted for more xeric environments, and a decline in aquatic forms due to the reduction of surface water area. The occurrence of large testudinids from 7.3 Ma on may represent an influx of xeric (though not exclusively so) species. Aquatic taxa do not show decreases in diversity or abundance prior to 6.3 Ma, however. The largest specimens of all aquatic taxa occur between 6.6 and 6.3 Ma, and there is no demonstrable decrease in reptile abundance per locality after 7 Ma. Overall, reptile fossils

from 7 Ma on indicate that even with the increased aridity, large, permanent aquatic environments persisted, allowing both rich taxonomic diversity and the attaining of long life spans/body sizes in the aquatic herpetofaunas. Further research is required to confirm or deny these preliminary observations, as this study is still in its infancy. Future analysis will include changes (or lack thereof) in reptile diversity over a greater range of time, as well as spatial variations in herpetofaunas, through the Siwaliks. Additionally, further collection of specimens may allow observations of species longevity and evolutionary transitions of reptiles over time.

H/108. Hemphill, W.R., & Kidwai, A.H., 1973. Stratigraphy of the Bannu and Dera Ismail Khan areas, Pakistan. *US Geological Survey, Prof. Paper 716-B*, 36p.

The Bannu and Dera Ismail Khan quadrangles cover an area of more than 8,600 square miles in north-central Pakistan, between lat 31 and 33°N and long 70 and 71°E. This area contains two main physiographic units: the alluvial lowlands, which include the structurally undisturbed Indus and Bannu plains and the folded belt which includes the Khisor, Marwat, Bhattanni and Sulaiman Ranges, as well as the highlands of Waziristan. These ranges and highlands form a nearly continuous mountain system between the Salt Range-Potwar Plateau region to the northeast and Baluchistan to the southwest.

Total stratigraphic thickness exceeds 14,000 feet in the Khisor and Marwat Ranges. Sedimentary rocks of the following age are present: Cambrian (?). Permian, Triassic, Jurassic, Cretaceous, middle and late Tertiary, and Quaternary. Lower Tertiary rocks are not present. Stratigraphic terminology for rocks in the Khisor and Marwat Ranges is the same as that used in the Salt Range and Potwar Plateau region to the northeast.

Total stratigraphic thickness exceeds 38,000 feet in the Sulaiman Range-Waziristan area. Sedimentary rocks of Jurassic, Cretaceous, Tertiary, and Quaternary age are present. Rocks of Paleocene and Eocene age are particularly well developed in this region, in places exceeding 13,000 feet. Stratigraphic terminology for units of Mesozoic age is the same as that used in Baluchistan to the southwest. New names are proposed and type sections are designated for seven units in the eastern foothills of the Sulaiman Range. These units are the Baska Shale of early Eocene age; the Domanda Shale and Drazinda Shale Member of the Kirthar Formation, middle and late(?) Eocene age; the Chitarwata Formation of late Oligocene to late Miocene age; and the Vihowa, Litra, and Chaudhwan Formation of Pliocene and Pleistocene (?) age.

H/110. Henderson, G. & Hume, A.O., 1873. Lahore to Yarkand incidents of the route and Natural History of the countries traversed by the expedition of 1870 under Forsyth, T.D., Roy. Geographic Society, London, 370p.

On the return to India of the Yarkand Expedition it was believed that sufficient materials had been collected, during the journey, for a paper in some scientific journal, on the Zoology and Botany of the countries traversed, but in preparing the notes for the press it was soon found that their bulk was so great as to necessitate a separate. After everything was ready for publication, the Secretary of State for India in Council most liberally subscribed for a number of copies of the work, sufficient to relieve the Authors of almost all risk. The sale of such a work as the present must necessarily be very limited. The Authors have to acknowledge with thanks the assistance they have received from many kind friends. Dr. Hooker most liberally allowed the Kew Herbarium to be freely consulted in identifying the Botanical specimens, and he and Mr. Bentham have written the descriptions of the new species of flowering Plants, all of which have been figured by Mr. Fitch, under Professor Oliver's supervision; and Mr. James Britten, late of the Kew Herbarium and now of the British Museum, gave very great assistance in identifying specimens of Plants; he also kindly undertook to revise the proof sheets of the botanical portion of the work. The identifications and descriptions of Algae, Diatomaceae, &c., as also the drawings of these, are by Dr. Dickie of Aberdeen, Mr. Fitch having lithographed the drawings. The Ornithological portion of the work has been edited by Mr. E. B. Sharpe, and Mr. H. W. Bates has exercised a general supervision over the work, whilst it was passing through the press. The analysis of the water of the Pan gong Lake was kindly undertaken by Dr. Frankland, and is published with his permission. Mr. Etheridge, of the Royal School of Mines, kindly identified the only fossil which was found in Yarkand territory, and his prognostication that coal would probably be found in Yarkand has already turned out to be true, for Mr. Shaw has informed Dr. Henderson that specimens of coal have since been obtained in Yarkand territory. Mr. Scott, of the Board of Trade Meteorological Office, kindly allowed the observations of the barometer, boiling-point thermometer, and the wet and dry bulb thermometer to be worked out in his office. The Map was drawn by Mr. Oulet at the Royal Geographical Society's rooms, under the supervision of Mr. Bates. The Plates which illustrate the Narrative, if not all works of art, have at least this recommendation, over woodcuts, that they give a truthful representation of the places, without leaving any margin for the imagination of the artist; all these Plates are done by the new Heliotype process, from negatives which were never very good, and which suffered greatly by the rough treatment they were subjected to during the march. It should be mentioned that these views are all reversed i.e., the right hand side of the picture should have been at the left side, and vice versa; this was caused by the negatives having been varnished at the time they were done, which prevented the film being taken off and reversed. The Plates of Birds are all by Keulemans, and with scarcely an exception they are all very accurately done. Few who have not themselves attempted it can realize the difficulty of getting through the press a volume like the present, containing such a variety of information; notwithstanding all the care that has been taken some mistakes may have been over-looked.

Key Words: Lahore, Yarkand, Expedition, Natural history.

H/111. Henderson, W., 1859. Memorendum on the nature and effects of the flooding of the Indus on 10th August 1858 as ascertained at Attock and its neighbourhood. Journal of the Asiatic Society of Bengal 28, 199-219.

As this account does not have an abstract, the first few pages of this account are given for information.

I begin by observing that this is not the first flood of the sort, but that one on a somewhat larger scale, but in other respects very similar, took place in May, 1811. I have seen two very brief accounts of this flood, one I think collated by Col. Abbott, the other furnished by Col. Cunningham. I have also collected at Attok and the neighbourhood some

information on the effects of this earlier flood; and as the two are very similar and mutually throw light upon one another, I shall have to refer to that of 1841, and so premise this allusion to it.

The first point on which information is called for is the spot where the obstruction took place. This can only be ascertained by sending up an Officer by way of Cashmere. In the meantime I may offer a few observations.

The obstruction of 1811, took place in the upper part of the valley of the Shayok River or northern Indus which joins what is considered as the main Indus at Keris, and I think brings down more water than the other, which from its long and straight course is naturally considered the principal or parent stream. The blocking took place in the part of the Valley where the stream runs at the back of a high range which separates it from the Nubra Valley. I have been over this ground and was struck with the frequency and solidity of the glaciers which occupy almost every valley in the range, with their tributary glens also. The range is granite, and large rough blocks of that rock form an important component of these glaciers.

The first information was received in the neighbourhood of Attok about the middle of July 1858, and of all that I have heard of, that which appeared most worthy of credit was a letter forwarding what purported to be a general warning by the Syuds of Kangra or Kangri. The Attok boatmen declared at once that the warning received in 1841, emanated from the same place; they recognized the style and stated that the same form of adjuration was employed and that the signatures appended were the same, except that two or three individuals, who might fairly be supposed to have died in the interval, were omitted from the later document. Search was then made in the house of Bulloo, the oldest of the Mullicks of the boatmen, but though it was well known that the paper was preserved there till a year or two ago, the search proved unsuccessful.

There is a village named Kangri marked in the Surveyor General's map of the Punjab and adjoining countries, and I believe this is the place alluded to, it is at no great distance from the Nubra and Shayok Valleys, and if the fact be that both papers issued from it, a fair inference is that in both cases the obstruction was at no great distance from its site; for in these valleys such news would not travel far except it were down the course of the river. We know that the damming of 1841, took place within two or three days' march of the village, and, till better evidence be obtained, can but conjecture that this also occurred in the Shayok or in the Nubra valley. Both are well adapted for the purpose, being wide with estrangulations at intervals, having comparatively a small slope of bed and being supplied from large glaciers above with considerable and unfailing streams of water. For though the main fall of the Indus-bed takes place between Kangri and Attok, yet the general character of all the streams I have observed in the Himalayas is to fall in steps, a comparatively sluggish portion intervening below the first rush of the minor tributaries, to be succeeded by the main stream making its way in a series of rapids for two or three hundred miles. Both the Nubra and the upper Shayok are thus comparatively slow flowing, and in the former especially there are numerous quicksands.

I have two or three times crossed the Shayok, and found it in the summer time a stream of considerable size. On the other hand, and contradictory to the above, all Major Becher's information pointed to the river of Gilgit, and that pretty consistently; but as this cannot be reconciled to the facts I have noted, as I understand them, I am inclined, till more evidence is obtained, to discredit it. I do not find in the map alluded to glaciers marked so far west as the River of Gilgit nor are the mountains from which it comes so high or so snow-clad as those to the eastward. Indeed I do not know in any part of the Himalayas a region so likely to give birth to catastrophes of the kind as that around the upper part of the Shayok.

The solution of the point is, however, very easy. The whole Indus above the Gilgit river is open to travellers proceeding under the protection of the Maharaja of Cashmere, and any officer starting from that valley and striking the Indus at the foot of the Nunga, Purbut, (a route which I recollect an officer of the artillery following in the summer of 1855,) and thence marching upwards, would very soon ascertain positively the exact locality of the obstruction. I should be glad if opportunity offered to proceed further for the purpose, and regret that when in that country before, I gave less attention to the matter than I should have done had I thought that a flood like that of 1841, could by any chance occur again in any definite number of years.

The second point mooted is the nature of the obstacle. We may pronounce with almost certainty that this was the sudden irruption into a comparatively narrow valley of an immense fragment of a glacier. I have already alluded to the glaciers of the region where I suppose the obstruction to have taken place. I have never seen those of Switzerland, but from what I have heard of them I think that the ones now referred to differ from the character ordinarily assigned to those in Europe, as they certainly greatly excel the latter in magnitude. Yet even in Europe a catastrophe similar to those which have taken place in the Indus valley occurred in that of the Drance in 1818. When crossing from the Nubra to the Shayok valley in August 1855, my companion, who had been in Switzerland, would at first hardly admit that the enormous mass of earth, rock and ice commingled and agglomerated together, with a broad stream of the dirtiest brown water issuing from its foot, and which I pointed out, filling up a tributary valley on our left, was really a glacier; (There are however glaciers in every direction and some remarkable ones. Eds.)

and several hundred miles farther south crossing the great shed between the Lanskar and the Chenab, he pointed out the features he had been accustomed to see, and which we generally find in description, clear ice of various tints of green, and deep crevasses crossed by snow bridges, and with comparatively clean water running within them. The formation in this case was lime-stone, in the former case granite. With regard to the magnitude of these glaciers

I need only say that I travelled nearly a whole day along one which was upwards of fourteen miles in length, varying in width from half a mile to two miles, and several hundred feet in depth.

The glaciers are, it is well known, in constant motion; their progress being subject to the same laws which regulate the motion of rivers. As they advance, their ends melt away and the Moraine gets washed down by the streams that issue from the body of the glaciers. The flow of one glacier measured by Prof. Forbes showed an onward movement of about 450 feet per annum, and it is evident, that where a glacier is cut off above the melting point by a stream running past its end, this motion must make it tend very considerably to encroach into the valley of the stream.

A landslide in one of those huge banks is quite a conceivable contingency, and in no case more likely than when the glacier protrudes with a narrow base and extended top from a small feeding glen coming in, nearly at right angles, into a narrow valley, whose stream crosses the path of the glacier, washing away the narrow foot which the mass behind protrudes, and on which it rests. This foundation being once undermined, the falling forward of a piece of the glacier is the result to be expected; and it is possible that this result often takes place, but that it is not often that circumstances so combine as that the process is delayed till a mass of formidable dimensions topples over.

The northern suture, also known as the Main Mantle Thrust, separates the Kohistan island arc from the Karakoram-Hindukush terrains. Its western end occurs in the Chitral area. The NE trending Shishi valley to the north of Drosh marks the trace of the junction between the volcanic and other rocks of Kohistan and the Karakoram-Hindukush terrain. The suture is marked by a *mélange* and contains slivers of ultramafic rocks.

Frequent and large temperature shifts across freezing point are well-known features of tropical and sub-tropical high mountains (Troll). In a mountain environment particularly, these temperature shifts can powerfully influence weathering, mass-movements and run-off. Such was very apparent during field work in the Karakoram. So far as the writer is aware, there has been no attempt to analyse the freeze-thaw conditions in the semi-arid Himalaya. This paper sets out to reduce the gap in our knowledge by presenting in detail results from meteorological observations made in 1961-62 in Central Karakoram; and with the aid of certain other published records, to establish the altitudinal and seasonal migration of freeze-thaw belt.

The Karakoram and Alaska–Yukon region between them account for perhaps 90% of the known surging glacier events. While modern research and information is available for the latter region, the Karakoram, though often referred to, remains virtually unknown except in a very general sense. The prime aim of this paper is to collate all the information that is available for the Karakoram from the usually old and inaccessible documents where it is found. It establishes eleven instances of surges with reasonable certainty and the probability of many more. The (rare) instances of detailed descriptions of the phenomena are quoted. A short discussion is given of the degree to which the information, and knowledge of the Karakoram environment, equate with various mechanisms put forward to explain surging glacier events.

H/127. Hewitt, K., 1982. Natural dams and outburst floods of the Karakorum Himalaya. IAHS-AISH Publication 138, 259-269.

Glacier dams and outburst floods ("jokulhlaups") have been reported in many glacierized mountain regions, and may create hazards for human populations. Specially large and dangerous examples occur where the rivers of extensive ice-free zones are blocked. This hydrological anomaly has been rare in modern times except for two areas: the southern Alaska-Yukon ranges and Karakoram Himalaya. In the Karakoram some 30 glaciers may form substantial dams on the Upper Indus and Yarkand river systems. Many more interfere with the flow of rivers in a potentially dangerous way. There is evidence of some 35 disastrous jokulhlaups since 1826. Rarer landslide dams have resulted in the largest dam-burst floods. The paper provides a record of known dams and related events, and identifies the glaciers involved. It indicates the role of the regional environment in the widespread potential for these glacier dams and catastrophic outbursts. Some data are given on the dimensions of past dams and the nature and impact of the flood waves. No dams were reported from the mid 1930's until 1978 when satellite imagery showed a 6 km glacier lake on the Upper Yarkand. The absence of dams in recent decades relates to a general glacier recession here. Renewed activity creates serious problems for water resource development and settlement growth that occurred in the recent, unusually favourable period.

Within the highly glacierized Karakoram Himalaya situated largely within Pakistan, there have been many cases of catastrophic floods, some the result of river damming by landslide, others the result of river damming by glacier ice with subsequent dam failure. The purpose of this case study is to show, by reference to one particular example, the magnitude and consequences of a glacier outburst flood and possible ways of alleviating the social and economic impact of such floods. This case study is taken from a much more extensive paper on the subject by Hewitt (1982).

The paper examines the nature and geomorphic influences of deposits from rock avalanches that obstruct rivers. Most of the 115 rockslide–rock avalanche events identified in the Karakoram Himalaya straddled one or more stream valleys. At least 73 of these landslides formerly dammed the Indus or its tributaries. Upstream of the barriers, remnants exist of once very extensive lacustrine deposits. The stability and long-term survival of dams from large rock avalanches is addressed, and the reasons for the gradual or phased, rather than catastrophic and sudden, breaching. Case histories emphasise the erosional and depositional forms associated with the barriers. They are reconstructed in terms of the emplacement and properties of the deposits from rock avalanches, and the response of the river to interruption by them. These barriers have exerted a substantial control over stream response and development for most of the Holocene at least. Today, they are associated with distinctive features of channel form and thalweg, river terrace systems, intermontane sediment sinks and sources, and local erosional forms in bedrock. More broadly, the landslide barriers have created a naturally fragmented river system. Deposition and erosion in the lower few tens or hundreds of meters of the Upper Indus stream valleys have been dominated by epicycles of aggradation, trenching, and downcutting that mainly reflect the scale, timing and history of each barrier. The landforms involved are only indirectly related to the late-glacial and paraglacial conditions that have, hitherto, been regarded as the main explanation.

H/141. Hewitt, K., Wake, C.P., Young, G.J. & David, C., 1989. Hydrological investigation at Biafo Glacier, Karakorum Range, Himalaya; An important source of water for the Indus River. *Annals of Glaciology* 13, 103-108.

Over 80% of the flow of the Upper Indus River is derived from less than 20% of its area: essentially from zones of heavy snowfall and glacierized basins above 3500 m elevation. The trans-Himalayan contribution comes largely from an area of some 20 000 km² of glacierized basins, mostly along the axis of the Greater Karakoram range and especially from 20-30 of the largest glacier basins. Very few glaciological investigations have so far been undertaken in this the major glacierized region of Central Asia. Biafo Glacier, one of the largest of the Karakoram glaciers, drains south-eastwards from the central Karakoram crest. Its basin covers a total area of 853 km², 628 km² of which are permanent snow and ice, with 68% of the glacier area forming the accumulation zone. This paper describes investigations of snow accumulation, ablation, glacier movement, and glacier depth undertaken in the period 1985-87, set against a background of investigations carried out over the last 130 years. Biafo Glacier differs from most of the other Karakoram glaciers in being nourished mainly by direct snowfall rather than by avalanching; this has the advantage of allowing extensive investigation of accumulation over a broad range of altitude. Snow-accumulation studies in the Biafo Glacier basin have indicated that annual accumulation varies from 0.9 to 1.9 m of water equivalent between 4650 and 5450 m a.s.l. This suggests an annual moisture input above the equilibrium line of approximately 0.6 km³. Monopulse radar measurements indicate the presence of ice thickness as great as 1400 m at the equilibrium line, although these results may not be completely reliable. Mean surface velocity during the summer of 0.8 m d⁻¹ has been measured near to the equilibrium line. Calculations of annual ice flux through the

vertical cross-profile at the equilibrium line indicate a throughput of 0.7 km³ a⁻¹. Estimates from stake ablation measurements also suggest that ice loss on Biafo Glacier is about 0.7 km³ a⁻¹. The close agreement between these three sets of measurements is reassuring, indicating that the ablation zone of Biafo Glacier, whose area covers 0.09% of the whole Upper Indus basin, produces approximately 0.9% of the total run-off. However, it should be mentioned that this estimate does not include water originating from seasonal snow melt, either above or below the equilibrium line, or from rainfall. Net annual ice losses due to wastage of the glacier since 1910 are probably of the order of 0.4-0.5 m a⁻¹; this would represent between 12 and 15% of annual water yield from melting ice.

H/142. Hewitt, K. & Young, G.J., 1993. The Snow and Ice Hydrology Project: A Pakistan-Canada Research and Training Programme. In: Young, G.J. (Ed.), *Snow and Glacier Hydrology - Proceedings of the International Symposium, Kathmandu, 1992*. Wilfrid Laurier University, Waterloo, Ontario, 49-59.

The paper describes the inception, implementation and possible future developments of the Snow and Ice Hydrology Project (SIHP), a joint Pakistan-Canada venture. Conceived in 1981, the project entered its first of five summer field seasons in 1985. The project was requested by Pakistan's Water and Power Development Authority (WAPDA), and was funded jointly by WAPDA and by Canada's International Development Research Centre. It involved several Canadian and other universities. In Canada the project was coordinated by the Cold Regions Research Centre of Wilfrid Laurier University. Recognizing that the Indus river is fed largely by melting ice and snow in the Karakoram Mountains and that there is insufficient understanding of the processes of snow and ice melt in this region, the SIHP's main objectives have been to set up within WAPDA a capability for undertaking relevant research, initiating and developing that research and laying the basis for a more operationally focused programme in the future. Field projects have included the setting up of meteorological monitoring stations at relatively high elevations, monitoring snowmelt in basins with and without glaciers and monitoring glacier ice melt in several basins in the Central Karakoram. Office work has included analysis of the data collected as well as the setting up of data bases and inventories of glacier coverage of the region. Technology transfer has been achieved through Canadian professors and students undertaking field work in Pakistan with their counterparts and through several Pakistani officers undertaking formal studies at Canadian universities. Based on the understanding and the experience gained through SIHP, the project has now entered an operational phase with involvement of the Canadian International Development Agency. Recommendations for future work are given.

H/143. Hildebrand, P.R., 1996. The Structure, Metamorphism and Magmatism Observed in a Transect through the Hindu Kush, Northwest Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 62.

The Hindu Kush range of Northwest Pakistan is the along the strike equivalent of the well exposed and geologically relatively well studied southern Karakoram Range (Searle, 1991) and also what probably lies beneath South Tibet. The range occurs in the axial zone of two converging crustal subduction systems (the northward subducting Indian plate and the southward subducting Tadjik-Tarim plate) which are marked by the most seismically active zone on earth, where earthquakes have been recorded to depths of 300 km.

The transect studied occurs to the northwest of Chitral and the Shyok Suture which separates the Kohistan island arc from the Asian margin, and runs along the roughly west-east flowing Lutkho River. It is bounded to the east by the Reshun fault, which is a reverse fault, with a top to the east sense of movement, and which places greenschist grade phyllites of the Asian margin onto relatively unmetamorphosed sediments of the Shyok Suture (Pudsey et al., 1985). The section contains metamorphosed and post-deformation garnet-tourmaline to mica leucogranite dykes and plutons.

The earliest recognizable deformation event (D1) occurred after the intrusion of the early porphyritic granites. D1 produced a penetrative WNW dipping schistosity (S1) that developed during and after the first recognizable metamorphic event (M1), which was up to garnet-staurolite grade. Near horizontal stretching lineation (L1) suggest that some strike-slip movement was associated with this early deformation.

Late deformation (D2) is spatially associated with the intrusion of leucogranites, and takes two forms, which may or may not be contemporaneous. The first form is associated with the intrusion of the large Gharam Chasma

leucogranite, pluton, which folds S1, producing horizontal N trending fold axes and crenulation lineations (L2), and has no effect on M1. The second form is associated with the emplacement of leucogranite dykes and sills during top the east movement along S1. Like the first form, this event produced folds with N trending, sub-horizontal fold axes (L2), suggesting that D2 involved dip-slip movement (as opposed to the D1 strike slip movement). However, this second form of D2 differs from the first in that it has a thermal overprint on M1, characterized by sillimanite-in and staurolite-out.

A limited amount of whole rock major and trace element geochemistry has been carried out on the Hindu Kush granites. The pre-deformation porphyritic granites are apparently different from the pre-collisional granites of the Karakoram, in that they are higher in K and Rb, and slightly lower in Sr, Ba and Ti. The post-deformation two mica-garnet-tourmaline leucogranites are typical peraluminous, near minimum crustal melt granites. They differ in their trace element compositions from the Karakoram post-collision Baltoro granites in that they are not similarly enriched in large ion lithophile elements and Th and Zr. The trace element compositions are more like the High Himalayan leucogranites such as those found at Langtang.

Key words: Structure, metamorphism, magmatism, Hindu Kush.

H/144. Hildebrand, P.R., 1997. Leucogranite gneisses in the Hindu Kush. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 47.

The Hindu Kush Range of Northwest Pakistan is the along strike equivalent of the well exposed and geologically relatively well studied southern Karakoram Range (Searle, 1991) and also what probably lies beneath South Tibet. The range occurs in the axial zone of two converging crustal subduction systems (the northward subducting Indian plate and the southward subducting Takjik-Tarim plate) which are marked by the most seismically active zone on earth, where earthquakes have been recorded to depths of 300 km.

Leucogranites in the Hindu Kush occur within highly graphitic, pelitic metasediments with minor amounts of calc-silicate and amphibolite. The pelitic sediments have been subjected to an early metamorphic event of garnet-staurolite grade. The leucogranites are associated with a later thermal metamorphism, characterized by sillimanite, andalusite and sometimes K-feldspar. This later metamorphism and leucogranite emplacement is also associated with late thrusting movement along faults.

The leucogranites occur as a large pluton (the Gharam pluton, Calkins et al., 1981), deformed bodies within migmatites, dykes and pegmatites. The structural relationships between these varieties are complex and difficult to interpret, although it appears that they are all broadly contemporaneous. They are peraluminous and consist of quartz, K-feldspar, plagioclase, biotite, muscovite and sometimes, tourmaline and/or garnet. Although the structural relationships suggest a common origin between the garnet ± staurolite schists, the migmatites and the varieties of leucogranites, geochemistry suggests that this is not the case. In particular the Sr isotope ratios for the Gharam Chasma ($^{87}\text{Sr}/^{86}\text{Sr}=0.720\text{--}0.742$). Interestingly these Sr ratios for the pluton are similar to those from the Baltoro pluton (Searle et al., 1992), suggesting a common origin.

H/146. Hildebrand, P.R., Noble, S., Searle, M., Parrish, R. & Shakirullah, 1998. Tectonic significance of 24 Ma crustal melting in the eastern Hindu Kush, Pakistan. *Geology* 26, 871-874.

Northward-directed subduction has continued beneath the Hindu Kush from the Mesozoic, when the region formed part of the southern margin of Asia, until today. The Kohistan arc was accreted at ca. 100 Ma, followed by the Indian plate at 54–50 Ma. After the India-Asia collision, a regional crustal-melting event occurred at ca. 25–21 Ma to the east of the Hindu Kush in the Karakoram Range, producing the Baltoro pluton. In the eastern Hindu Kush Range, most of the granitoids appear to be subduction-related plutons that predate the India-Asia collision. However, the Gharam Chasma pluton is a two-mica (± garnet ± tourmaline) leucogranite that has intruded into staurolite-grade schists and (sillimanite ± K-feldspar)–grade migmatites. U-Pb ages on monazite, xenotime, and

uraninite from undeformed samples of the Gharam Chasma pluton and a leucogranite dike that crosscuts the migmatites indicate that crustal melting occurred at ca. 24 Ma, synchronous with the Baltoro melting event. This age also provides an upper limit on the age of the regional staurolite-grade metamorphism in the eastern Hindu Kush.

Key words: Tectonics, crustal melting, granite magmatism, Hindukush.

H/147. Hildebrand, P.R., Searle, M.P., Noble, S.R. Parrish, R.R., Shakirullah, 1998. The tectonic significance of 24 Ma crustal melting in the eastern Hindu Kush, Pakistan. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 77-79.

Northward directed subduction has taken place beneath the Hindu Kush from when it formed part of the southern margin of Asia in the Mesozoic, and still continues today. Accretion of the Kohistan arc took place at about 100-85 Ma, followed by the Indian plate at 55-50 Ma. After the India-Asia collision, a regional crustal melting event occurred around 25-21 Ma to the east of the Hindu Kush in the Karakoram range, producing the Baltoro pluton. In the eastern Hindu Kush range, most of the granitoids appear to be pre-India-Asia collision, subduction related plutons. However, the Gharam Chasma pluton is a two mica garnet $\pm$ tourmaline leucogranite that has intruded into staurolite grade schists and sillimanite K-feldspar grade migmatites.

U-Pb ages on monazite, xenotime and uraninite from undeformed samples of the Garam Chasma pluton and a leucogranite dyke that cross cuts the migmatites indicate that crustal melting took place in the eastern Hindu Kush at around 24 Ma. This is contemporaneous with the event that produced the Baltoro pluton in the Karakoram, 400 km to the east. This extends the range and confirms the importance of widespread crustal melting in the southern margin of the Asian plate around the earliest Miocene.

The presence of lamprophyres with the same early Miocene age as the Baltoro pluton support the possibility of a mantle heat input to promote the crustal melting in the Karakoram [8]. In the eastern Hindu Kush, there is no indication of any lamprophyres or other potentially mantle derived melt that could potentially have a similar 24 Ma age, so alternative heat sources are required. The leucogranites in the Gharam Chasma area are spatially associated with sillimanite grade metamorphism and migmatites. Consequently, a more likely model for the generation of these leucogranites would appeal to peak metamorphism and decompression provide the heat and conditions necessary for melting. Such a model would be similar to models proposed for the generation of the High Himalayan leucogranites.

H/148. Hildebrand, P.R., Searle, M.P., Shakirullah, Khan, A.Z. & Heijst, H.J.V., 2000. Geological evolution of the Hindu Kush, NW Frontier Pakistan: active margin to continent-continent collision zone. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.) *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 277-293.

A geological map of the eastern Hindu Kush, northwest of Chitral, Northern Pakistan, is presented. The lithologies are placed into two main categories, divided by the Tirich Mir Fault Zone. To the northwest, the units of the eastern Hindu Kush are dominated by monotonous sequences of graphite-rich pelitic rocks. Southeast of the fault, the phyllites and diamictites are thought to be lateral equivalents of the Northern Sedimentary Belt of the Karakoram. A structural analysis of the area studied identifies a major, early deformation phase which is usually characterized by tight to isoclinal folding with a well developed axial-planar schistosity. This deformation is thought to have been related to the northward-directed subduction and accretion beneath the southern margin of Asia during the Mesozoic, and may have taken place over a considerable period of time. A major phase of crustal melting at c. 24 Ma generated migmatites and biotite + muscovite $\pm$ garnet $\pm$ tourmaline leucogranites (including dykes and the Gharam Chasma pluton). This age is comparable to that of the Baltoro pluton in the Karakoram to the east, confirming the regional importance of crustal melting along the southern margin of the Asian plate during the earliest Miocene. The crustal melting was associated with thrusting and folding of the earlier schistosity. Subhorizontal stretching lineations indicate a phase of strike-slip deformation that is thought to have been associated with anticlockwise rotation of the regional foliation strike from E to NE and N after the emplacement of the Gharam Chasma pluton at c. 24 Ma. This deformation and rotation was probably a directed result of the northward-moving Indian plate forcing Kohistan to indent into Asia, resulting in a left-lateral transpressional tectonic environment.

which remains today. The anomalous height of the Tirich Mir massif, relative to other peaks in the Hindu Kush and the nearby Hindu Raj, may be accounted for by the onset of this transpression.

Intensely active seismicity to depths of 300 km beneath the Hindu Kush is associated with seismic shear wave velocities that are significantly faster than those beneath Tibet, where earthquake occurrence is restricted to the upper crust, and previous geophysical studies indicate elevated thermal conditions and possible crustal melts. U-Pb ages suggest that post-India-Asia collision crustal melting beneath the Hindu Kush is restricted to c. 24 Ma, whereas in the Karakoram, the record is both more voluminous and more continuous from c. 37 to c. 9 Ma. These observations reflect major differences in the thermal histories of these regions, where the relatively cooler condition beneath the Hindu Kush are associated with continental subduction-related seismicity.

H/150. Hirayama, J., Karim, T., Okamura, N., Hada, S. & Sato, M., 1995. A geological study and some feasibility considerations for the production of fused magnesium fertilizer (FMP) in Pakistan. *Proceedings of Geoscience Colloquium; Geoscience Lab, Geological Survey of Pakistan, Islamabad*, 11, 3-147.

Fused magnesium phosphate (FMP) is a phosphatic fertilizer consisting of P_2O_5 , MgO, CaO, and SiO_2 . It is ordinarily produced by fusing and quenching a mixture of quality-ore of phosphate containing more than 30 % of P_2O_5 and serpentinite. Substituting serpentinite as the material by magnesite is considered to not only make the utilization of low-grade ore of phosphate in the Hazara area possible but also promote the exploitation of under-developed magnetite in the same area. To verify the idea, a JICA team consisting of a mining engineer, a manufacturing engineer, and a fertilizer and marketing specialist was invited to conduct an extensive survey on mining costs of raw materials, production costs and the marketability of FMP under a close cooperation with Geoscience Laboratory, Geological Survey of Pakistan between May 23 and June 12, 1994. The conclusion of the study is that the manufacturing of FMP with 20% of P_2O_5 is feasible in Pakistan, if the following requirements are met:

1. The effectiveness of FMP be verified through experiments for various crops to be conducted by competent authorities;
2. Infrastructures required for the project, including access roads to mining sites and power supply, be consolidated by the Pakistani authorities concerned;
3. The Pakistani governments, Federal and Provincial, actively participate in implementing this project to extend necessary supports;
4. Financial and technical assistance for opting this project be offered from external resources including JICA.

H/163. Hubbard, M.S. & Spencer, D.A., 1990a. Indian plate deformation between Babusar pass and Nanga Parbat, NW Himalaya, Pakistan. In Abstract volume, 5th Himalaya-Karakoram-Tibet Workshop, Milano, 22.

The Nanga Parbat region of the northwest Himalaya has seen a complex tectonic history from the subduction of the oceanic India plate rocks beneath the Kohistan island arc; to collision of continental Indian plate rocks with Kohistan and southeast directed thrusting of Kohistan along the Main Mantle Thrust (MMT); to rapid exhumation of the Nanga Parbat massif, possibly by a combination of thrust faulting and erosion. We present preliminary results of a structural analysis of Indian plate rocks between Babusar Pass and Nanga Parbat. This study is aimed at a better understanding of the deformational history of this region and will help provide the much-needed geologic constraints for tectonic models of the area. Specifically we hope to distinguish deformation which is associated with the early collisional processes from later deformation which may be related to the exhumation of the Nanga Parbat massif.

A traverse was made from Babusar Pass eastward to the Barai valley, the Toshe Gali area and north to the Indus valley at the village of Bunar. Work was predominantly within the Indian plate where lithologies are similar to those in the adjacent, upper Kaghan Valley. Gneiss, granitic-gneiss, and metapelite are overlain by a sequence of amphibolite, marble, and quartzite. In situ granitization of probable Himalayan age has affected the structurally lower units of the area. A pervasive stretching lineation is oriented EW to S50W with a shallow plunge. The origin and age of this lineation is, as yet, unknown. Folds are found from hand sample-scale to nappe-scale and the orientations of fold axes are parallel to the stretching lineations suggesting rotation of folds during the stretching deformation. Strike of schistosity is $\pm$ N45-55E in the western part of the study area, but becomes more NS toward the west, near the contact with the Nanga Parbat gneiss. The stretching lineation is less pronounced in the Nanga Parbat gneiss. Future fieldwork will target: the possibility of late, brittle faulting in the area; the geometry of the nappe-scale; the relationship of the stretching lineation to MMT deformation or to the exhumation of the Nanga Parbat massif.

Key words: Deformation, Indian plate, MMT, Kohistan, Himalaya, Karakoram.

H/164. Hubbard, M.S. & Spencer, D.A., 1990b. WSW-trending deformation between Babusar pass and Toshe Gali area, northern Pakistan. Geological Bulletin, University of Peshawar 23, 101-110.

The Himalaya and Karakoram Mountain ranges of northern Pakistan are the product of multiple deformational phases from continental collision events that trapped the Kohistan island arc between the Asian and Indo-Pakistan plates to the development and emergence of the Nanga Parbat syntaxis. Fieldwork along the Main Mantle Thrust (MMT) and within the Indo-Pakistan plate rocks in the area between Babusar Pass and Toshe Gali was aimed at an understanding of the kinematic relationship between these deformational phases. The MMT is the suture between rocks of the Indo-Pakistan plate and rocks of the Kohistan sequence. Workers in adjacent areas have found evidence that the MMT has southeast-directed transport of the Kohistan rocks over the Indo-Pakistan plate. In the study area that deformation has been overprinted by a ductile fabric that has top-to-the-WSW sense of shear on a shallowly WSW-plunging stretching lineation. This ductile fabric is pervasive at the MMT contact, within the Indo-Pakistan plate cover sequence below the MMT, but decreases in intensity in the Indo-Pakistan plate basement rocks and the Nanga Parbat gneiss. If this ductile fabric represents normal fault movement then this deformation may have been responsible, in part, for the exhumation of the Nanga Parbat massif.

Key words: Deformation, Indian plate, MMT, Kohistan, Himalaya, Karakoram.

H/165. Hubbard, M.S. & Spencer, D., 1991. Top to the WSW displacement along the MMT, Babusar pass Nanga Parbat region, Pakistan. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Auris, France, 49.

The Himalaya/Karakoram mountains of northern Pakistan are the product of multiple deformational phases from continental collision events that trapped the Kohistan island arc between the Asian and Indian plates, to the development and emergence of the Nanga Parbat Syntaxis. Fieldwork along the Main Mantle Thrust (MMT) and within Indian plate rocks in the area between Babusar Pass and Toshe Gali was aimed at an understanding of the kinematics and temporal relationship between these deformational phases. The MMT is the suture between the Indian plate rocks and rocks of the Kohistan sequence. Workers in adjacent areas have found evidence that the MMT had southeast directed transport of the Kohistan rocks over the Indian plate. In the study area, that deformation has been overprinted by ductile fabric with a shallowly WSW-plunging stretching lineation. Quartz grain shapes, asymmetric augen, and shear bands suggest a top-to-the-WSW sense of shear. This ductile fabric is pervasive at the MMT contact, within the Indian plate cover sequence below the MMT, but decreases in intensity in the Indian plate basement rocks and the Nanga Parbat gneiss. This top-to-the WSW sense of shear represents normal, or extensional, shear relative to the Nanga Parbat massif. If there has been sufficient displacement across this zone then the WSW- trending deformational phase may have been responsible, in part, for the exhumation of the Nanga Parbat massif. Shallowly WSW-plunging stretching lineations have been reported in the adjacent areas to the northeast by Butler et al., 1989 and to the west by Greco, 1989.

Key words: Deformation, Asian plate, Indian plate, MMT, Kohistan.

H/166. Hubbard, M.S., Spencer, D.A. & West, D.P., 1995. Tectonic exhumation of the Nanga Parbat massif, northern Pakistan. *Earth and Planetary Science Letters* 133, 213-225.

Structural analysis in the Nanga Parbat region of northern Pakistan indicates that extensional deformation has been, in part, responsible for the exhumation of gneissic rocks of the Indian plate basement complex that dominates the Nanga Parbat massif. This massif has been mapped as a syntaxis at the boundary between the Indian and Asian plates in the northwest Himalaya and has received recent attention for evidence of rapid exhumation within the last 10 Ma. Field work along the Main Mantle Thrust (MMT) and within the Indian plate rocks in the area between Babusar Pass and Toshe Gali, southwest of the peak of Nanga Parbat, provided us with evidence from shear fabrics and a shallowly WSW-plunging stretching lineation for a dominant phase of extensional deformation. During this deformation rock of the Kohistan sequence and the Indian plate cover sequence moved to the WSW relative to rocks of the Indian plate basement including the Nanga Parbat gneiss. A post-metamorphic ductile shear fabric pervades the MMT contact, the Indian plate cover sequence below the MMT, but decreases in intensity in the Indian plate basement and the Nanga Parbat gneiss. Using $^{39}\text{Ar}/^{40}\text{Ar}$ geochronology of hornblendes we have constrained the age of pre-deformational, amphibolite facies metamorphism to be $\leq 40\text{--}56$ Ma. Published cooling ages from the Babusar Pass region further document that the extensional deformation was completed by ~ 20 Ma. We interpret this ductile, extensional shear as the mechanism responsible for significant tectonic exhumation of the gneissic and granitic rocks of the Nanga Parbat massif.

H/168. Hughes, R.E., 1984. Yasin Valley: The analysis of geomorphology and building types. In: Miller, K. J. (Ed.), *The International Karakoram Project 2*, 253-288. Cambridge University Press.

The author's previous paper in these proceedings attempted to define a methodology for the study of building. This involves the examination of building construction, behavior and decay with all aspect being related to the environment.

A second theme showed that structural deformations and material decay if not remedied by "maintenance", "restoration" or "conservation" inevitably significance to the people than the less frequent, though more catastrophic, events such as earthquake and floods.

The intention of this paper is to show how the methodology was applied to the study of the Yasin Valley. It firstly concentrated on the geomorphology and relates to the inhabitants' awareness of, and response to, natural hazards. The buildings are then examined in detail: materials, construction, structural performance and decay. Methods for improving the houses are then discussed.

Of all the field studies undertaken by the author, this is considered the most important as there is a real and practical application, in conjunction with the UNDP development proposals, for benefiting the inhabitants.

H/169. Humayun, M., 1985a. A rapakivi granite occurrence from Swat. Geological Bulletin, University of Peshawar 18, 198-199.

The Rapakivi granites of Swat are locally developed facies within large lensoidal bodies of biotite granites occurring in a mylonite zone at the base of the Swat granitic gneisses (Humayun, 1985). Large bodies occur just south-east of Manglaur and extending north of Dangram to Shamelai (Humayun, 1985, Fig. 1). They show intrusive relations with associated mafic rocks. The biotite granites have been tourmalinized in places. These appear to be the first known metamorphosed Rapakivi granites and the first reported occurrence from Pakistan.

The typical rapakivi texture consists of euhedral pinkish phenocrysts of orthoclase mantled by plagioclase. Unmantled ovoids and euhedral phenocrysts of orthoclase are also common. The biotite granites are apparently undeformed in the centre of a typical body, such as that at Shamelai, but show incipient metamorphism, mortar texture and recrystallization of biotite. On the contacts, however, the granites are mylonitized. A spectacular spotted gneiss results when a mylonite of rapakivi granite is seen in a section perpendicular to the lineation.

H/170. Humayun, M., 1985b. Tectonic significance of mylonites from Mingora, Swat. Geological Bulletin, University of Peshawar 18, 137-146.

Rocks below the Swat gneisses, formerly thought to be a single unit, are a varied assortment of thrust slices consisting of rapakivi granites, sillimanite gneisses, marbles, and schists, in a mylonite zone. This zone is interpreted as the base of a large thrust. Thus, the overlying Swat gneisses and associated schists constitute a crystalline thrust sheet or nappe (?), that probably formed in response to the obduction of the Kohistan island arc.

H/171. Humayun, M., 1986. Petrology of the Swat amphibolites and the development of a "lesser Himalayan" Basin. Geological Bulletin, University of Peshawar 19, 83-100.

A geochemical study of amphibolites from the lower Swat valley, Lesser Himalayas, identifies a suite of continental flood basalt erupted over a gneissic basement of probable Late Cambrian age. Fractionation of clinopyroxene and plagioclase controlled chemical variation in the protolith. Metamorphism, retrogression and granitic intrusion strongly affected the alkali and mobile trace element contents. The magmatism was probably associated with the early rifting stage of the development of Paleotethys. Subsidence of the rifted margin followed the extrusion of the basalt, and arkosic continental sediments gave way to marine carbonates and clastics. The carbonates belong to a reefoid association of Middle Paleozoic age. The basin extended over much of present-day northwestern Pakistan with probable analogues along the length of the Lesser Himalayas.

H/172. Humayun, M., Jan, M.Q. & Khan, M.J., 1987. A review of "Evidence of an incipient Paleozoic ocean in Kashmir, Pakistan" by K.A. Butt, M.N. Chaudhry & M. Ashraf. Kashmir Journal of Geology, 5, 121-126.

Geochemical data presented in the paper under review is shown to be erroneous. Severe overestimation of Al₂O₃ and underestimation of TiO₂ and MnO, with evidently altered alkali and silica contents, render the analyses invalid for proposing a new tectonic model. The treatment does not prove the stated conclusion that the Punjal basalts are

MORB, and cannot even prove whether the rocks are tholeiitic, alkaline or otherwise. Finally, the rocks are claimed to be primitive, which we do not agree with.

H/173. Humayun, M., Mayeda, T.K., Clayton, R.N., Petterson, M.G. & Windley, B.F., 1991. Oxygen isotope study of the Kohistan Batholith. Abstracts, Fall Meeting, American Geophysical Union.

The Mesozoic Kohistan island arc of northern Pakistan represents a major addition of juvenile crust to the Asian landmass. The arc was formed at a convergent plate margin by northward subduction of the Neotethys ocean. The Kohistan sequence is unique in that it is tilted to expose a complete section through the crust of a fossil island arc. The Kohistan sequence comprises a lower crust of mafic amphibolites and mafic-ultramafic granulites. This is overlain by a mid-crustal batholith, an extension of the Trans-Himalayan batholith, which is intrusive in its upper reaches into greenschist grade metavolcanics and metasediments.

We present oxygen isotopic data on the Kohistan batholith with evidence regarding the nature of crustal differentiation in island arcs. Geochronological work shows the rocks of the batholith to have formed in three discrete phases of magmatism. Stage I: trondjemites and K-rich diorites emplaced ca. 100 m.y., and subsequently metamorphosed; Stage II: gabbros, diorites and granodiorites emplaced 85-40 m.y., and constituting about two thirds of the batholith; Stage III: peraluminous leucogranites emplaced ca. 30 m.y., as minor dykes and veins. Diorites and granitoids from Stages I+II have $\delta^{18}\text{O} = 6.7\text{--}7.7\text{‰}$. Sr and Nd isotopic characteristics of mantle derived materials. We believe that these rocks formed by partial melting of the juvenile arc crust in Kohistan, and that the Sr and Nd isotopic and trace element ratios are entirely inherited from the (subarc) mantle source. We consider the higher $\delta^{18}\text{O}$ to be the result of a mixture of submarine weathered volcanic (+ sedimentary ?) material ($\delta^{18}\text{O} = 10\text{‰}$) with a plutonic component ($\delta^{18}\text{O} = 6\text{--}6.5\text{‰}$) in the lower crustal sources of the batholith. Such a source is conceivably found in the amphibolite belt underlying the batholith.

Stage III peraluminous Parri leucogranites pose something of an enigma. These rocks postdate collision of Kohistan with the Indian plate, and are mineralogically similar to and coeval with the Higher Himalayan leucogranites (HHL). Isotopic characteristics distinguish these rocks (initial $^{87}\text{Sr}/^{86}\text{Sr} = 0.7052$ and $\delta^{18}\text{O} = 8.4\text{--}9.2\text{‰}$) from HHL granites (initial $^{87}\text{Sr}/^{86}\text{Sr} = 0.727\text{--}0.785$ and $\delta^{18}\text{O} = 10.9\text{--}14.0\text{‰}$). It is quite obvious that the Kohistan leucogranites formed by partial melting of arc crustal materials, too. The slightly higher initial $^{87}\text{Sr}/^{86}\text{Sr}$ (0.7052 VS. 0.7044) can be entirely accounted for by Rb decay during residence in the arc source (> 10 m.y.), while the higher $\delta^{18}\text{O}$ may result from isotopic exchange between the fluid-rich leucogranite melts and country-rock metasediments.

The Kohistan batholith provides an excellent example of intra-crustal differentiation in island arcs, without the participation of pre-existing continental crust. Juvenile mafic crust is remelted during basaltic underplating of the lower crust to form granitic batholiths. Felsic crust made in island arcs is subsequently laterally accreted to the edges of continental plates, and can be incorporated in the interiors of continents by collisional events, as in the case of the Kohistan arc.

H/177. Husain, V., Ghani, A. & Qureshi, K., 1994. Vast export potential in dimension stone sector of Pakistan. Abstracts, Second SEGMIITE International Conference on the Export Oriented Development of Mineral Resources and Mineral Based Industries, p.16.

In recent years there has been the development of a "New Stone Age" with the increasing use and production of dimensionstone. Its demand in the international market is increasing with an average of 6% per year. Another important development has been the rise in production and export from developing and newly industrialized countries. In 1990 India and China contributed 7.4% and 5.9% to the total world exports of dimensionstone respectively. This industry plays most important role in the economy of even rich and developed country like Italy, which has 25% share in total global exports of dimension stone.

Despite huge deposits of large varieties of marble, granite and other building stones occurring in Northern areas, North West Frontier, Sindh and Balochistan provinces of Pakistan, dimensionstone industry remains backward, unorganized and unprotected by the government. Thus the exports of mostly raw blocks and small manufactured items from Pakistan is only 30 million US\$ per year, which can touch the mark of 3 billion US\$ per year in next 5-7 years, provided following steps are taken on urgent basis. Due importance is given to the buildingstone mining and manufacturing industry by the government.

Making and implementing clear cut national dimensionstone policy to encourage modern mining and processing methods and to attract non-traditional and big local and foreign investment in this sector. Providing soft term loans and other facilities as India, China and Brazil have done to make export oriented development of dimensionstone industry in recent years.

Providing road, rail network and other infrastructure including supply of electricity and water in the marble granite mining and processing districts. Close coordination among dimensionstone related businessmen and professionals in Pakistan for organizing seminars and exhibitions in the country and abroad and to raise issues confronting the dimensionstone industry before local and federal governments.

Key words: Dimension stones, export potential.

H/178. Husain, V., Haneef, M., Khan, H. & Siddiqi, F., 1990. Barite deposition near Haripur, Hazara. In: Siddiqi, F., Husain, V., Kaifi, Z. & Ghani, A. (Eds.), Proceedings, First SEGMIITE Conference on Industrial Minerals, March 1990, Peshawar, 22-28.

A barite district about 10 km north of Haripur occupies about 30 km² area. About a dozen vein deposits of barite occur in quartzites and dolomites. Regional analysis of this district suggests that barite occurs as veins and lenses in fractures and breccia zones. Field and laboratory evidence indicates that the barite deposits have good potential and are suitable for chemical paint and other industries. The occurrence is described in detail, together with stratigraphy, and chemical analyses of six barite ores and five of their associated rocks.

Key words: Barite, Haripur, Hazara.

H/179. Husain, V., Jan, N., Bilquees, R. & Ahmad, N., 1990. Petrology, mineralogy and origin of Hazara phosphates. In: Siddiqi, F., Husain, V., Kaifi, Z. & Ghani, A. (Eds.), Proceedings, First SEGMIITE Conference on Industrial Minerals, March 1990, Peshawar, 45-52.

Sedimentary phosphate deposits of Hazara have proven reserves of over 8 million tons. The phosphatic beds occur in two horizons-cherty dolomite (Abbottabad Formation) and siltstones (Hazira Formation) of Early Cambrian age. Tectonic activity resulting in highly complex structural features have disrupted and segmented the deposits. Two distinct types of phosphorite are common in the area; very fine-grained phosphorite and ovel-shaped pellets. The deposits may have formed authigenically by direct precipitation of fine-grained mud (carbonate fluorapatite), which subsequently modified into pellets. Deposition seems to have taken place in shallow waters within low paleolatitudes like major phosphorite deposits of the world.

Key words: Mineral deposits, phosphate, Abbottabad

H/180. Husain, V., Jan, N. & Siddiqi, F., 1990. Mineralization of Kumhar magnesite, Hazara, NWFP. (short communication) Pakistan Journal of Scientific and Industrial Research 33(9), 325.

Key words: Mineralization, magnesite, Hazara.

H/181. Husain, V., Khan, H., Husain, M., & Bilqees, R., 1997. Composition, origin and economic potential of Kakul, Lagarban and Tarnawai Phosphorite deposits of Hazara, Pakistan. Pakistan Journal of Scientific and Industrial Research, 40(1–4), 6–40.

The carbonate fluorapatite, dolomite, calcite, quartz, hematite, magnetite, feldspar, kaolinite, montmorillonite and illite were important minerals identified by XRD and microscopy. Apatite mainly occurs as microspherite and oolitic or disc shaped pellets of variable size. The P₂O₅ content of these phosphorites range from 22 to 36% with major impurities of silica, magnesium, iron oxides, alumina and alkalis. All field and laboratory data generated on these phosphorites suggest that Hazara phosphorites were formed authigenically and underwent various phases of deformation, variable degree of weathering and recrystallization to produce pelletal or granular phosphorites.

Key words: Petrography, economic geology, phosphorites, Hazara.

H/182. Husain, V., Khan, H., Qureshi, K., Ahmad, N. & Ali, I., 1991. Mineralogical and analytical studies of the southwestern Tanol Barite District, Hazara, Pakistan. Pakistan Journal of Scientific and Industrial Research 34, 2-3, 65-00.

The Southwestern Tanol mineralized area north of Haripur is one of the most promising areas of barite deposits in NWFP. Several vein type barite deposits occur in Lower Cambrian quartz and dolomite of Abbottabad Formation. Barite veins have a direction that is parallel to the general trend to the host and associated rocks. Barite, quartz, calcite, feldspar, pyrite, illite and chlorite were identified by XRD and microscopy. Barite and quartz are predominant. Some textural features like the absence of primary bedding, coarse grain size of barite and cherty quartz with cross cutting relationships suggest an epigenetic origin. To date, Kag deposits have been mined by open pit method to 300 feet below the surface and the ore veins are expected to continue further deep. The mineralization occurs in lens shaped bodies having strike length of several hundred meters. The barite content of vein deposits range from 53-97% BaSO₄ and impurities include quartz, calcite, dolomite, pyrite and limonite. The physical and chemical characteristics of the barite from this district suggest that these barites are suitable for drilling and chemical industries. They can also be used as filler in paint, plastic, paper and rubber industries.

Key words: Mineral deposits, Barite, Hazara.

H/184. Husain, V., Khan, M., Husain, M. & Siddiqi, F.A., 1994. Petrochemical and flotation studies of barite deposits near Haripur, NWFP, Pakistan. Sindh University, Research Journal 26, (1&2), 145-156.

The vein type barite deposits occur in Kag, Aluli and Darwaza near Haripur in NWFP. The coarse and interlocking grains of barite are hosted in quartzite and dolomite belonging to Abbottabad Formation. The barite is mostly whit to creamy, dark gray to brown in color. Barite textures vary systematically from coarse bladed to finely crystalline or massive. The specific gravity varies from 4.26 to 4.63. It contains 75-92% BaSO₄. Quartz, calcite, dolomite, pyrite, goethite and hematite are the principal impurities.

The purpose of the present study is to describe Kag, Darwaza and Aluli barite deposits from the economic point of view. The description includes the petrological, mineralogical and chemical characteristics of the ore. The flotation studies have also been carried out on these barite samples and results have been discussed.

Key words: Petrochemistry, barite, Haripur, Hazara.

H/185. Husain, V., Khan, M.M. & Siddiqui, F.A., 1990. Vein type barite deposits in Kag, Alulai and Dawaza near Haripur, NWFP, Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 9-10.

Vein type barite deposits occur in Kag, Aluli and Darwaza near Haripur, NWFP. Coarse and interlocking of grains of barite are hosted in dolomite and quartzite of Tanawal Formation. The barite rock is mostly grayish white to snow-white and massive, having a specific gravity that averages about 4.0 and contains 65-98 percent BaSO₄. Quartz, calcite, dolomite and iron oxide are the principal impurities. Preliminary flotation studies have indicated that quartz and other impurities can be removed from low-grade barites.

Key words: Barite, Tanawal formation, Hazara.

H/186. Husain, V., Sultan, S., Bilqees, R., Mateen, A. & Khan, B., 1993. Petrographic and geochemical studies of some phosphorite deposits of Hazara, Pakistan. Pakistan Journal of Scientific and Industrial Research 37, 6-7, 245-00.

Samples from Kakul mine and trenches of several phosphorite deposits were studied. These phosphorites occur in gradational contact with siltstone, dolomite and chert belonging to Abbottabad Cambrian System. Thinly bedded phosphorites occur mostly as pellets and microspherulites, while the intraclasts and pseudo-oolites are rare. Fluorapatite is abundant in all the samples, while quartz, calcite, dolomite, feldspar, illite and hematite occur in minor phases. These phosphorites are primary marine formed mostly by direct precipitation. Recrystallization is due to intense diagenesis, whereas ferruginization suggest weathering of phosphatic horizons in Hazara.

Key words: Petrography, geochemistry, phosphorites, Hazara.

H/187. Husnain, T. & Chaudhry, M.N. 1997. Strata-bound volcanic hosted gold, silver and sulphite mineralization occurrence in Paleocene-Eocene Dir volcanic group, District Dir, NWFP, Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 2p.

Dir volcanic group which hosts Au, Ag and sulphide mineralization is composed of calc alkaline volcanic flows, tuffs, agglomerates and ignimbrites. The volcanic and volcanoclastic horizons are often intercalated with and are underlain by shallow marine meta-argillites and quartzites. Therefore, at least the lower part of the Dir volcanic group is submarine. Upper part was deposited under marine to sub areal conditions. The age of this group is constrained by Eocene larger benthic Foraminifera which occur in the slightly metamorphosed marl and shales at the base of this group. Dir volcanic group represents the final stages in the magmatic/volcanic evolution of the Kohistan island arc terrain (Searle, 1991).

Although the Kohistan island arc itself was intra oceanic yet this volcanic group was laid down after the suturing of India with Asia sandwiching the Kohistan island arc. Therefore, these eruptions are in the nature of Andean type continental margin formed after the collision of Kohistan with Asia and closing of the Shyoke suture zone.

The rock which hosts gold, silver and copper anomalies occurs within the Dir volcanic group. The Dir volcanic group is composed of a lower Bawal Banda tuff and upper Utror volcanics. It represents the roof zone of the Kohistan batholith. One possible mechanism for mineralization is the late phase of southeast directed thrust sheets which cut the roof zone of the Kohistan batholith thus providing pathways to the hydrothermal copper rich fluids and strata bound mineralization in the Dir area. (Sullivan, 1989).

The geochemical studies of the mineralized zone show that Au varies from 3 to 11 ppm Ag varies from 6 to 200 ppm and Cu from 1% to 6.5%. The results are given in Table-1. Field observation and geochemical studies show that mineralization is strata bound type. Since the anomaly appears promising, therefore detailed studies should be carried out in the region to assess the potential of this mineralization.

Data analyzed on Atomic Absorption Spectrophotometer by Chemistry Division, GSP, Quetta.

Key words: Sulphide mineralization, gold, silver, Paleocene, Eocene, Dir volcanics.

H/191. Hussain, A., 1974b. Antimony, lead and zinc occurrences of Chitral District, North West Frontier Province, Pakistan. Geological Survey of Pakistan, Information Release 75, 31p.

An evaluation study of antimony, lead and zinc showings of Chitral district North West Frontier Province was made during the field season of 1971-72. Numerous showings of economic significance occur in Kamal gol (Krinj), Awrit gol and Pakhturi areas. In Kamal gol area (Krinj) the antimony ore is emplaced into Chitral slate at and near its faulted contact with the marble of Reshun Formation. The ore is being mined from Kamal gol 2A mine; the other mines viz. Angargun and Kamal gol 1A mines are closed since long. Probable reserves of 10,638 tons of ore has been estimated from Kamal gol 2A mine. In Awrit gol area, the high grade lead-antimony ore with some zinc is intermittently exposed for about 2000 feet along the faulted contact between the marble of Reshun Formation and phyllites of Kafirstan-Partsan area. Probable reserves of 57,142 tons of ore has been estimated.

In Pakhturi area, a hillock of calcarious quartzite and sandstone is traversed by a network of nineteen quartz veins containing lead-zinc ore with some copper. Reserves of exposed ore are small but the wide distribution of mineralization indicates the possibility of larger deposits at depth. Geophysical survey and exploratory development work at Kamal gol, Awrit gol and Pakhturi areas are recommended.

Key words: Metallic minerals, Lead-Zinc, Chitral.

H/192. Hussain, A., 1975. Silica sand deposits of Khisor and Marwat Ranges, North West Frontier Province, Pakistan. Geological Survey of Pakistan, Information Release 91, 22p.

This report gives details of Silica sand deposits in Khisor and Marwat ranges, D.I.Khan. The deposits are at the base of the Datta formation, with an average length of 4.2 miles in Marwat Range and 3 miles in Khisor Range. The deposit with a little effort at beneficiation can be made used for making flint glass containers, table ware, sheet, rolled and polished glass.

Key words: Silica sand, Khisor-Marwat Range, D.I.Khan.

H/193. Hussain, A., 1976. Silica Sand Deposits of Munda Kachha Area, District Hazara, NWFP, Pakistan. Geological Survey of Pakistan, Information Release 95, 21p.

An evaluation study of Silica sand deposits of Munda Kachha area, District Hazara, N.W.F.P. was conducted during the field season of 1972-73. The silica sand deposits are found in quartzose sandstone beds which is considered equivalent of Abbottabad Formation. The deposits occur in a broad syncline which extends from Sunda Gali to

Lugga Gali for a strike distance of four miles. The estimated reserves of silica sand upto a workable dip depth of 300 feet are found to be 57 million tons.

The average chemical analyses of 22 channel samples from silica sand outcrops of Munda Kuchha area contain SiO_2 95.93%, Fe_2O_3 0.61%, Al_2O_3 1.26% CaO 0.52%, MgO 0.79%. The sieve analyses results indicate that a major portion of silica sand lies between -20 mesh to -120 mesh which is the required grain size for the manufacture of glass sand. The deposit with a little effort at beneficiation can be made usable in glass manufacture. The sand in the area fall in the 3rd, 5th, 7th and 9th category according to US Bureau of standard specification for glass sand and is suitable for the flint glass, green glass and amber glass.

Key words: Silica sand, Munda Kuchha, Hazara.

H/194. Hussain, A., 1978a. An interim report on high grade limestone deposits around Attock, Nizampur area, North West Frontier Province, Pakistan. Geological Survey of Pakistan, Information Release 100, 21p.

A study of high grade Limestone deposits of Attock-Nizampur area, NWFP, was carried out on the request of State Cement Corporation of Pakistan for setting up of a Cement plant. The limestone is exposed in the form of five isolated outcrops which belong to Paleocene and Eocene ages. A reserve of about 930 million tons upto a workable dip depth of 200 feet in the area has been estimated.

The average chemical analyses of ten representative channel samples from the outcrops reveals CaO 51.34%, MgO 1.85%, SiO_2 3.42%, Fe_2O_3 0.5%, Al_2O_3 0.94%, SO_3 0.15% and L/ig. 40.96%. The limestone is suitable for the manufacture of Port land Cement and also suited for other industrial uses. The area is easily accessible and located close to rail and road links. This report is an interim document and will be followed by a more elaborate publication.

H/196. Hussain, A., 1978-80. Electrical Resistivity Survey for ground-water exploration in Mardan Township Area, District Mardan, NWFP. M.Sc. Thesis, Punjab University, Lahore, 76p.

This report presents the results of ground-water geoelectric investigations carried out in the Mardan Township area during the month of August, 1982, with the collaboration of Hydrological Directorate, WAPDA, Peshawar. The purpose of investigation was to collect the data to delineate the sub-surface geology of the area, and give some suitable sites for the installation of tubewells.

Mardan Township comprised an area of over 2 miles². Total 23 resistivity probes were run in the area. The electrical resistivity measurements were made with Georesistivity meter using the schlumberger electrical configuration. The common depth of exploration at these resistivity stations was 600 meter. The electrical resistivity curves obtained in the field were evaluated, interpreted and sub-surface geological cross-section based on true resistivity values were prepared to determine the vertical and horizontal extent of the sub-surface materials and aquifers.

Two-test hole upto a depth of two hundred feet were drilled and test wells were installed to determine hydrologic characteristics of the sub-surface sediments. The results of these studies indicate that within explored depth of 600 meters, the project area is under by sediments that consist dominantly of clay and silty clay. Beds of gravel and sand are present in the northwestern part of the project area extending further in the north-west. These beds of sand and gravel, constitute the aquifers in the subsurface, which may yield a fair supply of ground water discharge of these aquifers will be insufficient to meet the requirements of the area, which prohibits the installation of heavy duty tubewell in the project area.

H/198. Hussain, A., 1985-87. The geology and petrography of Sharda-Kel area, Neelum valley (Azad Kashmir) with special emphasis on granites. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 96p.

A geological map of 80 Sq. Km, between Sharda-Kel area is presented at the scale of 1: 25,000 on toposheets Nos 43 J/5 and 43 J/1 issued by survey of Pakistan. Metasediments comprised of garnet mica schist, granite gneiss, amphibolites and migmatites which host small and large sheets of granites. Metamorphic rocks from Sharda to Kel area represent inverted sequence which is conformable to rocks south of MCT in occupied Kashmir. Petrographic analysis identifies deformation features which more likely are attributed to thrusting. Field and petrographic study of granites of the project area indicates that granites are S-type and are formed by high degree of partial melting of metasediments in catazone environments. Economic mineral deposits like marble, garnet and kyanite are identified.

H/199. Hussain, A., 1989. Geology of Dunga Gali-Barian Area District Abbottabad. M.Sc. Thesis, Punjab University, Lahore, 105p.

Geological and structural mapping of Kotli-Nikial-Khuiratta area of about 300 square km was carried on 1:50,000 scale of toposheet No's 43 K/2, 43 K/3, 43 G/11 and 43 G/15 of survey of Pakistan. The lithostratigraphic units described range in age from Pre-Cambrian to Pleistocene and consist mainly of sedimentary rocks. The Pre-Cambrian rock formation is Dogra Slate and Cambrian rock unit is Sirban Formation. In this area apart from Lower Cambrian, all the formations of Paleozoic and Mesozoic are missing. Either they were not deposited or were weathered to form Bauxite/Fireclay representing an unconformity of a big gap. In the Tertiary period, Patala Formation, Margala Hill Limestone, Murree Formation and rocks of Siwalik Group were deposited. Section measurements were done to establish the stratigraphy.

The rocks are folded and faulted comprising the major and minor structures of the area. The major folds of the area are khuiratta-Kohali anticline (11pp/325pp), Devigarh-Palana anticline (04pp/313p), Tattapani-Karela anticline (6pp/116pp) and Khad-Bahni syncline (6pp/228pp). The major fault is the Himalayan Frontal Thrust with minor thrust like Gala Thrust and Khad Thrust. Deformational events and stereographic projection of the area have been interpreted. The tectonic setup has been also discussed. About eighty five rock samples were taken from the field and carried back to the laboratory for petrographic studies. In the field of economic geology, a number of deposits including Fireclay, Bauxite, Coal, Limestone, Chalk and Dolomite are of economic interest.

Key words: Mapping, geology, Abbottabad.

H/200. Hussain, A., 1989-90. Geology and structure of Kotli-Nikial Khuiratta area with special emphasis on Himalayan Frontal Thrust and related structures. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 111p.

This report incorporates a comprehensive geological study of nearly 25 sq. km. area between Dunga Gali and Barian on the Murree-Abbottabad road. The study includes the preparation of a geological map on the scale 1:7040.

Stratigraphically the rock units range from Upper Jurassic to Eocene and represent the sequence of the Hazara Province of the Kohat-Potwar Basin. It is primarily a limestone-shale sequence reflecting a stable shelf facies. Structurally, the area shows the development of a few synclinoria and anticlinoria, within which a generally tight parallel to similar asymmetric to overturn style of folding predominates. A number of dip-slip-strike faults, both of the normal and reverse type are present. A petrographic study of all rock units, based on fairly representative field sampling, is also present.

H/202. Hussain, A., 1997-98. Geological mapping and hydrological studies of Rawalakot area (District Poonch) A.K., with special emphasis on quality of water. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 96p.

The pearl valley, investigated for water resources is present in the lesser Himalayas and exposed rock units are from Pre-Cambrian to Recent age. MBT and Pir Panjal thrusts are two main structural elements nearer to the area. The area under investigation is mostly in hilly regions. There were three main available sources of water, springs, streams and wells. The springs water and ground waters are polluted by organic, inorganic and biological contamination and by domestic and other wastes. Chemical and physical quality of water is at intermediate to high risk but microbiological and pollutant results showed that drinking water is at high risk. Chemically the quality of water is at low to high risk. The chemical constituents (Ca, Mg, Na, K, HCO₃, CL, SO₄, NO₃, I, Fe, NO₂ and F) indicate the water is at high risk. T.D.S, T.S.S and temperature enhance the growth of bacteria in water. The toxic metals in water cause diseases like kidney stone, liver stone, blood cancers, vomiting, abdominal problems and headache etc. It is concluded that the drinking water available from springs, streams and ground water are at intermediate to high risk.

Key words: Cement raw material, limestone.

H/204. Hussain, A., & Arbab, M.S.H., 1997. Cement raw materials and their requirements in the North West Frontier Province. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1 p.

The main raw material components for cement production are limestone providing CaO and clay/shale/slate providing SiO₂, Al₂O₃ and Fe₂O₃. When the set points for certain constituent are not met by using only two raw material components, then the additive admixtures which include Si-Carrier (sand), Al-Carrier (bauxite) and Fe-Carrier (laterite/iron ore) have to be added in the raw mix. The content of oxides in the cement are approximately as follows:-

Calcium oxide	(CaO)	62-68%
Silica	(SiO ₂)	21-24%
Alumina	(Al ₂ O ₃)	4-8%
Ferric oxide	(Fe ₂ O ₃)	2-5%

The North West Frontier Province is gifted with extensive deposits of suitable grade raw materials for the manufacture of Portland cement. The potential calcareous raw material comprises of Shekhai Limestone of Precambrian age, Samana Suk Limestone of Jurassic age and Lockhart Limestone of Eocene age. The argillaceous raw materials include Manki Slate of Precambrian age, Patala Shale of Paleocene age. Kuldana Shale of Eocene age and Lacustrine deposits of Quaternary age. The additive admixtures include iron ore and silica sand deposits of Data

Formation of Triassic age and the laterite deposits at the unconformable contact between the Cretaceous and Paleocene rock sequence.

The chemical analysis of the channel and core samples from these deposits show that all the elements are within permissible limits for the production of the Portland cement. The reserves of the raw materials are vast and several cement plants can be installed within Nowshera. Haripur. Kohat. Dera Ismail Khan and Federally Administrative Tribal Areas. Water, electric power. road links and other infrastructural facilities are also available in the areas. Cement is in considerable demand in Pakistan and there are also bright prospects for exporting cement to the neighbouring countries.

Key words: Cement raw material, limestone.

H/205. Hussain, A., Arbab, M.S.H. & Pogue, K.R. 1998. Stratigraphic and structural evolution of the Peshawar Basin, Pakistan. Regional Postgraduate Training Course in Plate Tectonics, Punjab University, 32-33.

The Peshawar intermontane basin is a broad, oval shaped and low-lying depression at the southern margin of the Himalayas (Pakistan). It lies to the north of the Attock-Cherat

Range and contains rocks transitional between the sedimentary fold- thrust belt to the south and a metamorphic terrane to the north.

The basin came into existence as the Kalachitta Range was faulted south on the Main Boundary Thrust (MBT) pushing the Siwalik foreland basin still farther south. The basin fill sediments predominantly comprise of lacustrine, deltaic and fluvial deposits which are overlain by loess, flood-plain and alluvial-fan deposits of younger age. The study of the Landsat data, aerial photographs and subsequent field studies indicate a zone of late Quaternary deformation that extends across the southern margin of the Peshawar basin. Lacustrine, fluvial and alluvial-fan deposits that are dated at 2.8 to 0.6 Ma are tilted, folded and faulted along four left-stepping pressure ridges that extend for nearly 60 km.

Alluvial-fan and fluvial sediments are also folded and faulted at the Tarbela Dam and the base of the Indus River appears to be displaced by a reverse fault with its northwest side up. Additional small lineaments and faults occur parallel and oblique to the major fault structures. As a result of the present study, especially the finds of conodonts, the bed rock sequence of the Peshawar basin established previously, has been modified and revised. An almost complete sequence of rocks ranging from Precambrian to Triassic in age has been established for the first time in the Peshawar basin.

H/214. Hussain, A., Khan, S.R. & Saeed, G., 1990. A new look at the coal occurrence In Cherat area, N.W.F.P., Pakistan. In: Siddiqi, F., Husain, V., Kaifi, Z. & Ghani, A. (Eds.), Proceedings, First SEGMITE Conference on Industrial Minerals, March 1990, Peshawar, 34-37.

Small occurrences of coal deposits occur in Late Paleocene to Early Eocene Patala Formation in several places in the province. The Cherat coal, instead, occurs in the Early Paleocene Hangu Formation. The general stratigraphic setup of the Cherat Range comprises 1) Precambrian Dkhner Fm That is unconformably overlain by 2) Jurassic Samana Suk Fm, itself overlain by 3) Hangu Fm, 4) Paleocene Lockhart Limestone, Patala Fm, and unconformably overlying Early Miocene Murree Fm. Reserve estimates are not available, but the occurrence of coal in abandoned mine workings and boreholes suggest that its occurrence is widespread. The coal deposits of Aurakzai Agency and Makerwal are also located in the Hangu formation, raising the possibility of widespread occurrence of the coal of this age.

H/218. Hussain, A., Pogue, K.R. & DiPietro, J.A., 1998. Stratigraphic and structural framework of the Himalayan foothills between Panjal-Khairabad thrust and MMT, Peshawar Basin, Northern, Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, p.82.

The Panjal-Khairabad Thrust form the boundary between the Lesser Himalayan and Tethyan section, a function performed by the Main Central Thrust (MCT) in the Central Himalaya of India and Nepal. All pre-Cenozoic rocks north of the Panjal-Khairabad Thrust have been metamorphosed. The metamorphism increases from south to north from greenschist to kyanite grade. An almost complete sequence of rocks ranging from Precambrian to Jurassic age has been established for the first time in the area. The Proterozoic rocks represented by Gandaf Formation and Manki Formation with associated carbonate form the base of the stratigraphic section. These rocks are overlain by Precambrian and Cambrian Tanawal Formation; Cambrian (?) Ambar; Ordovician Misri Banda; Llandoveryan to Pridolian Panjpir Formation, Lochkovian to Frasnian Nowshera Formation and Kinderhookian to Westphalian Jafar Kandao Formation. The Karapa Greenschist, consisting of metamorphosed lava flows separate the Jafar Kandao from Upper Triassic (Carnian) marble of Kashala Formation. The upper Triassic and Jurassic (?) Nikanani Ghar Formation forms the top of the section.

Correlatives to the stratigraphic setup of the Peshawar Basin are present in the Khyber-Mohmand to the west and Hazara to the east. The sequence contrasts markedly with the Paleozoic and Mesozoic sequence exposed to the south of Panjal-Khairabad Thrust. The newly - dated Carboniferous to Triassic rocks provide age constraints on the high-grade metasediments of Swat exposed to the south of MMT. The dating has also provided age constraints on pre-Himalayan tectonism and intrusions. The stratigraphic information combined with geochemical analyses and radiometric dates on the igneous rocks of the area permits the recognition of a major phase of Paleozoic rifting in the Peshawar Basin.

H/220. Hussain, A., Pogue, K.R. & DiPietro, J.A., 2001. Stratigraphy of the Precambrian rocks of the northwest Himalaya, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.28.

The Precambrian rocks of the northwest Himalaya, Pakistan consists of Proterozoic and Archean (?) crystalline basement rocks overlain by a Proterozoic sedimentary and metasedimentary cover sequence. The effect of regional metamorphism increases gradually from south to north. South of the Main Boundary Thrust (MBT) Upper Proterozoic evaporites (the Salt Range Formation) unconformably overlie Proterozoic metamorphic and igneous

complex exposed in the Kirana Hills of Sargodha, Chiniot and Sangla areas (Gee, 1989). Between the MET and the Panjal-Khairabad thrust (PKT), the Proterozoic sedimentary cover is represented by sandstone, argillite, slate, and limestone of the Dakhner Formation in Attock-Cherat Range and its eastern equivalent the Hazara Formation in Hazara. Gypsum intervals in the Hazara Formation imply that the Hazara and Salt Range Formations may be lateral equivalents. Between the PKT and Darband Fault, the oldest exposed Precambrian rocks are slate and phyllite of the Manki Formation, which are interpreted as the metamorphosed equivalent of the Hazara/Dakhner Formation. The Manki Formation is overlain by limestone and argillite of the Shahkot, Utch Khattak, and Shekhai Formations. These limestones thin northward to be replaced by quartzite and argillite of the Tanawal Formation. Near Tarbela Lake, the Tanawal Formation overlies marble and graphitic schist of the Gandaf Formation, which is interpreted as a higher-grade equivalent of the Manki Formation. The Gandaf Formation thickens northward in the Indus syntaxis and unconformably overlies graphite-muscovite plagioclase schist and tremolite marble of Karora Formation of Proterozoic age. The metaconglomerate is found at the base of Karora Formation where it unconformably overlies small outcrop of quartzo-feldspathic rock, gneiss, and quartzite of Kishar Formation of Early Proterozoic age. The entire Precambrian sequence around Tarbela Lake is extensively intruded by Cambrian granodiorite (the Mansehra and Swat Granites), Late Paleozoic alkaline granitoids (the Ambela intrusive complex), and Permian mafic dikes and sills. In the Indus Syntaxis north of Tarbela there is evidence of plutonism of Early and Late Proterozoic age by the granodiorite gneiss, orthogneiss and leucogneiss of Besham Complex, orthogneiss of Kotla Complex and biotite orthogneiss and migmatite of Black Mountain Complex.

Key words: Stratigraphy, Paleozoic, Peshawar basin.

H/222. Hussain, A., Pogue, K.R., Khan, S.R. & Ahmad, I. 1991. Paleozoic stratigraphy of the Peshawar basin, Pakistan. Geological Bulletin, University of Peshawar 24, 85-97.

An almost complete Paleozoic sequence of sedimentary rocks is exposed in the ranges fringing the Peshawar basin. The present study establishes a revised stratigraphy and modifies the stratigraphic nomenclature of the previous workers. The Pre-Cambrian – Cambrian Tanawal Formation forms the base of the sequence and is overlain unconformably by the Ambar Formation (Cambrian?). The Misri Banda Quartzite unconformably overlies the Ambar Formation and contains Cruziana ichnofossils, which indicate an Early to Middle Ordovician age. The limestone at the base of the Panjpir Formation contains siluric zone conodonts (Ludlovian) and unconformably overlies the Misri Banda Formation. The Early to late Devonian Nowshera Formation overlies the Panjpir and contains a reef facies first recognized by Stauffer in 1968. The youngest recognized Paleozoic unit is the Jafar Kandoa Formation from which Carboniferous conodonts have been obtained. The section outlined above has possible correlatives in the Khyber and Hazara regions, but differs dramatically from the Paleozoic sequence of the Salt Range to the south. The tectonic setting of the area is transitional between a sedimentary fold belt to the south and a metamorphic terrane to the north.

Key words: Stratigraphy, Paleozoic, Peshawar basin.

H/223. Hussain, A., Siddiqui, F.A. & Arbab, M.S.H., 1994. Prospect and potential of the light weight aggregates in Pakistan. Abstracts, Second SEGMITE International Conference on the Export Oriented Development of Mineral Resources and Mineral Based Industries, p.19.

Lightweight concrete aggregates are expanded rock material weighing less than the conventionally used aggregates of sand, gravel and crushed stone. These aggregates are produced from natural deposits of pumice, scoria, volcanic cinder, tuff and diatomite; by industrial cinder; and by the application of heat to expand clay, shale, slate, diatomaceous shale, perlite, obsidian and vermiculite. In Pakistan workable occurrences of these material except for

clay, shale and slate are either non-existent, at present, or are found in such remote regions that the cost of their mining and transportation to the consuming centres, is prohibitive.

Bloatable argillaceous raw material suitable for use in the making of lightweight aggregate has been proved to exist in large quantities in the region between Islamabad and Peshawar. This raw material comprising of Eocene shale and Precambrian slate is exposed in parts of the Margalla and the Attock-Cherat Ranges respectively. Low cost open pit mining can be applied for its extraction. Field and laboratory studies conducted jointly by the GSP and the Pakistan Council of Scientific and Industrial Research have established that the unit weight and compressive strength of the cubes (test) made from this material (expanded compares well with the ASTM specification for the structural concrete).

The clay deposits are widely found in the country but most of these attain the desired level of bloating only after the addition of organic matter. This raises the production cost and often creates processing problems.

Investigations in other parts of the country for lightweight aggregates are planned to be undertaken in the near future.

Key words: Light weight aggregates, sand, gravel.

H/227. Hussain, A., Yeats, R.S. & Pogue, K., 1989a. Stratigraphy and structural events around the southern margin of Peshawar basin, Pakistan. Geological Bulletin, University of Peshawar 22, 45-54.

The Peshawar intermontane basin is superimposed on the fold-thrust belt at the southern margin of the Pakistan Himalayas. In the southern part of the basin the first Ordovician rocks were identified near Nowshera on the basis of discovery of trilobite trace fossils and consequently the Paleozoic stratigraphy of the area has been revised and modified. The Attock-Cherat Range forms the southern boundary of the Peshawar basin and includes rocks transitional between metasediments of Lesser Himalayas and foreland basin strata of Kala Chitta Range to the south. The range is dominated by slate, less metamorphosed argillaceous and arenaceous strata and subordinate limestone of Precambrian to Paleozoic age. These rocks are unconformably overlain by a thin cover of Jurassic, Cretaceous (?), Paleocene, Eocene and Miocene rocks. The structural events close to the Peshawar basin are recognized in pre-Paleocene, pre-Pliocene and late Quaternary times. The Peshawar basin formed as the Kala Chitta Range was faulted south on the Main Boundary Thrust (MBT) pushing the Siwalik foreland basin still further south. Evidence for active tectonics is found in four left-stepping en-echelon pressure ridges formed within Peshawar basin parallel to its southern margin.

Key words: Stratigraphy, structure, Peshawar basin.

H/235. Hussain, I., 1990-92. Sedimentology of Middle Jurassic Samana Suk Formation, District Abbottabad, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 186p.

The Samana Suk Formation is a part of Mesozoic sequence, starting from Early Jurassic Datta Formation to Upper Cretaceous Kawagarh Formation. This sequence is interrupted by one break in deposition.

The sedimentology of Samana Suk Formation exposed at Sikhar ridge (Sangar Gali) and Thai Barrier (near Abbottabad) is based upon thorough section measurements, collection of more than three hundred samples followed by extensive laboratory work. The Samana Suk Formation represents five shallowing upward cycles. Every cycle is topped by hard ground surface on ooidal grainstone. The sediments have been subjected to various diagenetic events, out of which dolomitization is significant phenomenon. At least two phases of dolomitization have been determined. The zonation in the dolomite crystals not only represents the pore water chemistry but also varied

environments of formation. Dedolomitization has led to the development of porous horizons. The third order sea level curves based upon microfacies assemblage and diagenetic events generally match with P.R. Vail's curves.

Key words: Sedimentology, Samana Suk Formation, Datta Formation, Mesozoic, Jurassic, Abbottabad.

This thesis presents a geological map of the 30 sq .miles of project area (DAREL) on scale 1" = 1 mile. The project area (Darel) lies in Gilgit Agency, district Diamer. The area is located in the centre of Kohistan. Area is disturbed tectonically, being involved in Himalayan orogeny. The area is composed of igneous and metamorphic rocks. The main rock units in the area are Norite, Diorite, Amphibolites and Granodiorites. Mineralogical description and petrographic analysis of these rock units are reported in detail. An attempt is made to interpret the petrogenesis of rock types. The Thesis presents a detailed geological and petrological investigation of the project area. Norite and amphibolites represent oceanic crust while Diorite and Granodiorite etc. represent plutonic equivalents of arc. To achieve this goal a period of 45 days was spent at the site during July, August 1984.

Key words: Petrology, diorite, amphibolite, Diamir.

H/240. Hussain, M., 1988. Report on Geology and Structure of Balakot-Kummi Area. M.Sc. Thesis, Punjab University, Lahore, 100p.

The present work constitutes a comprehensive report on the geology of Balakot-Kummi area and is submitted in partial fulfillment of the requirements for the degree of M.Sc. at the University of Punjab. The report includes a detailed geological map at 1:6,000 of about 65-km²-area alongwith a number of geological sections and sketches. The various chapters include geomorphology, stratigraphy, structure and tectonics. Stratigraphically, the Balakot-Kummi area includes a number of diverse sedimentary and metamorphic elements ranging in age from Precambrian to Miocene with a fairly large gap in the Mesozoic period. Structurally, the area incorporates part of the core and western limb of the Hazara-Kashmir syntaxis and through it pass the major Murree and Panjal Faults. The Balakot-Muzaffarabad anticline is the major fold overturned and overthrust to the southwest. No major economic mineral deposit was found within the project area, although a lot of material is available as rock crush, aggregate components and building stones.

Key words: Mapping, structure, sedimentary rocks, metamorphic, Precambrian, Miocene, Balakot, Hazara.

H/241. Hussain, M., 1990-92. Geology and structure of Changla Gali Area, District Abbottabad. M.Sc. Thesis, Punjab University, Lahore, 170p.

Large-scale (1:7000) geologic mapping of a small segment of the Lesser Himalaya in the Chhangla Gali area is presented. A Jurassic to Eocene succession mainly comprising shallow shelf carbonates, with an important unconformity at the Cretaceous-Tertiary boundary, is part of the southern Hazara sedimentary province. A petrographic microfacies study of measured sections of Lockhart limestone reveals that the formation comprises 31 microfacies of mudstone, wackestone and packstone. Structurally the area comprises NE-SW trending double plunging folds constituting anticlinoria and synclinoria. The folds are tight to isoclinal with a general vergence to the southeast. The folded sequence is disrupted by a number of high angle dip-slip strike faults especially within or on the margins of anticlinoria.

Key words: Structure, petrography, Jurassic, Eocene, Abbottabad.

H/243. Hussain, M. & Siddiqi, R.A., 1993. Phosphorite prospecting in Nizampur area, District Peshawar, NWFP. Geological Survey of Pakistan, Information Release 539.

Geological and geochemical investigations were conducted in Nizampur area, district Peshawar, NWFP, for the phosphorite prospecting. Rock units exposed in the area belong to the formations ranging in age from early Triassic to recent deposits. Field and camp chemical tests were conducted for P_2O_5 content in the samples collected from the outcrops. Detailed analyses were also done of few selected samples from different formations.

The work concluded that two formations i.e., Chichali formation (early Cretaceous to late Triassic) and Lumshiwal formation (early Cretaceous) have Phosphatic nodules which contain upto 27% and 28% P_2O_5 respectively. The size and percentage of these nodules are varying whereas the matrix is mostly devoid of P_2O_5 content. There is no economic significance of these phosphatic rocks. However the green sand part of the Lumshiwal formation which has 1-2% P_2O_5 and quite friable can directly be applied in the fields to give better crops. Green sand has also been used as potassic fertilizer and water softener in different parts of the world. It was observed that crops growing on green sand bearing area, were looking better and reportedly giving better yield in comparison to the one's on the other rock units.

Key words: Geochemical prospecting, phosphorite, Nizampur, Peshawar.

Patala Formation having khaki Shales with fossiliferous limestone bands. The environment is shallow marine, (Circa littoral sub-zone). Margala Hill Limestone is fossiliferous, nodular limestone. It shows deep sea depositional environment. Chorgali Formation consists of limestone with marl, having abundance of fossils. It shows shelf

environment. Kuldana Formation mainly has shale, marl and sandstone with gypsiferous bands. The Formation was deposited in shallow marine oxidizing conditions. The climate was hot and arid and the rate of evaporation was high. The thin section slides from Jurassic to Eocene rock units have been studied. Petrographically Lockhart Limestone (Paleocene) and Margala Hill Limestone (Eocene) have been studied in detail. According to Folk's (1962) classification, Lockhart Limestone is normally Wacke to pack stone while according to Dunham's (1962) it is fossiliferous to packed biomicrite. Margala Hill Limestone is mainly wacke stone, mud stone and packstone (Folk's) and it is biomicrite, biosparite and biosparry micrite (Dunham's). The measured stratigraphic sections of the rock units from Jurassic to Eocene are presented in Lithologs No 1 to 4 (Pocket). Tectonically the area is highly disturbed, being involved in Himalayan Orogeny. Geological sub surface structures are described with the help of cross section. Almost all the major structures follow the general trend NE-SW. From the cross-section line along AA' shows that there is intrusive deformation in the area. Some important folds are Hili-Bagla anticline, Seri and Kuhmal synclines. The project area is highly faulted. The major faults Malat Thrust fault and Kohala-Darkot Thrust fault running parallel to sub parallel following general trend. These faults are reverse and thrust steeply dipping to SE. The Economic potential of limestone of various rock units, Laterite and aggregates have been

H/247. Hussain, M.S. & Ahmad, S., 1969. A study of analcime mineral in some soils of West Pakistan. Pakistan Journal of Scientific and Industrial Research 12, 34-36.

Three out of a total of nine soil samples from West Pakistan showed unusually high (more than 100) exchangeable sodium percentage (ESP) when determined according to the conventional methods. But the pH of these soils ranged from 7.0 to 7.6. This was regarded as an unusual result. It was suspected that the high ESP in the soils may be due to "zeolitic sodium" released from analcime mineral. An intensive mineralogical investigation showed that there is no analcime mineral present in these soils. The high ESP in the soils was therefore not caused by analcime mineral. Low pH values (7.0-7.6) might be regarded as the main obstacle in the way of the synthesis of analcime in the soils under study.

About 130 sq. km Doarian, Dudhnial, Khoja-Seri area a part of Neelum valley (Azad Kashmir) has been mapped at a scale of 1:50,000. The area is characterized by high relief and v-shaped valleys. The rocks of the area are metamorphic of lower Pre-Cambrian, injected by later intrusions of igneous bodies, granites with some basic. Regional metamorphism and accompanying penetrative deformation post-dates the granite intrusions, because the granite itself is involved in the deformation. Field evidences and laboratory studies favour magnetic origin for the granitic bodies. The area is tectonically highly disturbed being involved in Himalayan orogeny. For petrographic analysis thirty thin sections were studied. Petrogenesis of the rocks of the area is interpreted. Major and minor structures of the area are described. Geological history of the Project area is worked out in comparison with adjoining areas of Punjab Himalayas and northern peninsular India. Economic minerals found in the area are listed.

Key words: Tectonics, structure, metamorphism, Muzaffarabad, Azad Kashmir.

H/251. Hussain, S., 1983-85. Biostratigraphy of the Jhalar Area-the Kala Chitta Range, Attock District. M.Sc. Thesis, Punjab University, Lahore, 90p.

A geological map of the Jhalar area-the Kala Chitta Range, on a scale of 1" to 0.789 mile or 1:50,000 and covering an area of 16.43 miles² has been prepared to discuss the stratigraphy and micropaleontology of the area. An attempt has been made to discuss the importance of foraminifera content of these rock units, for determining the depositional pattern and age. The geological sequence of the Kala Chitta Range with a view to recognize the continuity or unique aspects of the lithostratigraphic units in the adjoining area. The various geological events that occur in the area and their geological implications have also been discussed. In the Kala Chitta Range there are some eighteen lithostratigraphic units but the area under discussion comprises ten lithostratigraphic units mostly of marine environments and with non-marine units.

Key words: Stratigraphy, micropaleontology, Foraminifera, Kala Chitta, Attock.

H/252. Hussain, S., 1999-2000. Geological mapping of Kohala-Muzaffarabad area with special emphasis on slope stability problems identification analysis & remediation along Kohala Muzaffarabad Road Azad Kashmir. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 75p.

Gullian, Dulai and Rara is an area of high landslides hazards. The landslides are at the right bank of the River Jhelum, characterized by high and narrow divides separated by steep tributaries cut into bedrock. The rocks are highly fractured and jointed with steep dipping slopes agitated by (MBT) and pore water pressure. The abundance of clays and silty soils and humid climatic condition of the area contribute to landsliding in Muzaffarabad region. The situation is aggravated by cutting for road widening and destabilization of slopes by earthquakes resulting in major landslides. Rock fall, rock topple shear failure. Earthflow, slumps and combination of these are most common modes of failure. Gullian (1-2)) Dulai and Rara landslides were investigated in detail because of the proximity to roadways. Topographic and geological maps were prepared for each soil and soil samples were collected to establish engineering properties and stratigraphic succession involved in failure. It has been concluded that the slope failure is mainly in the areas where Murree clays are involved. The swelling potential of Murree clays, pore water pressure, Main Boundary Thrust (MBT) and uneven drainage also contribute to landsliding. It is suggested that the improvement of drainage pattern calculation of overburden material, pore water pressure and after the consideration of seismic loads retaining walls should be constructed. At places piling is also necessary.

H/255. Hussain, S.S., Chaudhry, M.N. & Dawood, H., 1992. Emerald mineralization of Barang, Bajaur Agency, Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.57.

Consult the following account.

Key words: Emerald, gemstone, mineralization, Bajaur.

H/256. Hussain, S.S., Chaudhry, M.N. & Dawood, H., 1993. Emerald mineralization of Barang, Bajawar Agency, Pakistan. *Journal of Gemmology* 7, 402-408.

This is the first account of emerald mineralization from Barang, Bajaur Agency, NW Pakistan. Emerald mineralization is associated with talc carbonate host of the Indus suture ophiolitic mélange. The mineralization is pneumatolytic and hydrothermal late to post tectonic and structurally controlled. For the first time it is being recognized and proposed that the source of beryllium bearing fluids responsible for emerald mineralization are the Tertiary minor granites of S-type occurring in the area. This is contrary to the already held views that beryllium fluids emanated from a trench or arc source. The color of Barang emerald varies from light bluish green to deep green and the crystal range from minute to 2.5cm. This paper for the first time presents cell dimension of emerald from Pakistan by using an advanced computer program and four cycles of refinement.

Key words: Emerald, gemstone, mineralization, Bajaur.

H/257. Hussain, S.S., Chaudhry, M.N., Dawood, H. & Anwar, J., 1989. Geology and emerald mineralization of Barang-Turghao area, Bajaur Agency, Pakistan. *Kashmir Journal of Geology* 6 & 7, 87-102.

Geology and emerald mineralization of Barang-Turghao area have been studied for the first time. Rocks of the area are comprised of (a) granite gneisses, arenaceous, calcareous and argillaceous metasediments (rocks of Indian Plate) and (b) greenschists, greenstones, quartzites, gabbros and talc-carbonates (ophiolitic melanges zone). Emerald mineralization is associated with talc-carbonates. Petrographic and field studies reveal that this mineralization is pneumatolytic, post tectonic and structurally controlled. The source of the beryllium bearing fluids, responsible for emerald mineralization could be the non-foliated younger granites in the surroundings. It is also supported by the presence of the blue beryl in the area. Other minerals which may have some economic significance are hessonite garnet, green garnet, epidote, graphitic and apatite.

Key words: Emerald, gemstone, mineralization, Bajaur.

H/258. Hussain, S.S. & Dawood, H., 1996. Beryl Mineralization of Higher Himalayas and its implications for emerald mineralization in Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 69.

Blue and green beryl in granites of Higher Himalayan Crystalline Block in Malakand Agency and district Dir has been found at a number of places. Emerald is being mined from the adjoining areas of Seat district and Bajaur Agency since the late sixties. The beryl mineralization has been studied in detail with the aim of determining its nature and to see its implications for emerald mineralization in the region.

Stratigraphically, the Higher Himalayan Crystalline block exposed to the south of the Main Mantle Thrust (MMT) is comprised dominantly of (i) granitoid-migmatitic complex with metasedimentary enclave and abundant pegmatites, (ii) pelite-psammite sequence with abundant pegmatites, intrusive granites and contact migmatites and (iii) pelite-psammite of kyanite-sillimanite grade with pegmatites and granites. The beryl mineralization has been noted in simple pegmatites and hydrothermal/pneumatolytic veins including quartz veins, quartz-feldspar pegmatites, quartz-feldspar-mica pegmatites and quartz-feldspar-mica-fluorite pegmatites. The pegmatites and veins are of variable dimensions up to a few meters long and wide. Besides, in Dir District, quartz, quartz-calcite and quartz-ilmenite veins are observed to contain beryl mineralization. From the field observations it is noted that beryl mineralization phase is younger than quartz ilmenite phase.

The beryl mineralization is observed in pockets or cluster. The color of beryl varies from light blue, through deep blue to greenish blue. The crystal is usually small sized and fractured, opaque to translucent and slightly transparent. Five samples of granite gneiss from the mineralized areas have been studied petrographically. These are mostly hypidiomorphic granular. Granite gneisses of Barh and Kot (Malakand Agency) have dominant orthoclase with only up to 2% albite, whereas Turghao and Agra gneisses have 34% and 35% albite/plagioclase respectively. Amphibole

(0.5% in each) is present in two samples. Muscovite and biotite occur as elongated flakes and impart gneissic structure to the rock. Feldspar shows alteration to clay. Calcite, epidote, sphene and ore minerals are the other accessories.

Two beryl samples from Badwan and Ramial, district Dir were analyzed chemically. Among the major elements, SiO₂ is 62.74% and 65.80%, Al₂O₃ is 13.23% and 16.08% and BeO is 12.99% and 7.31% in Badwan and Ramial samples, respectively. Comparison of major and trace elements in beryls from Badwan and Ramial (Dir) and Swat emeralds shows that Na is high in beryls as compared with emeralds, whereas Bi, Co, P, W and Zn is high in beryls found in hydrothermal/pneumatolytic veins than in pegmatitic beryls as well as emeralds. Cr, Ni and V are high in emeralds, which is attributed to the host ultramafics.

Beryls from Ramial and Badwan (Dir) and Barh and Batoo (Malakand Agency) have also been studied by XRD techniques. The cell dimension of beryls were found to cover the ranges: $a=9.9216-9.259\text{\AA}$ and $c=9.189-9.219\text{\AA}$. The densities of beryl range from 2.611 to 2.633. It is the lowest case of the Badwan beryl.

The granites represent different episodes of magmatism. The younger fine-grained Tertiary granites intrude older Proterozoic granitic gneisses. The mineralized veins and pegmatites cut gneissic as well as younger fine-grained granites. Beryl mineralization found in quartz veins and pegmatites associated with Proterozoic granite gneisses as well as younger, undeformed Tertiary granites is widespread.

Based on field and laboratory studies, it is considered that the Be-B-F-Al bearing solutions, which gave rise to beryl as well as emerald mineralization originated from the post-tectonic Tertiary granites. In the case of emeralds, the required Cr was imparted by the host talc carbonates.

Key words: Emerald, beryl, gemstone, mineralization, Malakand, Dir.

H/259. Hussain, S.S., Dawood, H. & Chaudhry, M.N., 1990a. Application of geochemistry to emerald exploration in Swat, Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 25-26.

Geochemistry has been rarely used for emerald exploration. The present studies for finding geochemical Pathfinders for emerald mineralization in Swat are significant.

Geochemical characteristics of the emerald bearing rocks of Emerald Mines have been determined. For this purpose, rock and stream sediment analyses of mineralized and non-mineralized areas were carried out using Induced Couple Plasma Emission Spectrometry. Multi-variate studies on the analytical results of 105 samples reveal that high Be, along with high Li, Sr and La may be taken as pathfinders for emerald mineralization in the Swat Emerald Mines.

Malam was selected as the target area where talc carbonates have the same physical and mineralogical characters like that of the Swat Emerald Mines. In this area, no significant anomalies could be distinguished using the geochemical model of Swat Emerald Mines; however, high Be and Li anomalies are evident in Malam stream sediments. Such geochemical studies, if carried out in conjunction with mineralogical and structural studies of a particular area, would be more helpful for pinpointing its emerald mineralization.

Key words: Emerald, gems, exploration, geochemistry, Swat.

H/260. Hussain, S.S., Dawood, H. & Chaudhry, M.N., 1990b. Ophiolite related manganese mineralization in Kassai, Lower Mohmand Agency and Shangla, Swat, Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 47p.

Ophiolite related manganese mineralization in Kassai area, lower Mohmand Agency has been studied and its comparison with that of the Shangla area, Swat has been done. Kassai Mn mineralization is observed as hydrothermal lenses and veins in tectonic block of quartzite in the Kot-Prang Ghar melange complex. Petrographic and chemical analyses of eight samples are presented. Samples of manganese ore of Kassai and Shangla contain upto 60% and 32.46% MnO₂ respectively. Field observations reveal that Kassai area might contain more mineable reserves of similar nature.

Field and laboratory studies indicate that the manganese mineralization of Kassai and Shangla is of hydrothermal origin related to the volcanic activity during the closure of Tethys ocean. It is assumed that manganese has been incorporated hydrothermally in the oceanic sediments in shallow ocean environments during the tectonic activity.

Key words: Ophiolites, ultramafics, manganese, mineralization, Mohmand Agency, Shangla, Swat.

H/261. Hussain, S.S., Dawood, H. & Chaudhry, M.N., 1990c. Application of geochemistry to emerald exploration in Swat, Pakistan. Geological Bulletin, University of Peshawar 23, 45-65.

There are very few cases in the world where geochemistry has been used for emerald exploration. The present studies to fine out geochemical pathfinders for emerald mineralization in Swat are hence significant.

Geochemical characteristics of the emerald bearing rocks of Swat Emerald Mines have been determined. For this purpose rock and stream sediment analyses of mineralized and non-mineralized areas are carried out using Induced Couple Plasma Emission Spectrometry.

Univariate and multi-variate studies on the analytical results of 105 rocks and stream sediment samples of Swat Emerald Mines and Malam area were carried out. These studies reveal that high Be along with high Li, Sr and La may be taken as pathfinders for emerald mineralization in the Swat Emerald Mines.

Malam was selected as target area where talc-carbonate have the same physical and mineralogical characters like that of the Swat Emerald Mines. In this area no significant anomalies could be distinguished using the geochemical model of Swat Emerald Mines, however, high Be and Li anomalies are evident in Malam stream sediments. Such geochemical studies, if carried out in conjunction with mineralogical and structural studies of a particular area, would be more helpful for pinpointing its emerald mineralization.

The authors briefly described the Indus Suture rocks and associated ophiolitic mélange. A number of metallic/non-metallic mineral and gemstone reported from the suture include emerald/beryl, manganese, chromite, nickel, green garnet, epidot, rodingite and talc.

Key words: Mineral deposit, Suture zone, Himalayan

H/264. Hussain, S.S., Dawood, H. & Chaudhry, M.N., 1995b. Green Garnet (Tsavorite) Mineralization in Higher Himalayan Basement Rocks of NorthWest, Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

This is the first detailed account of the vanadium and chromium bearing green garnet (tsavorite) mineralization associated with metasediments and carbonatites of Higher Himalayan crystalline slab of Bajaur and Malakand agencies and Swat district, north- west Pakistan.

Euhedral and anhedral tsavorite in Jambil, Swat is found in quartz veins within graphitic schists which are part of Proterozoic basement pelitic-psammitic metasediments, metamorphosed to upper amphibolite facies and intruded by granitic rocks of Tertiary? as wells as 400 Ma, 51 0-560 Ma, 580-600 Ma, 1517 Ma, 1970-2031 Ma in age. These rocks make the northern margin of the Indian plate, south of the Main Mantle Thrust.

In Mairagai (Swat), Selai Patti (Malakand Agency) and Bagh-Turghao (Bajaur Agency) green garnet bearing carbonatites are exposed in a linear belt of more than 100 kms and occur as sheets, sills, ring type and lensoidal bodies of variable dimensions. These rocks are generally medium to coarse grained, white, earthy white to brownish in colour having sugary texture.

Selai Patti (Malakand Agency) and Bagh-Turghao (Bajaur Agency) carbonatites show alteration to feldspathic material along joints and in certain zones, which are mineralized. However, in Mairagai (Swat) no such alteration has been seen. The altered parts of carbonatite in Selai Patti and Bagh-Turghao areas lack the ferro-magnesian minerals however non-crystalline green garnet is present in these zones as aggregates. The carbonatites are

composed of calcite, siderite with variable quantity of amphibole, pyroxene, biotite, vermiculite, sphene, apatite, pyrite and garnets. At places crystals of amphibole, pyroxene and vermiculite flakes occur as aggregates. Sphene and apatite are transparent to translucent. The carbonatites in Selai Patti area locally contain a few apophysis of undeformed Tertiary? granite. Quartz, feldspar and amphibole bearing pegmatites also cut these carbonatites in Mairagai and Selai Patti area. The carbonatites and pegmatites show tight folding and appear to have suffered multiple deformation. In carbonatites the green garnet occurs either as disseminated crystals or their aggregates and range in size from tiny specks to 1 cm across. These are generally transparent to translucent. The colour varies from light pale green, olive green to mottled green.

The garnet of Jambil area is generally dark green and occurs as disseminations and crystal aggregates in hydrothermal quartz veins and in the graphitic schists adjacent to the quartz veins. Inclusions of graphite and mica are common. These transparent to translucent garnets can be cut in exquisite melle sized gems.

The cell dimensions of two crystals of Jambil (Swat) green garnet and one each of Turghao and Mairagai were determined on X-ray diffractometer. In Jambil green garnet the cell dimensions are 11.8902 Å and 11.8809 Å with SD of 0.0005 and 0.0087 respectively. Turghao and Mairagai garnets have 11.8453 Å with SD of 0.0125 and 11.8650 Å with SD of 0.141. Chemical analyses of green garnets from these areas are also presented in this paper. The green garnet of Jambil is high in Ca, typical of grossular garnet. High V and small quantity of Cr impart deep green colour to the Jambil green garnet. However the garnets in carbonatites have both V and Cr but in very small quantity compared with that of Jambil. The occurrence as well as physical and chemical properties of green garnet indicate their mineralization in two different geological environments.

Key words: Garnet, mineralization, Swat.

H/265. Hussain, S.S., Dawood, H. & Chaudhry, M.N., 1997. Talc/magnesite deposits along Main Karakoram Thrust zone, N. Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

Extensive occurrences of talc/soapstone and magnesite from Shishi Valley. Chitral and from Yasin and Lshkuman valleys. Gilgit are being reported and studied in fair detail for the first time. These talcose rocks occur within the Main Karakoram Thrust Zone (MKTZ), which extends for a distance of more than 300 kms from the Pak-Afghan border near Mirkhini. Chitral and continues in the east through Shishi. Yasin. Lshkuman, Hunza and Shigar valleys, Northern Areas. The ultramafics which variably alter to talc carbonates are serpentinite, serpentinitized harzburgites and serpentinitized dunite. These studies have revealed that the talc rich bodies are intimately associated with border areas of talc carbonates. Talc may constitute upto 70% of these rock and in a few bodies it may go as high as 80%. Petrographic and chemical analyses of these rocks are also presented. These bodies are measurable from a few metres in tens of metres wide and upto hundred of metres long. These talcose rocks, thus, have huge reserves. The laboratory scale beneficiation test show that these rocks can be upgraded for commercial use. Magnesite can also be obtained from these rocks as a bye-product. These talcose deposits merit detailed economic evaluation.

Key words: Talc, magnesite, MKT, Chitral, Yasin.

H/266. Hussain, S.S., Dawood, H., Chaudhry, M.N. & Weiss, M., 2001. Geochemistry and genesis of manganese mineralization in Kasi and Moto Shah area, Mohmand Agency, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.68.

Manganese mineralization occurring in meta-cherts of the Indus suture zone melange in Mohmand Agency has been studied in detail. The mineralized meta-cherts in Kasai and Moto Shah areas. Mohmand Agency are part of the Kot-Prang Ghar melange complex where all the lithologies of ophiolites, intact as well as dismembered, are exposed (Hussain et al., 1984).

Petrographically the Kasai ore comprises upto 30% manganese ore minerals. The manganese ore and gangue of Kasai area are characterized by the presence of 3% and 60% piemontite and 20% & 5% garnet, respectively. The manganese ore of Kasai contains upto 60% MnO₂. The associated spessertine garnets are quite rich in manganese with 32.65 to 37.14% MnO₂ whereas SiO₂ ranges from 36.11 to 42.97%, Al₂O₃ from 19.75 to 21.18% and CaO from 3.57 to 4.20%. Microprobe studies were also carried out on two samples, which show that the Kasai manganese ore comprises brahinite as well as rhodonite.

Fe/Mn ratio of manganese ore in Kasai ranges from 0.035 to 0.037 whereas in Moto Shah this ratio is 2.05. The trace element contents and Fe/Mn ratio suggest that Kasai manganese mineralization is hydrothermal whereas that of

Moto Shah appears to be hydrogenous. The presence of spessartine garnet, piedmontite and other associated minerals in the Kasai manganese deposit suggest that these rocks suffered low temperature, high-pressure metamorphism. Geochemistry, morphology and sedimentological & geotectonic setting of these deposits suggest that manganese mineralization in Kasai, Mohmand Agency originated as a result of submarine hydrothermal activity in the Tethyan Ocean.

Key words: Geochemistry, manganese, mineralization, microprobe, Mohmand Agency

H/268. Hussain, S.S., Khan, T., Dawood, H. & Khan, I., 1984. A note on Kot-Prang Ghar melange and associated mineral occurrences. Geological Bulletin, University of Peshawar 17, 61-68.

Lower Mohmand and western part of Malakand Agency are characterized by ophiolitic Late Jurassic to Cretaceous Melange Complex. Middle to Late Paleozoic metasediments, and Malakand-Kot and Silai Patti-Kolangi granitic gneisses of Cambrian age make up the rest of the rock sequence within the area. Thrust faults, intricate folds, joints and complex foliation planes are the major structural features. These structures are the result of multiple tectonic events in this region. Gemstone and metallic ore mineralization has taken place in the Melange Complex, of which emerald, epidote, beryl, rutile, jadeite/nephrite, manganese and chromite may be of economic significance.

H/272. Hussain, S.T., 1973. Appearance Hipparion in the Tertiary of the Siwalik Hills of north India, Kashmir and Pakistan. Nature, 246-531.

The earliest occurrence of *Hipparion*, a tridactyl fossil equid, in the Tertiary of the Siwalik Hills (Pakistan and India) has been discussed by Simon et al. Their statements are confusing and they have misinterpreted one of my publications. Simons *et al.*¹ reject a possible Chinji occurrence of the genus, partly because "Hussain has pointed out that regardless of the validity of occurrence of the *Hipparion* reputed to have been found near the base of the Chinji, the teeth of these specimens are very large. It is implausible that such animals should have preceded in time the small and structurally different species *Hipparion nagriensis* Hussain".

H/273. Hussain, S.T., 1984. Paleo-environmental studies of continental sediments in Pakistan. Abstracts, First All Pakistan Geological Congress, Lahore, p.43.

The study of paleoenvironments in the geological time is of great importance for the evaluation of life and processes of mineralization. In the continental sediments, paleo-channels and paleoriver systems have been studied which point out sources of certain minerals and animal life. It has been established that Indo-Pak Plate collided with Asia in Paleocene times, the first evidence of land mammals has been seen in early Eocene in Pakistan. The biostratigraphic and chronostratigraphic relationships of certain orders. The biostratigraphic and chronostratigraphic correlations within Pakistan help in the determination of similar paleoenvironments which may lead to the formation of certain mineral deposits and development of life. The process of evolution is a complex one which involves chemistry of the animals and the morphology changes in spurts. The evidence is seen in certain groups such as trilobites, reptiles and mammals. The change in environments can also produce abnormal chemistry which ultimately may result in pathologic morphology.

H/274. Hussain, S.T., 1986. First appearance of land mammals on Indo-Pakistan subcontinent. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, p.18.

The artiodactyl rodents and several specimens of a new dichobunid artiodactyl, *Discodexis Pakistanensis* have been found in the Kuldana Formation of the Kohat area. These are the earliest land mammals ever found on the Indo-Pakistan Subcontinent. The artiodactyls from Kohat, one of the oldest records of the super-family, have lophodont upper cheek teeth. The micro-structure of the enamel of the incisors is diversified. The discovery of *Discodexis Pakistanensis* in Kohat establishes the presence of *Discodexis* on all continents of the northern hemisphere at the beginning of the Eocene and possibly suggests an Asian Origin for the Artiodactyla. It is now established that the land mammals arrived on the Indo-Pakistan Subcontinent from Central Asia approximately 50 million years ago. This confirms that the Indo-Pakistan Subcontinent, which was originally part of Africa, collided with Asia prior to this time. Soon after that there was a major influx of land vertebrates, particularly of mammals into the Indo-Pakistan Subcontinent.

H/282. Hussain, T., 1984-85. Geology and structure of Reshian-Lamnian-Panhkot-Nauseri Area Neelum-Jhelum valleys District Muzaffarabad, Azad Kashmir, Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 78p.

This report comprises a complete geological study based on mapping of nearly 180 sq. km. located between Beehian-Nauseri of Jhelum and Neelum Valleys respectively. Special emphasis has been put on describing the tentative stratigraphic correlation of the rock units. In the project area a large number of rock units including volcanics, microaugengneiss, micaceous quartzites, quartz mica schists, granite gneiss, sandstones, shale, and siltstones are encountered. A stratigraphic sequence has been worked out. The rocks extend in age from Devonian to Miocene and have been correlated with Tanawal Formation, Agglomeratic Slates, Panjal Formation and Murree Formation respectively. Structurally, the rocks are folded into a number of major structures which are now separated from each other by mostly north dipping high angle thrust faults. The area comprises of two major thrusts known as Murree Thrust/Main Boundary Fault and Panjal thrust. Hazara Kashmir syntaxis has a great influence on the stratigraphy, structure and tectonic of the investigated area. That is why we have generally interpreted our results with respect to the syntaxis, as the project area lies on its eastern limb. In the field of economic geology a number of economic deposits including marble, graphite, gypsum and building-stone have been discussed. This report also includes a petrographic description of the rock units as well as numerous sketch section and photographs, illustrating the geology of the area.

H/283. Hussain, T. & Naqvi, A.A., 1973. High aluminous clay deposits of the Punjab province, Pakistan. Geological Survey of Pakistan, Information Release 59, 16p.

Deposits of fire Clay/bauxite of commercial significance occur in the salt range and the Kala Chitta Range. These deposits have been investigated under a joint project of G.S.P. and P.C.S.I.R. Geological mapping of these deposits has been carried out by the G.S.P.

Mineralogical and chemical tests of the samples discussed in this report indicate that the clays are free from any visible impurities, their plasticity varies from fair to moderate and their slacking behaviour is slow. As a whole the composition and characteristics of the high aluminous clay deposits of Salt Range and Kala Chitta range are fairly conformable with the specifications laid down by the Soviet experts for the clays required for the proposed Karachi

Steel Mill. The total reserves estimate of the deposits discussed in this report are a little over 85 million tons and as such these are enough to meet the annual requirement of 75,000 tons of clay for Karachi Steel Mill for several decades.

Two basic types of phosphorites have been recognized within the Kakul stratigraphic sequence: 1) authigenic microcrystalline phosphorite mud (microphorite) or orthochemical phosphorite which has precipitated either biochemically or physiochemically, and 2) pelletal phosphorite or allochemical phosphorite which has been modified into discrete clastic particle from microphosite mud. Microscopically, the primary component is the carbonate fluorapatite matrix with cryptocrystalline dolomite, calcite and quartz. Also there are detrital grains of quartz, dolomite, and calcite with disseminated ferruginous matter.

Key words: Stratigraphy, phosphorite, Kakul, Abbottabad.

H/293. Hylland, M.D., Riaz, M. & Ahmad, S., 1988. Stratigraphy and structure of the southern Gandghar Range, Pakistan. Geological Bulletin, University of Peshawar 21, 1-14.

The southern Gandghar Range is composed of a succession of marine strata of probable Proterozoic age, consisting of a thick basal argillaceous sequence (Manki Formation) overlain by algal limestone and shale (Shahkot, Utch Khattak, and Shekhai Formations). These rocks are thrust southeastward over the Kherimar Hills succession along the Panjal fault. The Gandghar Range and Kherimar Hills successions correlate with the northern and central blocks of the Attock-Cherat Range, respectively, indicating that the combined Panjal-Khairabad fault juxtaposes two major, laterally continuous structural blocks.

The rocks of the southern Gandghar Range occur in two structural blocks juxtaposed along the Baghdarra fault. The hanging wall consists entirely of isoclinally-folded Manki Formation, while the footwall consists of the complete Manki-Shekhai succession which has been deformed into tight, northeast-plunging, generally southeast-verging disharmonic folds. The Baghdarra fault is apparently deformed along with the footwall strata, indicating that it is older than, and is being carried piggy-back style on, the Panjal fault. Phyllite near the Baghdarra fault displays asymmetric deformation of foliation around garnet porphyroblasts, kink bands, and a poorly-developed s-c fabric. These features are consistent with conditions of dextral shear, indicating reverse slip displacement along the fault.

I/2. Ibrahim, M.Y.H., 1992-94. Sedimentology of Murree Formation and lithostructural mapping of Barian Area, Southern Hazara, Northwestern Himalaya-Pakistan. M.Sc. Thesis, Punjab University, Lahore, 124p.

A detailed geological study of a small part of the Attock Hazara Fold and Thrust Belt in Khaira Gali-Kuldana area of Galliat was carried out. Geological mapping at the scale of 1:21120 of an area of 50 square kilometers was carried out in detail. Lithostratigraphic units in the study area range in age from Middle Jurassic to Upper Eocene in age. Samana Suk Limestone of Middle Jurassic age is an oolitic dolomitic limestone and represents shallow carbonate shelf sedimentation. The Chichali Formation is composed of black shale condensed sequence deposited in a basin of restricted circulation and represents deepening of the basin. This continues into glauconitic Lumshiwal Formation deposited in middle subtidal conditions. Further deepening of the basin deposited pelagic Kawagarh Formation of Cretaceous age. It was deposited in lower subtidal conditions near the shelf edge. This was followed by sudden regression due to contact between Kohistan Island Arc and Indian plate, which resulted in general uplift continental conditions. Residual Hangu Formation of Danian age was thus developed on top of Kawagarh Formation. This was followed by a rise in sea level and deposition of shelf foraminiferal Lockhart Limestone of Paleocene age which is overlain by Patala Shale, Margalla Hill Limestone and Chorgali Limestone and Marl. All these are open shelf foraminiferal deposits. At this point in time collision between India and Asia took place mixed marine continental Kuldana Formation developed. This was followed by a rise of Himalaya, which shed debris in the foredeep. This formed fluvial Murree Formation molasses.

The sedimentary package is composed of lower Marine sequence from Jurassic to Middle Eocene dominated by carbonates with a residual lateritic horizon of Danian age. The upper part of the package starts from mixed marine fluvial sequence (Kuldana Formation) and an upper molassic sequence (Murree Formation) of Upper Eocene to Miocene age. Structurally the area is mapped in detail and is composed of Chumbi Anticlinorium, Khaira Gali Synclinorium, Kali Mitti Synclinorium and Darya Gali Anticlinorium. The area is also cut by Thrust faults. General trend of the rocks is northeast to southwest. The rocks are cross folded and double plunging. The folds are tight to isoclinal with a general vergence to southeast. Murree Formation of Upper Eocene to Miocene age is a molassic fluvial sequence deposited by a meandering river system. This sequence was derived from rising Himalaya after the collision of India with Asia in Eocene times. Facies, microfacies, diagenesis and provenance of this formation were studied in detail. For the purpose of foregoing sedimentological studies a section between Darya Gali and Kuldana Chowk was measured and sampled in detail. The Murree Formation is composed of an alternating sequence of gray to grayish gray sandstone and chocolate, maroon and brown shale. Conglomerates, breccias, limestone and marl are minor lithologies. This sequence was derived from rising Himalaya to the north as well as upper part of Kohistan Island Arc. The sandstones are lithic arenites which are texturally sub-mature and compositionally immature.

I/5. Iftikhar & Jehanzeb, 1987. Report on the groundwater resources in Daggar valley, Buner, Swat, N.W.F.P. M.Sc. Thesis, University of Peshawar, 55p.

A programme for groundwater investigation in Daggar valley, Buner in the North West Frontier Province of Pakistan started in January 1984. The objective of the investigation was the determination of the ground water potential of the valley and the most suitable area for withdrawal.

In order to determine the hydraulic characteristics of the sub-soil, hydrogeologic studies were carried out and six testholes were drilled. Four of them were converted into testwells of which one is suitable as potential production well. The results of the studies show that the alluvial fill can be considered as aquifer of mainly fine grained material with some sand and gravel layers varying both in lateral and vertical sense. The alluvial fill is more than 100 m thick and occasionally more than 200 m. the transmissivity of the wells ranges from 300 -0 500 m²/day in the western part of the valley, and only 20-100m²/day in the eastern parts. The depth to the ground-water table is generally less than 15m except in the south-western part from Jowar to Tursak and on the higher elevated old river terranes. Recharge of the ground-water occurs near the mountainous boundary by inflow from the bedrock (mainly limestone) and run-off from the mountains and precipitation on the plain percolating downward through the alluvial fill. Ground-water development with tubewells is only feasible in the valleys south-west of Daggar, due to the availability of sufficient sand and gravel layer in the alluvial fill.

The recharge of the ground-water in this area is 23x10⁶m³/year pf 18870 acres feet/year and it is recommended during ground-water development not to withdraw more than this amount initially. Water levels should be monitored at regular intervals to assure the effects of the ground-water development.

Key words: Groundwater, Buner, Swat.

I/7. Ikramuddin, M., Fan, F., Tahirkheli, R.A.K., Jan, M.Q., Majid, M., Haneef, M., Shah, M.T., & Afridi, G.A. 1987.Reconnaissance lithogeochemical survey of parts of northwest Pakistan. GSA Abstract with program, 19(7).

Several recent studies have demonstrated that hydrothermally altered rocks associated with various types of mineral deposits generally contain high contents of Ti and low K/Ti ratios. In order to further test the usefulness of Ti and K/Ti ratio as guides to mineralization, a reconnaissance lithogeochemical survey of northwest Pakistan was carried out. About 200 rocks, collected from various parts of the area extending from Peshawar to Gilgit, were analyzed for Tl, Rb, K, and Au. The rocks studied include ultramafics, gabbro, diorite, granodiorite, granite, pegmatite, aplite, quartz veins, andesite, dacite, rhyolite, gneisses, schists, amphibolite, greenstone, and carbonates. Most of the rocks studied are fresh and unmineralized with the exception of a few samples from Besham area, which are associated with Pb-Zn mineralization. The majority of the rocks have very low contents of Au ranging from 0.1 ppb to 5 ppb. The mineralized rocks of Besham area, however, contain high contents of Au, one sample containing 250 ppb. There are at least 5 different rock types, collected from unmineralized areas, which contain Au concentrations 5 to 10 times higher than the background levels. The Tl contents of rocks are generally low varying from 0.01 ppm to 1.5

ppm with ultramafic rocks containing the lowest values and acidic rocks the highest values; each type of rock has a very narrow range of values. The rocks from mineralized area of Besham contain up to 20 ppm T1. There are several localities in the area which contain significantly higher T1 contents and lower K/T1 ratios compared to the background values. The T1 contents and K/T1 ratios of the rocks from Pakistan suggest that the detailed lithogeochemical and pedogeochemical surveys of certain areas may prove to be very useful in locating potential mineral deposits.

I/10. Ilyas, W., 1983-85. Geotechnical studies of landslides with special emphasis on slope stability along Karakoram Highway between Thakot and Besham, District Swat. M.Sc. Thesis, Punjab University, Lahore, 117p.

Engineering geological investigations were carried out about the landslides and slope stability problem along the Karakoram Highway between Thakot and Besham. The project area mainly comprises of Thakot metasediments, Lahor granite, Shang granite gneiss and mineralised scree (near Besham). These are mainly controlling the rugged topography and other geomorphological features of the Project area. The general trend of stresses is SE.-NW.

So far the stability of the region is concerned; the detailed analysis for critical slopes is performed. Among different modes of failure encountered, the plane failures are proved to be unstable particularly near Maira and at Kandaurgai. Other than this a large variation in discontinuities is observed that controls sliding in hard rocks and highly weathered rocks which are responsible for mass wasting and rock fall. Road alignments were studied keeping in view landslide problems and slope stability, for potentially unstable regions remedial measures are also given. 1 h: 2V cuts slopes and benches are proposed. Benches may be provided at each 8 meters interval.

Key words: Geotechnical, landslides, slope stability, KKH, Thakot, Besham.

I/14. Iqbal, A., 1997-99. Petrophysical interpretation, reservoir geology modeling and reserves estimation of Silver Gas Field, Middle Indus Basin, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 159p.

This thesis deals with Petrophysical interpretation and development geology of "Silver Gas Field" which is a fictitious name of an existing Gas field in Punjab plat form within middle Indus basin. Drilling record shows that stratigraphic column in the gas field is table (2.1) with their thicknesses. Based upon various kinds of data (mud log and wire line log data), different reservoir parameters were determined individually and reservoir zonation was also described. Variation in reservoir properties were illustrated with the help of various maps including, structural cross-section, stratigraphic cross section iso-porosity maps, iso-saturation maps, net pay maps and net lime maps. Reserves estimation of the "Silver Gas Field which was at its discovery stage has been accomplished on the basis of volumetric equation. Structurally "Silver Gas Field" is a broad gently dipping monocline with conjugate normal faults in the NNW of the area. Only the original gas in place of Samana Suk formation was estimated which is about 124 billion cubic feet (BCF). For the reserves estimation, well data of five wells was used all of which were gas producing.

I/16. Iqbal, I., 1989-91. Slope stability analysis and feasibility studies of sub-grade along Murree-Kohala Road. M.Sc. Thesis, Punjab University, Lahore, 140p.

Landslides are wide spread in Pakistan like other Countries and cause enormous economic loss as well as loss of human lives, particularly when engineering structures are designed and constructed without analysing the slope stability conditions. Pakistan has a very intricate Geological history with numerous active tectonic zones. The project area (Murree –Kohala road) has a very diverse sliding phenomenon particularly along the road. The climate conditions of the project area are such humid to semi-arid. The major part of the road is on the escarp face with variety of slope conditions, from strategic and regular communication point of view, Murree –Kohala road has great national importance. It is the shortest land route bridging Pakistan and Azad Kashmir for the supply of basic needs. This road is also important from defence point of view.

The road (Murree -Kohala) originated as a foot -way, then it developed into mule track, further it took the form of jeepable track and finally to overcome the expenditure, the same track was constructed in the form of road.

Key words: Slope stability, feasibility, Murree-Kohala.

I/17. Iqbal, M., 1973. Geology and Petrology of Aligam-Kabal Area, Swat District. M.Sc. Thesis, Punjab University, Lahore, 99p.

A geological map on a scale of 3 inches to a mile, covering more than seventeen miles area around Aligam-Kabal, Swat District, is presented. The rocks of this area, previously mapped as a single unit, are now subdivided into four map able units on lithological basis. Detailed petrography, mineralogy and structural features of these four litho-types are described. Modal analysis and mineralogical data on 40 thin sections is included. Joints orientation diagrams of measurements on perfectly developed joint surfaces are given. Based on field and laboratory evidence, plausible explanations regarding the petrogenesis of the rock exposed in the area are given.

Key words: Petrology, structure, stratigraphy, Swat

I/18. Iqbal, M., 1990-91. Structure, stratigraphy and petrography of the western limb of the Hazara-Kashmir Syntaxis, Garhi Habibullah-Shinkiari area, Northern Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 105p.

The Garhi Habibullah-Shinkari area lies along the western limb of the major northwest plunging antiformal structure known as the Hazara-Kashmir syntaxis. The 293 km² area has been mapped in this study. The western limb of the Hazara-Kashmir syntaxis has been divided into four fault-bounded tectonostratigraphic zones. These are named as the Muzaffarabad-Balakot zone, the Garhi Habibullah-Abbottabad zone, the Panjal zone and the Mansehra zone. These zones belong to different tectonic and stratigraphic provinces which have been juxtaposed during the Himalayan thrusting. The Muzaffarabad-Balakot zone lies to the east of Main boundary fault. This zone constitutes late Proterozoic to Cenozoic sequence. This sequence is involved in the Muzaffarabad-Balakot southwestward overturned anticline. The late Proterozoic Dogra formation forms the core of the Muzaffarabad-Balakot anticline. The Dogra formation is unconformably overlain by the early Cambrian Muzaffarabad formation. The Ordovician (?) Yadgar formation disconformably overlies the Muzaffarabad formation. The Yadgar formation is unconformably overlain by the Paleocene-Eocene sequence which includes the Hangu Formation, Lockhart Formation, Patala Formation and Margala Hill Limestone. This was followed by the late Eocene Kuldana and Miocene Murree molasses. The most of the Paleocene to Miocene sequence along the overturned limb of the Muzaffarabad-Balakot anticline is faulted.

The Garhi Habibullah-Abbottabad zone lies between the Main boundary fault and Garhi Habibullah fault. This zone is involved in the Garhi Habibullah syncline. The Cambrian Abbottabad group lies in the core and Hazara formation along the limbs of the anticline. In the Garhi Habibullah syncline, the late Proterozoic Hazara formation is unconformably overlain by the Cambrian Abbottabad group of rocks. The Jurassic sequence has been eroded from the core of the syncline due to later Himalayan uplift.

Key words: Structure, stratigraphy, petrography, Hazara-Kashmir syntaxes.

I/19. Iqbal, M., 1994. The Geology of Siwalik rocks in Potwar area. Geological Survey of Pakistan, Information Release 269.

The field work was sponsored by the Geological Survey of Pakistan in collaboration of YALE and HOWARD Universities, U.S.A. to interpret the geology of Siwalik rocks in Potwar Area.

Moreover, in GSP Museum, there were not a sufficient number of vertebrate specimens. It was a great help for the development of palaeontological museum.

I/22. Iqbal, M.I.A., 1985-87. Geology of Dunga Gali-Barian Area, District Abbottabad. M.Sc. Thesis, Punjab University, Lahore, 105p.

This report incorporates a comprehensive geological study of nearly 25 sq. km. area between Dunga Gali and Barian on the Murree-Abbottabad road. The study includes the preparation of a geological map on the scale 1:7040. Stratigraphically the rock units range from Upper Jurassic to Eocene and represent the sequence of the Hazara Province of the Kohat-Potwar Basin. It is primarily a limestone-shale sequence reflecting a stable shelf facies. Structurally, the area shows the development of a few synclinoria and anticlinoria, within which a generally tight parallel to similar asymmetric to overturn style of folding predominates. A number of dip-slip-strike faults, both of the normal and reverse type are present. A petrographic study of all rock units, based on fairly representative field sampling, is also present.

Key words: Geology, mapping, stratigraphy, Jurassic, Eocene.

This is an exhaustive study of gastropod and bivalve fauna of Paleocene age. The three areas are well known for their rich faunal assemblage and have been investigated by several workers in the past. The present detailed compilation also contains three maps, three charts, five figures and nine plates.

Key words: Paleocene, Paleontology, Sind, Salt Range, Samana Range, Hangu.

I/26. Iqbal, M.W.A., 1981. The Tertiary bivalves and gastropods of Pakistan. Geological Bulletin, Punjab University 16, 141-145.

The purpose of this paper is to present a resume of the paleontological research on the Tertiary bivalves, and gastropods of Pakistan. The writer (Iqbal, 1972a) presented a detailed account on the subject for the first time during the 13th Session of the Science conference, Scientific Society of Pakistan, March, 1972.

Later on a brief paper on the Tertiary bivalve and gastropods of Sind was also published (Iqbal, 1972).

The writer (Iqbal, 1974) also presented a paper on the Baluchistan fauna during the Seminar on Development in Geological Sciences in Pakistan, University of Baluchistan, September, 1972. The biostratigraphic research conducted by the writer during 1963 to 1980 has given more emphasis to the Tertiary bivalve and gastropod fauna, In most of the cases, the bivalve and gastropod species were found extremely useful in determination of the specific stratigraphic problems and reconstruction of the depositional history of the geological formations in which they occur. Moreover, the world-wide geographical distribution and comparative analysis of the fauna proved helpful in understanding of the basinal distribution, the possible oceanic connections in between the various n certain, geological time, and the genetic relationship between certain species.

Key words: Tertiary, Palaeontology, Bivalves, Gastropods.

I/27. Iqbal, M.W.A., 1983. Tertiary biostratigraphy study based on bivalve and gastropode fauna. Geological Bulletin, Punjab University 18, 9-17.

The biostratigraphic study of the Tertiary formations based on bivalve and gastropod fauna includes large faunal collection from different lithofacies representing various basinal provinces and covering a large geographic areas of Sind, Baluchistan, Punjab and NWFP. Forty six sections representing twenty six major localities were measured. The study consists of systematic treatment and description of 373 species including 36 new species) revision and redesignation of previously described faunal distribution within and outside Pakistan, determination of Index Species, assignment of age and correlation and paleoecology paleontology.

(eds.), *Geology, Geochemistry, Economic Geology and Rock Magnetism of the Kohistan Arc*. Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad, 15, 57-68.

Reconnaissance studies were made on δ^{34} SCDT of trace amounts of sulfides contained in various rocks and on magnetic susceptibility of Paleozoic to Cenozoic granitoids exposed along the Karakoram Highway. Kamila amphibolites of oceanic crust (?) give "mantle-value" of 1.3 permil, while pyroxenite and hornblendite of the infracrustal rocks yields 2.6 permil. Pelitic metamorphic rocks are more deviated to the positive values (2.3 - 10.2 0/00, average 5.2 0/00). Cretaceous-Tertiary granitoids of the Kohistan Arc and Eurasian Plate have average δ^{34}

SCDT values of 2.9 and 3.0 permil, respectively, and related ores are depleted in ^{34}S . These granitoids are generally ilmenite series, except for the northern part of the Kohistan batholith where small mineral showings have been discovered. Scarcity of oxidized granitic rocks in the high level plutonic zones of the Kohistan Block and Eurasian Plate may be one of the significant reasons for paucity of sulfide-forming mineral resources in northern Pakistan.

I/37. Ismail, M., 1973. Magnetic Survey of Chalt (Gilgit). M.Sc. Thesis, Punjab University, Lahore, 100p.

The magnetic survey in Chalt, district Gilgit, was carried out in the months of November and December 1974; January, February and March 1975. The purpose was to know the extension of the magnetite body, which was exposed at one place in the area. The portable Proton Magnetometer Model G-816 was used which measure the total intensity of earth's magnetic field. About 712 magnetic stations covering an area of about 5 miles² were made. The rough topography or systematic profiles. The profiles were laid along the pony tracks, jeepable road, on the bed of river and on top of the hill. Magnetite stations were plotted on the map with the help of the odolith. Readings were taken at each magnetic station by Proton Magnetometer. The observed readings were then corrected for diurnal variations. A total magnetic intensity map was constructed with the corrected data. The scale of the map was taken 1:2400 and the map was contoured at an interval of 50 Gamma. The total intensity map was interpreted. No appreciable anomaly was cited on the map.

I/39. Iturrizaga, L., 1999. On the close connection between the development of postglacial debris accumulations and the Late Glacial glaciation history with case examples from subtropical mountain regions in High Asia (Hindukush and Karakorum Mountains). In: Book of Abstracts. XV. INQUA Congress. The Environmental Background to hominid evolution in Africa. Durban, South Africa 87.

A research study on a typology of postglacial debris accumulations in High Asia revealed that a considerable part of the debris accumulations in the Hindukush, Karakorum and Himalayas results from re-sedimentation of moraine deposits by postglacial slope processes. Especially the semi-arid mountain regions, which feature a high quantity of debris accumulations suggesting intensive weathering processes, show that in many valley sections the secondary debris production, i.e. the dislocation of glacial sediments, exceeds the primary debris production. The conventional classification into talus cones, alluvial cones, mudflow cones and related forms proves to be insufficient for an appropriate typology of debris accumulations in High Asia. It should be expanded to include in particular the glacial transitional debris accumulations as key forms of the secondary debris accumulation landscape. They contain the transformation of glacial sediments by slope processes into mixed forms of debris accumulations composed of glacial debris and slope material. The apparently homogeneous, mostly conical-shaped appearance of many debris accumulations may tempt one to classify them precipitously into the above-mentioned traditional division system and consequently leads to misinterpretations regarding their genesis. The residual debris accumulations provide homomorphologeous landscape elements in view of the talus cones, yet they do not represent accumulation forms but erosion forms formed from loose material. In many valley courses the disproportion between the size of the catchment areas and the corresponding debris accumulations is striking. This seemingly paradoxical relation can be

explained by taking into account the dislocation of moraine material deposited in the upper catchment areas. Another glacial-induced factor for debris supply is caused by the postglacial transformation of the glacially oversteepened trough valley flanks into the more stable form of the V-shaped valley, which results in various collapse accumulations. The misinterpretation of glacial sediments as pure slope sediments is one of the reasons in the controversial debate on the extent of the Last Glacial Maximum respectively the Late Glacial glaciation in High Asia. Therefore, it is necessary to establish detailed criteria for the differentiation of glacial and slope deposits in order to use them consistently as palaeoclimatic indicators.

In addition, characteristic features of the central-peripheric change of glacial transitional debris accumulations from the mountain centre to the foot hills and some aspects of the hypsometric change will be presented. In general, the debris landscape is conceived by means of genetic sequences. Important for the genesis and the chronology is the locational relationship between debris accumulations and glacier stages as well as to other geomorphological elements.

Field work was carried out in various valleys of High Asia including research areas in the E-Hindukush, NW-Karakorum, S-Karakorum (Mustagh-Karakorum), Nanga-Parbat Massif, Ladakh und Zaskar Range, Nun-Kun Massif, Kumaon and Garhwal-Himalayas (Kamet-, Trisul- and Nanda-Devi Massif) as well as in the Central Himalayas (Kanjiroba-, Annapurna-, Manaslu- and Makalu-Massif. In the presentation, representative case examples taken from the mostly semi-arid mountain regions for the glacially controlled formation of debris accumulations will be introduced.

Key words: Glaciation, paleoclimate, debris accumulation, Hindukush, Karakoram.

I/40. Ittekkot, V. & Arain, R., 1986. Nature of particulate organic matter in the river Indus, Pakistan. *Geochemica et Cosmochemica Acta* 50(8), 1643-1653.

Suspended sediments from the Indus River collected during 1981 through 1983 were analyzed for POC and its constituent fractions including amino acids, amino sugars and sugars. Percentage of POC decreased with increasing suspended matter concentrations, which suggested dilution of organic matter by mineral matter.

The concentrations of amino acids, amino sugars and sugars varied, respectively, between 180 and 2000 µg/l, 5 and 125 µg/l, and 60 and 1100 µg/l. Their contributions to POC varied between 2 and 60% for amino acids and amino sugars, and between 2 and 15% for sugars. They were high during low sediment discharge (February to June), and low during high sediment discharge (August and September). Suspended sediments associated with high sediment discharge periods were characterized by low ratios of:

(i) aspartic acid:β-alanine

(ii) glutamic acid:γ-aminobutyric acid

(iii) amino acids: amino sugars

(iv) hexoses: pentoses. These and the relative distribution pattern of the monosaccharides such as galactose, arabinose, mannose and xylose indicated that, not only dilution, but also differences in the sources and processes affect the POC transport in the Indus River. These result in transport of biodegraded organic matter during high sediment discharge periods: this appears to be common to other major rivers of the region, with depositional centers in deep sea areas. These rivers, with their high sediment loads, could contribute up to 8 to 11% of the global annual organic carbon burial in marine sediments.

Key words: Sediments, organic matter, Indus river.

I/41. Ivanac, J.F., Traves, D.M., & King, D., 1956. The geology of the N.W. portion of the Gilgit Agency. In: Haque, A.F.M.M. (ed.). *Geological Survey of Pakistan. Records*, 8(2), 27p.

This is one of the earlier and very important report of the geology of the Karakorum and Himalayan region of Pakistan. It contains details on stratigraphy, structural geology and petrography, along with information on the mineral deposits and a geological map. Descriptions are given for the Kohistan and Ladakh batholiths (granodiorites, granites, diorites, gneisses), Yasin group cretaceous clastic sediments, fossiliferous limestones, and volcanics, Chalt volcanics (greenstone complex), and Permo-Carboniferous (?) Darkot Group sediments.

I/42. Izatt, C., 1990. Thrust geometries and rates of shortening across the Himalayan external zones, Northern Pakistan. In Abstract volume, 5th Himalaya-Karakoram-Tibet Workshop, Milano, p.24.

As the Himalayan front of deformation migrated south across the Indian Shield the Mesozoic-Cenozoic passive margin and Tertiary Indo-Gangetic foredeep was progressively shortened and involved in the foldbelt. Gravity, seismic and field data confirm that basement under the passive margin was shortened only in the internal zones. Further south shortening in the external zones was "thin-skinned". Geometries of shortening depended upon mechanostigraphy and basement architecture, whereas facies/thickness changes led to changes in thrust front geometry.

The most important domains of shortening across the external zones are as follows:

MAIN BOUNDARY THRUST (MBT), emergent thrust system with ca. 130-km shortening, emplaced between 10-7.5 Ma.

SALT RANGE THRUST SHEET (SRT), emergent thrust propagating under the Potwar Plateau along an Eo-Cambrian evaporite horizon, c.a. 30-km shortening, emplaced between 4.5-0 Ma.

These shortening events give rates of shortening as high as 4-5 cm/yr, the total plate vector of India's flight north into Eurasia. Between 10-5 Ma most of the Himalayan shortening was taken up at the southern margin of the Himalayas rather than to the north.

Key words: Tectonics, thrust geometry, crustal shortening, Himalaya.

I/43. Izatt, C. & Chambers, A., 1992. Structure and stratigraphy north of the Main Boundary Thrust, Hazara and Kalachitta Hill Ranges, North Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, p.42.

The northern margin of the Potwar Plateau is marked by the Himalayan foothills of the Hazara and Kalachitta Hill Ranges. Outcropping in these foothills is an imbricated section of passive margin strata that are more resistant to erosion than the softer weathering foreland basin sediments to the south. These imbricates have been found to contain strata relating to the following mega-sequences Pre-Cambrian Hazara Slates, of a deep intra continental basin. Lower Jurassic to Upper Cretaceous shallow water marine shelf carbonates and clastics. Palaeocene to Middle Eocene shallow water limestones and shales, with an upper series of evaporitic sands and mudstones. Miocene foreland basin sediments of continental origin.

The dominant phases of Late Pliocene shortening are:-

D1- minor imbrication, thrusts dying out into fault termination folds.

D2- uplift of imbricated strata south over the foreland basin along the MBT.

D3- folding of imbricates and MBT, probably during shortening south in the N. Potwar Deformation Zone.

D4- uplift and shortening along the eastern margins of the Hazara Ranges associated with recent uplift in the Hazara syntaxes.

The topographic break between the Hazara/Kalachitta Ranges and the Potwar Plateau is not marked by the MBT, an alternative model is proposed.

Key words: Structure, stratigraphy, MBT, Kalachitta Range, Hazara.

J/1. Jabeen, N., 1992. Mineralogy and geochemistry of Koga syenites, carbonatites and fenites Buner, N.W. Pakistan. M.Phil. Thesis, University of Peshawar, 163p.

The Koga complex is composed of alkali granite, alkali syenite and nepheline syenite. The syenite and nepheline syenite are intruded and fenitized by carbonatite and ijolites at different places. The ijolites and carbonatites are exposed mainly in the western part of Koga complex.

Amongst the mafic minerals in the Koga syenite, the fenitic Na-pyroxene show trends of crystallization from acmitic to diopsidic and/or hedenburgitic components, which is reversed to the magmatic trend. The fenitic amphibole show a trend from magnesio-arvedsonite to richterite which is opposite to the magmatic subsolidus trend. The fenitic alkali feldspar solid solution series in the Koga fenitized syenite are anomalously low albite and maximum microcline. Temperature for this solid solution series is suggested as 350-500 C in contrast to the magmatic feldspar for which temperature is 800 – 1000 C.

From the whole rock geochemistry and petrography of Koga complex it is suggested that the carbonatite has produced two types of fenites: 1. Na- fenites and 2. K-fenites. Both the types of fenites show great differences in their Ba, Sr, Nb, and Th contents. K- fenites are depleted in REE as compared to the unfenitized rocks whereas Na-fenites show enrichment of REE,

The composition of Na –pyroxenes, Na –amphiboles, feldspars and whole rock geochemistry of Koga complex suggests that the rocks have been fenitized by the solution emanating from at least two carbonatites which have different Na/ K ratios.

J/2. Jabeen, N. & Mian, I., 1992. Alkali-feldspar from Koga syenites, Ambela granitic complex, NW Pakistan. Geological Bulletin, University of Peshawar 25, 77-84.

The Koga syenites are intruded at least two carbonatite intrusions, having different Na/K ratios. The carbonatite with high Na/K ratio has produced Na-fenites, while the other formed k-fenites. XRD study of low albite indicates that changes occur in the structural state of albite with increasing grade of fenitization. The Na-feldspar in the unfenitized rocks is low albite, while in the fenitized rocks is anomalous low albite. The degree of order increases with the increasing intensity of fenitization. The K-feldspar is maximum microcline in both the fenitized and unfenitized rocks. The tie lines between the co-existing Na- and K-feldspar deviate from the generally agreed magmatic trend.

J/4. Jackson, J. & King, G., 1984. Tectonic studies in the Alpine-Himalayan belt. In: Miller, K.J., (ed.), The International Karakoram Project, Volume 1. Cambridge University Press.

Plate tectonics has successfully explained the behavior of the major ocean basins. However, it has proved to be less successful in describing the processes of continental collision and its associated deformation. Seismic studies proved crucial in providing information on which plate tectonics was established. Recent developments in the study of seismic signals recorded on distant instruments and on portable seismographs temporally installed in the Alpine-Himalayan belt are beginning to reveal the relation between extension, sedimentation, compression and major strike slip faulting such as the Karakoram fault.

Key Words: Tectonics, seismicity, Himalaya.

J/5. Jackson, J. & Yielding, G., 1983. The seismicity of Kohistan, Pakistan: Source studies of the Hamran (1972.9.3), Darel (1981.9.12) and Pattan (1974.12.28) earthquakes. *Tectonophysics*, 91, 15-28.

Long period body waves are examined to show that the Hamran (1972.9.3), Darel (1981.9.12) and Patan (1974.12.28) earthquakes in Kohistan had focal depths of about 8–10 km. All involved high angle reverse faulting (thrusting) and had seismic moments of about 2.2 to $2.7 \cdot 10^{25}$ dyne cm. These shallow depths contrast with the deeper hypocentres found in the Hindu Kush and northeast Karakoram to the north and in Hazara to the south. The Hamran and Patan shocks were assigned depths of 45 km by the ISC, indicating that even well-recorded events in this region may have focal depths in error by 30 km.

Key Words: Seismicity, earthquakes, Hamran, Darel, Pattan, Kohistan.

J/6. Jackson, J.A. & McKenzie, D., 1984. Active tectonics of the alpine Himalayan belt between western Turkey and Pakistan. *Geophysical Society London Journal* 77(1), 185-264.

Over 80 new fault plane solutions, combined with satellite imagery as well as both modern and historical observations of earthquake faulting, are used to investigate the active tectonics of the Middle East between western Turkey and Pakistan.

The deformation of the western part of this region is dominated by the movement of continental material laterally away from the Lake Van region in eastern Turkey. This movement helps to avoid crustal thickening in the Van region, and allows some of the shortening between Arabia and Eurasia to be taken up by the thrusting of continental material over oceanic-type basement in the southern Caspian, Mediterranean, Makran and Black Sea. Thus central Turkey, bounded by the North and East Anatolian strike-slip faults, is moving west from the Van region and overrides the eastern Mediterranean at two intermediate depth seismic zones: one extending between Antalya Bay and southern Cyprus, and the other further west in the Hellenic Trench. The motion of northern Iran eastwards from the Van region is achieved mainly by a conjugate system of strike-slip faults and leads to the low angle thrusting of Iran over the southern Caspian Sea. The seismicity of the Caucasus shows predominantly shortening perpendicular to the regional strike, but there is also some minor elongation along the strike of the belt as the Caucasus overrides the Caspian and Black Seas.

The deformation of the eastern part of this region is dominated by the shortening of Iran against the stable borders of Turkmenistan and Afghanistan. The north-east direction of compression seen in Zagros is also seen in north-east Iran and the Kopet Dag, where the shortening is taken up by a combination of strike-slip and thrust faulting. Large structural as well as palaeomagnetic rotations are likely to have occurred in NE Iran as a result of this style of deformation. North-south strike-slip faults in southern Iran allow some movement of material away from the collision zone in NE Iran towards the Makran subduction zone, where genuinely intermediate depth seismicity is seen.

Within this broad deforming belt large areas, such as central Turkey, NW Iran (Azerbaijan), central Iran and the southern Caspian, appear to be almost aseismic and therefore to behave as relatively rigid blocks surrounded by active belts 200-300 km wide. The motion of these blocks can usefully be described by poles of rotation. The poles presented in this paper predict motions consistent with those observed and also predict the opening of the Gulf of Iskenderun NE of Cyprus, the change within the Zagros mountains from strike-slip faulting in the NW to intense thrusting in the SE, and the relatively feeble seismicity in SE Iran (Baluchistan). This description also explains why the north-south structures along the Iran-Afghanistan border do not cut the east-west ranges of the Makran.

Within the active belts surrounding the relatively aseismic blocks a continuum approach is needed for a description of the deformation, even though motions at the surface may be concentrated on faults. The evolution of fault systems within the active zones is controlled by geometric constraints, such as the requirement that simultaneously active faults do not, in general, intersect. Many of the active processes discussed in this paper, particularly large-scale rotations and lateral movement along the regional strike, are likely to have caused substantial complexities in older mountain belts and should be accounted for in any reconstructions of them.

J/7. Jackson, J.A. & Yielding, G., 1984. Source studies of the Hamran (1972.9.3), Darel (1981.9.12) and Patan (1974.12.28) earthquakes in Kohistan, Pakistan. In: Miller, K.J. (ed.), *The International Karakoram Project 2*, 170-184. Cambridge University Press.

Long period body waves are examined to show that the Hamran (1972.9.3), Darel (1981.9.12) and Patan (1974.12.28) earthquakes in Kohistan had focal depths of about 8 to 10-km. All involved high angle reverse faulting (thrusting) and had seismic moments of about 2.2 to 2.7×10^{25} dyne-cm. These shallow depths contrast with the deeper hypocenters found in the Hindu Kush and northeast Karakoram to the north and in Hazara to the south. The Hamran and Patan shocks were assigned depths of 45-km by the ISC, indicating that even well recorded events in this region may have focal depths in error by 30-km. The accurate focal depth control in Kohistan provided by the micro seismic network operated during the International Karakoram Project will be important in understanding how the deeper seismicity further north is related to that in the south.

J/10. Jacob, K.H., Pennington, W.D., Armbruster, J., Seeber, L. & Farhatullah, S., 1979. Tarbela reservoir, Pakistan; a region of compressional tectonics with reduced seismicity upon initial reservoir filling. *Seismological Society of America Bulletin* 69, 1175-1192.

The Tarbela reservoir is located on the Indus River in the lesser Himalayas of northern Pakistan, a region of considerable natural seismicity. A microseismic survey conducted prior to impounding has indicated that crustal shortening under horizontal north-south compression dominates present-day tectonics, resulting in thrusting and strike-slip motion along numerous faults.

The reservoir was first partially filled for a few weeks in 1974 and then completely filled in 1975. In both cases, the microseismic activity decreased slightly during the impounding period and recovered quickly upon commencement of drainage or establishment of a constant reservoir level. In tectonic environments where the maximum principal stress is horizontal and the tectonic system is compressive, a vertical surface load can move the crustal stresses away from a Navier-Coulomb failure criterion, and hence can temporarily decrease seismicity. The observed rapid recovery of seismicity may alternately be explained by: (1) high rates of tectonic strain accumulation which, in turn, increase horizontal stresses at crustal depths; they may quickly overcome the stabilizing effects of the small vertical stress changes and increased friction across faults from reservoir loading and, hence, may return the crustal stress system to one of failure; or (2) high diffusivity of the basement rock results in a pore pressure increase after a few weeks of raised reservoir head; the raised pore pressure equally reduces the effective horizontal and vertical stresses and brings the crustal system back to failure. Since direct monitoring of pore pressure at crustal depths is not available at Tarbela, it is presently not possible to distinguish between the two alternatives. Indirect

observations, such as long-term monitoring of space-time changes in seismicity, may aid in the resolution of this ambiguity.

A few reservoirs, located in regions with preferentially extensional or pure strike-slip tectonics, have triggered or induced seismic activity, whereas Tarbela reservoir, in a region of convergent tectonics, has (to present) only slightly modified the natural seismicity. Here, in a region of active Himalayan tectonics, it is likely that any severe earthquake to occur in the near future would occur sooner or later, regardless of the presence of the reservoir. Within hundreds of years a major earthquake near Tarbela appears tectonically inevitable. Yet the presence of the reservoir may strongly affect, say, the time of occurrence, exact location, and the details of rupture of an earthquake. The time most likely for inducing a tectonic stress release (if any) would be during or shortly after a rapid draw-down of the reservoir, when the decrease in pore pressure from its high level at crustal depths lags behind the instantaneous stress decrease from reservoir unloading.

In 1975–79, joint expeditions from Yale University and the Geological Survey of Pakistan (YGSP) recovered fossil loridids in the Siwalik Group of Pakistan from four localities, spanning a period before 10 Myr ago to about 7 Myr ago. In three of the localities, only isolated teeth or fragments were found, whereas the fourth and youngest locality yielded dental, cranial and some postcranial remains of a single individual described here as a new genus and species. These specimens are the first fossil loridids known from outside East Africa, and include the only recovered postcranial remains from slow-moving arboreal loridines. The findings indicate that significant tracts of forests in the Siwalik environmental mosaic may have been utilized by hominoid primates, notably *Ramapithecus*.

J/15. Jacobs, L.L., 1981b. The small mammal fauna of the Neogene Siwalik Group, Potwar Plateau, Pakistan. *Geological Bulletin, University of Punjab* 16, 11-22.

Thirty-five genera of small mammals have been recorded from the Siwalik Group (Miocene-Pleistocene) of the Potwar Plateau, northern Pakistan, by Yale, Geological Survey of Pakistan and Dartmouth-Peshawar expeditions. Preliminary range zones constructed for selected rodent taxa indicate non-synchronous appearances and last occurrences of taxa throughout the section. The small mammal fauna suggests that much of the Siwalik molasse was deposited in an area of warm moist climate. In the Pliocene to Early

Pleistocene, the trend toward modern warm dry conditions may have started. There is no evidence from the small mammal fauna to indicate a cold Pleistocene in the Potwar Plateau area.

J/18. Jaeger, J.J., Courtillot, V. & Tapponnier, P., 1989. Paleontological view of the ages of the Deccan Traps, the Cretaceous Tertiary boundary and the India-Asia collision. *Geology*, 17, 316-319.

Volcanism in the Deccan Traps of India occurred over at most three magnetic chrons, centered on a main reversed chron. Paleontological data indicate that this reversed chron must coincide with 29R, which contains the Cretaceous/Tertiary (K/T) boundary. Recent ^{40}Ar - ^{39}Ar data may therefore provide one of the best estimates of the absolute age of the K/T boundary, 65.7 ± 2.0 Ma. Moreover, the Eurasian character of K/T boundary terrestrial faunas in India suggests that this was also close to the time of India-Asia collision. This is significantly earlier than generally recognized, and implies about 4000 km of continental shortening in the collision zone, probably absorbed jointly by crustal thickening and strike-slip extrusion.

Geosciences Lab, GSP, Islamabad, 113-115.

The Salt Range and Potwar Plateau (SRPP) represents active Himalayan foreland deformation in north Pakistan. It is typified by a tapering wedge of Neogene clastic sedimentation. Magnetostratigraphic (Burbank and Reynolds, 1988; Johnson et al., 1982) and structure combined with seismic reflection and well data (Lillie et al., 1987) provide useful information's on the general features and mechanics of the SRPP. Such studies are critical to provide insight into the evolution of foreland basins.

The SRPP has evolved due to southward translation of a coherent slab (over 90 km) over a thick layer of Eocambrian evaporites. The southern part of this system is relatively undeformed. The northern part, North Potwar Deformed Zone (NPDZ), is characterized by complicated deformation with emergent and buried thrust fronts. The buried thrust front has a triangle zone geometry in the eastern NPDZ (Fig. 1). Here, a core wedge of allochthonous strata is bounded by the Dhurnal backthrust (Jaswal, 1990) and the Khairi-Murat thrust. The Khairi-Murat Range represents a thrust sheet with about 12 km of minimum shortening.

This is overlain by a duplex horse, further deformed by out-of- sequence thrusting, over the footwall flate of the Khairi-Murat thrust' (Fig. 1).

Magnetostratigraphy and zircon fission track dating limits the evolution of the triangle zone between 2.1-1.9 Ma (e.g. Raynolds, 1980). Timing of thrusting is important for an insight into the evolution and kinematics of the NPDZ. Previous models with foreland (Fig. 2B) and hinterland (Fig. 2C) translation of a roof sequence and possibility of an upper detachment at the top of the Eocene suggest 40 to 80 km of shortening. Considering subsequent to the deposition of Siwalik strata (Fig. 2D), piggyback thrusting remains an inadmissible model because Siwalik strata are not exposed north of the Khairi-Murat thrust (Fig. 1), shown as problem in figure 2A. Alternately, with established Dhurnal backthrust (Fig. 1), passive-roof duplex geometry is an admissible solution (Fig. 2E). However, timing of Siwalik sedimentation (13 I to 0 7), thrusting (prior to the 5 Ma motion along the Salt Range thrust, and sequential balancing suggest sedimentation simultaneous to thrusting Thus, we consider the possibility of a disconformity that has evolved into back thrusting and a triangle zone geometry in the eastern NPDZ. Besides, position of the roof thrust in Tertiary Rawalpindi Group strata will reduce shortening estimates to the half Examining of thrust geometries and timing of thrusting is critical to evaluate migration, accumulation, and entrapment of the hydrocarbons.

J/22. Jadoon, I.A.K., & Frisch, W., 1997. Hinterland-vergent tectonic wedge below the Riwat Thrust, Himalayan foreland, Pakistan; implications for hydrocarbon exploration. American Association of Petroleum Geologists, 81(3), 438-448

The Riwat thrust, with a surface trace of over 50 km, is one of the major faults in the footwall of the main boundary thrust in the Himalayan foreland of Pakistan. Surface geology shows that the Riwat thrust is a foreland-vergent thrust along which lower to middle Siwalik molasse strata are thrust southward over upper Siwalik strata. Seismic reflection interpretation shows that the Riwat thrust developed as a roof thrust of a hinterland-vergent tectonic wedge (triangle zone) underlain by evaporites. The Riwat thrust propagates upsection from a depth of about 4 km at the base of the Siwalik Group. At this depth, it merges into a hinterland-vergent blind thrust that propagates upsection as a ramp from Eocambrian evaporites covering the basement at a depth of about 6 km. Bounded between this set of conjugate faults, a tectonic wedge of Eocambrian (evaporites) to Neogene strata is thrust toward the hinterland to form a triangle zone. The roof thrusts of triangle zones have been widely mapped as backthrusts in deformed mountain fronts. Hinterland motion of tectonic wedges as in the Riwat thrust triangle zone may be a feature of the fold-and-thrust belts underlain by evaporites acting as an extremely weak decollement layer. Their recognition, with a trap-forming geometry below a thrust, is important for interpreting particular fold belts and for hydrocarbon exploration. These structures could be predicted by the surface geology data where hinterland vergence of a fold below a thrust is apparent; however, seismic reflection data appear to be critical in recognizing these structures.

Key Words: Tectonics, Riwat Thrust, Himalaya foreland.

J/23. Jadoon, I.A.K., Frisch, W. & Jaswal, T.M., 1996. Geometry of a latest Pliocene-Pleistocene triangle zone in the Himalayan foreland, North Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 72.

Hydrocarbon exploration and magnetostratigraphy from the Himalayan foreland in north Pakistan has provided new surface/subsurface data and informations on the evolution of an overthrust wedge. Surface geology combined with seismic reflection profiles and well data are used to reveal the geometry and

evolution of a latest Pliocene-Pleistocene triangle zone in the eastern North Potwar Deformed Zone (NPDZ). Surface expression of the mountain front is of monocline (Soan) and two thrust faults of opposite vergence (Fig. 1). The steep limb of the monocline is located over the bedding parallel south-dipping Soan backthrust in the Neogene molasse strata. The steep Soan backthrust becomes shallower to the south and dies out at a depth of about 2 to 4 km. At this depth, it merges into a north-dipping blindthrust that propagates upsection as a ramp from Eocambrian evaporites at a depth of about 8-km and makes a flat along a pelitic horizon in the Miocene molasse strata. The two faults bound a blind, tapered and below the backthrust show the undeformed planar and deformed (flat-ramp and pop-ups) geometry of the core wedge. We interpret three-dimensional geometry of the triangle with fault tip-line structures as pop-ups and a core wedge of an overall irregular flat-ramp-flat geometry. A major thrust with about of 12 km of shortening lies to the proximal side of the core wedge. Along and across strike variation of shortening has allowed recognizing the evolution of a linked fault system in the triangle zone.

Magnetostratigraphy and zircon fission track dating (e.g. Burbank and Reynolds, 1984; Reynolds and Johnson, 1985; Burbank and Beck, 1991) limits the evolution of the triangle zone between 2.1-1.9 Ma. We present section balancing and calculate horizontal contraction of 4.5 km along the core wedge and variable degree of uplift from about 3.2-6 km along the core wedge and the Soan backthrust respectively. The shortening and uplift (erosion) rates amount to a minimum of 22 mm/year and about 16 mm/yr. Presence of hydrocarbons (Dhurnal Oil Field) in such a young structural trap has important bearings for the exploration of oil and gas in the Himalayan foreland.

Key words: Structure, hydrocarbon, magnetostratigraphy, foreland basin, Pliocene, Pleistocene, Potwar, Himalaya.

J/24. Jadoon, I.A.K., Frisch, W., Jaswal, T.M. & Kemal, A., 1999. Triangle zone in the Himalayan foreland, north Pakistan. In: MacFarlane, A., Sorkhabi, R.B. & Quade, J., (Eds.). *Himalaya and Tibet: Mountain root to mountain tops*. Geological Society of America, Special Papers 328, 275-286.

Surface geology and seismic reflection profiles reveal the geometry of a triangle zone in the Himalayan foreland of Pakistan. Surface expression of the triangle zone is the Soan syncline (monocline), the northern foreland-dipping steep limb of which is located above a bedding-parallel backthrust in the Tertiary molasse strata. The hinterland-dipping Khairi-Murat thrust is located on the proximal end of the triangle zone. The steep Dhurnal backthrust becomes shallower to the south and dies out at a depth of about 2 to 4 km. At this depth, it merges with a north-dipping blind thrust that propagates upsection as ramp from a layer of Eocambrian evaporites at depth of about 8 km and forms a flat along a pelitic horizon in Miocene molasse strata. The two faults bound a blind, tapered wedge of allocthonous strata (core wedge) inserted below the backthrust. Coherent and dis coherent reflections above and below the Dhurnal backthrust show the undeformed planar and deformed (pop-ups) geometry of the footwall and hanging wall outside and inside the wedge.

We interpret the three-dimensional geometry of the triangle zone in terms of a core wedge having flat-ramp-flat geometry and internal as well as external pop-ups. The presence of blind faults of smaller lateral extent (about 10 km) and shortening (about 2 km) indicates the occurrence of more than one hydrocarbon trap in the triangle zone.

Published magnetostratigraphy limits the formation of the triangle zone between 2.1 to 1.9 Ma. On the basis of cross-section balancing, we calculate horizontal contraction of 4.5 km and rock uplift of about 2.8 km along the core wedge. The shortening and rock uplift rates amount to about 22 mm/yr and about 14 ± 2 mm/yr, respectively. The presence of hydrocarbons (the Dhurnal oil field) in such young structural traps in the Salt Range has important bearings for the exploration of oil and gas in the Himalayan foreland.

J/25. Jadoon, I.A.K., Frisch, W., Kemal, A. & Jaswal, T.M. 1997. Thrust geometries and kinematics in the Himalayan foreland (North Potwar deformed zone), North Pakistan. *Geol Rund.* 86:120-131

Hydrocarbon exploration and magnetostratigraphy from the Himalayan foreland (Salt Range/ Potwar Plateau) in North Pakistan has provided new surface/subsurface data and information on the tectonic evolution of an overthrust belt. A N-S balanced cross section constrained by seismic reflection and well data across the eastern North Potwar deformed zone (NPDZ) shows a buried thrust front with a triangle zone and ramp and flat structures. The triangle zone is characterized by core wedge of an irregular geometry bounded between a floor thrust in the Eocambrian evaporites and a roof thrust in the Rawalpindi group strata. A blind thrust propagates upsection from a depth of approximately 7 km above the basement and merges in the roof thrust at a depth of approximately 3.7 km. The core wedge is bounded by the Soan back- thrust and the exposed S-verging Khairi-Murat thrust. The Kheiri-Murat thrust soles out in the main decollement and is overlain by a plane-roofed duplex horse over the hanging wall flat of the former structure. Both the Khairi-Murat thrust and the duplex are deformed by out-of-sequence thrusting. The duplex geometry and out-of-sequence thrusting is responsible for the absence of the Siwalik strata and complex deformation north of the Khairi-Murat thrust. Nearly all the seismic lines show a step of approximately 800m in the basement with hanging-wall block down-to-the-north displacement. The basement normal fault seems to provide a buttress for thrusting at the deformation front in the eastern NPDZ.

Timing of Siwalik sedimentation (13.1 - 5.1 Ma) and thrusting (8 - 5 Ma) indicate sedimentation partly simultaneous to thrusting. We consider the possibility of piggyback thrusting and a disconformity prior to the development of a passive-roof duplex with backthrusting and a triangle zone in the eastern NPDZ.

A balanced structural cross section 40 km long is restored to an original length of 81 km. Forty one kilometres of shortening along balanced cross section added to the 14 km along the Golra thrust provides total shortening or approximately 55 km between 8 and 1.9 Ma in the NPDZ. Approximately 49.5 km of shortening has occurred between 8 and 5 Ma. The shortening rate of 16.5 mm/a is roughly 33% of approximately 50mm/a convergence rate between the Indian and Eurasian plates.

J/27. Jadoon, I.A.K., Khawaja, A.A. & Jamshed, S.Q., 1995. Thrust geometries and evolution of the eastern North Potwar deformed zone, Pakistan. *Geological Bulletin, University of Peshawar* 28, 79-96.

The North Potwar Deformed Zone is part of the active Himalayan foreland fold- and thrust- belt in northern Pakistan. Field work have been carried out mostly along a profile in the eastern North Deformed Zone, to gain an insight into this complexly deformed area of hydrocarbon interest. The results show triangle zone geometry and a set of imbricates between the Soan Syncline and the Main Boundary Thrust. The preserved triangle zone below the Soan Syncline is characterized by a floor thrust located at depth of 6 km in the Eocambrian evaporites. The floor thrust propagates upsection and merges in a roof thrust at depth of about 3 km in the Rawalpindi Group strata. The roof thrust has a hinterland vergence similar to backthrusts of the triangle zones in other fold- and thrust belts. Integration of structural and timing data for consideration of kinematics suggests that thrust imbricate north of the preserved triangle zone is exposed due to increasing uplift and erosion of a duplex.

A structural cross-section indicates that approximately 42 km of shortening has occurred across the NPDZ. The rate of shortening is 16 mm/yr considering deformation that has occurred between 4.5 – 1.9 Ma in the North Potwar Deformed Zone.

J/30. Jadoul, F., Erba, E. & Gaetani, M., 1992. Uppermost Triassic-Middle Jurassic evolution of the upper Hunza sedimentary cover: implications in the Jurassic geodynamic evolution of the North-Karakoram Microplate. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 115-116.

New data collected during the second Italian expedition in the Chapursan area permit a more detailed reconstruction of the Upper Hunza Jurassic stratigraphy. Two different successions have been recognized. They record, in different ways, the first Cimmerian orogenic episode in the Karakoram. The main stratigraphic characters of the successions, studied in different thrust sheets, are as follows:

- a) during the Norian-Rhaetian two different carbonate platforms were present: eastwards a mainly peritidal dolomitized succession (Guhjal type facies); westward and south-westward a calcareous, subtidal platform with Megalodons (Aghil Fm.), passing laterally to bedded, dark gray probably deeper carbonates.
- b) In the topmost Triassic-Earliest Jurassic the Aghil platform underwent a tectonic dissection ("flexural stage") with local drawing of a more subsident area with slope calcarenitic-ruditic facies deriving from a marginal Upper Triassic platform locally emerged (possible "peripheral bulge stage"). In other areas it is probable that an Upper Triassic-Liassic platform was still growing (Aghil with *Lithiotis*). An important tectonic escarpment was certainly present in the Lupghar area as testified by very thick breccias-paraconglomerates (200-300m thick) with prevalent clasts of micritic, recrystallized limestones rich in dark siliceous nodules.

In this time the early differentiation of the Jurassic sequences took place. An A-type succession characterizes the more subsident area with a prevalent fine siliciclastic euxinic basinal facies with also turbiditic sedimentation. The B-type succession represents a more continuous shallow-water sequence.

A-Type succession. In the forming foreland basin the overlying succession is characterized by a sequence with basal black shales passing upwards to a synorogenic turbiditic siltstones and dark quartzose hybrid sandstones. The petrography of the sandstones shows the presence of quartz, pelagic siliceous micrites with radiolarians, vetrophyric basalts, serpentine schists, granitoids and metamorphic rock fragments. The age of this succession has not been assessed; the stratigraphic position suggests an Early Jurassic age.

B-Type succession. Sparse outcrops would suggest that the Aghil carbonate platform or/and open shelf carbonates and may possibly continue in some area. But the datum is not well constrained.

c) Middle Lias. The B-type succession consists of open shelf dark limestones with many limestones and marls. Fossils, at the top of the succession, are Brachiopods (*Zeilleria* sp., "*Spiriferina*" sp.) followed by Foraminifers (*Haurania* sp.) and calcareous Nannofossils (*Lotharingius hauffii*, *Mitrolithus jansae*, *Schizosphaerella punctulata*) that record a Late Domerian-Early Toarcian age. Upwards there is a shallowing upwards regressive succession with bioclastic-oolitic calcarenites.

Middle Liassic facies have not been recognized in type A succession because of tectonic boundaries or the presence of an erosive unconformity between the synorogenic succession and the overlying basal conglomerates, shales and sandstones of the Yashkuk Fm. The undated shaly and turbiditic synorogenic succession (thickness more than 150 m) is possibly of Triassic age.

d) The Upper Lias-Lower Dogger is everywhere characterized by the deposition of the Yashkuk Fm. that represents an important orogenic event in the North Karakoram Plate (considered as Middle Lias by Gaetani et al., 1990). The Yashkuk Fm., in the B-type succession, is Toarcian and/or Earliest Aalenian in

age, not very thick and characterized by continental to marine transitional sandstones-siltstones passing upwards to fine siliciclastic and shallow-water marine carbonates that contain bioclastic calcarenites with Forams (*Mesoendothya* sp.). This unit overlays the Middle Lias without an evident unconformity.

In A-type succession the corresponding Yashkuk Fm. (Gaetani et al., 1990) is not dated and quite different, shows locally an evident unconformity over the shales and turbiditic sandstones. At the base are present carbonate conglomerates with prevalent clasts of Upper Triassic Aghil Fm. passing upwards to a thick (more than 130 m) continental red sandstones-siltstones sequence (Gaetani et al., 1990).

e) The Early Middle Jurassic marine transgressive sequence is well documented only in the B-type succession. Shallow-water carbonates with ooids, stromatolites, bioclastic calcarenites with mainly intercalations pass upward to dark gray-bedded limestones with frequent oncoids, ooids and thin mainly intercalations. The top of these shelf carbonates has been dated as Late Aalenian (Nannofossil: "small" *Hexalithus magharensis*). In Late Aalenian-Early Bajocian the shelf drowned and pelagic limestones prevail. A decametric intercalation of dark grey fossiliferous mass (Nannofossils: *Hexalithus magharensis*, "small" *Watznaueria manivatae*) documents an anoxic Bajocian event.

In the A-type succession, shallow-water, lagoonal dark grey limestones overlay, in transgression, the thick Yashkuk Fm. At the top of these carbonates a highly tectonized fine terrigenous marine-transitional-evaporitic unit crops out. In intercalated mass we have recognized a Nannofossil (*Watznaueria* cf. *W. communis*) that indicates Bajocian to Cretaceous age for this regressive succession.

The A-type succession is interpreted as a part of the sedimentary accretionary complex in which the dark shales and turbiditic sandstones represent the "starved flysch stage" derived from the erosion of the roof and wallrock of an area. This succession is unconformably channelized by the basal conglomerates, shales and red sandstones of the Yashkuk Fm. Eventually it is transgressed and sealed by the marine late Middle Jurassic fine terrigenous to carbonatic shallow-water sediments.

The B-type succession is considered to represent a more distal or external domain, whose mostly shallow-water environment is temporary, invaded by the terrigenous prism of the Toarcian-Earliest Aalenian Yashkuk red sandstones-siltstones. Both these successions are considered to reflect the first episode of the Cimmerian orogeny. To be noted that presently the A-type succession (accretionary prism) lies at south of the B-type, representing the external domain.

J/33. Jafery, S.S.A., 1996. Geology and mineral resources of the Collision Zone in Pakistan. Geological Survey of Pakistan, Information Release 444, 22p.

A research project on geology and mineral resources of collision zone in Pakistan under the collaboration of Geological Survey of Pakistan and Geological Survey of Japan was planned in March, 1987.

On behalf of the Director General of Agency of Industrial Science and Technology (AIST) under the ITIT programme, the author visited Japan in February, 89 to carry out the collaborator research, mainly the X-Ray Diffraction and field studies of the geology of Japan at several localities.

The report in general deals with the brief introduction of the geology of Pakistan with specific reference of the collision zones, and related mineral resources with Calc alkaline plutonic bodies intruded into volcanic and volcano-sedimentary rocks which have undergone low to high grade of metamorphism; laboratory examinations of the minerals and rocks of the collision zone using X-Ray Diffraction; and geological field examinations in Japan for comparative type of studies.

All the geological field trip related to the geology of collision zones were for comparative studies between Pakistan and Japan, the zoned pluton of the granite rocks of the Ibaraki (SE of Japan) is much interesting. Here the rocks grade from quartz diorite, granodiorite to adamellite.

The co-magmatic pluton sequences are cocentrally zoned pluton in which relatively magmatic rocks in the margins, composed of high temperature mineral assemblages pass inwards without discontinuities to more felsic rock in the core composed of high temperature. Such type of field studies can be carried out for the study of geological environments and possible mineral resources in Pakistan.

Above all, the studies in Japan provided a better understanding and guideline for the study of the genesis of mineral deposits in the collision zone and its application to the exploration techniques in Pakistan.

Key words: Collision zones, mineral resources, Japan, Pakistan.

J/34. Jaferi, S.S.A. & Rahimuddin, 1997. Contact demarcation using the heavy minerals in the rocks of the Siwalik and Rawalpindi Groups at Ex-Toot Well 7. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, 48-49.

The rocks of the Siwalik Group and the Rawalpindi Group are mainly sandstones, claystones and shales that are lithologically difficult to demarcate. Toot Well-7 was spudded in the Dhok Pathan formation of the Siwalik Group; and was drilled through a depth of 4612 m down to the Tredian formation of Jurassic age. The three rock formations within the Siwalik Group, i.e., Dhok Pathan, Nagri and Chinji, may be distinguished by the criteria given below.

Dhok pathan Formation: The presence of fresh, whitish, grey to light greenish grey sandstone, with high clay content and appearance of maroon siltstone in the Dhok Pathan formation.

Nagri Formation: Greenish grey, medium hard micaceous sandstone and brown soft silty clays.

Chinji Formation: Brownish clays with thin bands of sandstone. However, the contacts between the formations belonging to the two Groups are not always demarcable at precise levels due to gradations in lithology. In the present case, their heavy mineral contents are, therefore, deployed for more precise determination of the contacts.

The samples from various depths were sieved through 80 mesh size and treated with 15% chloric acid, washed and dried. Bromoform liquid of specific gravity 2.8205 was used to separate the heavy minerals whose percentage in rock samples provided the criteria deployed to mark the contacts as mentioned below. Contact between Chinji and Nagri Formations: Epidote is more dominant in the Chinji formation than in the overlying Nagri formation. At Toot Well-7, persistent dominance of epidote began at 1615 m.

Contact between Chinji and Kamliyal Formations: Epidote is higher in the Chinji formation than in the underlying Kamliyal formation of the Rawalpindi Group. At Toot Well-7, there is a distinct increase of tourmaline and decrease of epidote at 3105 m. The contact is assumed at 3110 m because the sampling interval is 10 m in contact between Kamliyal and Murree Formation: Epidote is more and tourmaline less in the Murree formation than in the Kamliyal formation. At the well site, tourmaline shows sharp decline at 3185 m, so the contact is positioned at 3190 m. The foregoing is an example of the use of heavy mineral content of sandstones and shales from flush cutting samples of the ex-toot well-7 in demarcating the contacts amongst rock formations of the Siwalik and Rawalpindi Groups.

Key words: Stratigraphy, lithology, heavy minerals, Siwaliks, Murree.

J/36. Jah, M.A., Wazir, A.K., Shah, M. & Ahmad, N., 1978. Geology of Lambidogi area in relation with the Kakul Hazara Phosphate Project. M.Sc. Thesis, University of Peshawar, 79p.

The writers were assigned the responsibilities of trenching including systematic logging and sampling, petrological study of the rocks and regional and detailed mapping of the area in May, 1976. The trenching, (see fig.7) systematic logging, and sampling was completed in September, 1976. The trenches were grouped according to the Village locations like "A & C" group extends from Kalure to Tiryan Village, "B" group from Lambidogi to Kalure and "D" group from Dakhan to Manga-di-Bandi village, during and before mapping the area was divided into different distinctive rock units. The plane table survey was undertaken from March, 1977 to mid May, 1977. The scale used for plane table survey was 1:500. A self reducing alidade was used as surveying instrument.

The data collected to the field was compiled into report which presents a comprehensive petrological study of south western facies of phosphatic youngest sediments in upper most part of the Sirban Formation which is conformably overlain by the Haziran siltstones. The upper most part is well exposed in the area. It extends from Lambidogi on the Banda Pir Khan Road to the crest of the ridge of Kakul mines. However, the area investigated extends upto Manga-di-Bandi south of the Lambidogi. The change that only occurs between Lumbidogi and Kakul west succession is the "C" unit which is sandy dolomite in thesis area and slabby/flaggy phosphatic dolomite to Kakul west.

Key Words: Geology, Lambidogi, Kakul phosphate.

J/38. Jamal, A., 1995-96. Structure, stratigraphy, micropaleontology and petrography of Jabri and Bodla areas District Haripur Hazara (NWFP), Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 78p.

The Jabri-Bodla area lies in the Attock-Hazara fold-and-thrust belt of the northwestern Himalaya of Pakistan. Precambrian to Cenozoic sedimentary rocks are folded and imbricated during the Tertiary-Himalayan collision.

The oldest exposed stratigraphic unit is the Precambrian Hazara Formation. The formation is composed of slates, shales and phyllites. The presence of ripple marks and graded bedding shows that the Formation is deposited in shallow water turbidity environments. The Middle Jurassic Samana Suk Formation, Late Jurassic to Early Cretaceous Chichali Formation and Early Cretaceous Lumshiwai Formation were deposited in shallow marine conditions. The late Cretaceous Kawagarh Formation was deposited in deep to shallow water shelf environment. The late Cretaceous to Early Paleocene uplift in the area caused the regression of the Tethyan Sea. The Tethyan regression initiated the deposition of ferruginous sandstone of the Hangu Formation.

The lower Tertiary sequence of Early to Late Paleocene Lockhart limestone, Late Paleocene Patala Formation, Early Eocene Margala Hill Limestone and Early to Middle Eocene Chorgali formation mark the complete cycle of transgression and regression of the Tethyan Ocean. The presence of early Paleocene to Late Eocene foraminiferal assemblage like globorotalia, globogorina, lockhartia, assilina and nummulites in the limestones and shales of the Lower Tertiary sequence show the tropical sub-tropical open sea upper slope to outer shelf environments. The Paleocene-Eocene boundary cannot be marked on the basis of microfossils in the area because the Patala Formation lacks microfossils. However, the tentative Paleocene-Eocene boundary between the Patala Formation and the Margala Hill Limestone can be marked at the base of Margala Hill Limestone on the basis of first appearance of Early Eocene microfossils. The structural analysis of the investigated area shows that the Precambrian to Eocene rocks record at least two major events of deformations i.e. D1 and D1 deformation phases. The D1 deformation is divided into D1a and D1b deformation phases. The D1a is associated with the southeast-directed thrusts and southeast vergent F1 folds. The second phase of D1b deformation is related with the backsteeping of the major thrusts and northwest overturning of the major F1 folds. The northwest plunging F2 cross-folds are recognized as D2 deformation phase in the project area. These F2 cross-folds are related with the development of the Hazara-Kashmir syntaxis.

J/43. Jan, M.Q., 1964. Geological report of the Makarwal area. Geological Bulletin, University of Peshawar 1, 19-25.

This report was prepared in Dec.1963, after a seven-day field study of the area, mainly along Miranwal Nala. Mr. Farooqui, a junior Geologist in W.P.I.D.C. guided us at times. The Makarwal area is on the South-Western extremity of the Surghar-Range. (Sur---Pashto word for “Red” and Ghar for “mountain”; since the general, colour of these mountains is reddish). The Surghar Range is included in the famous Salt Range series of West Pakistan, on the trans-Indus side between longitudes 71'-72° E and latitudes 31° 32' ~ N. The place is in South-West of Kalabagh at a distance of about 32 miles. The area is on the Western extreme of Mianwali District. The top of these mountains is the boundary between the Distts. of Kohat and Mianwali. Makarwal exposures are located on the East-scarp, slope of the mountain chain of Surghar Range. The place is connected with Kalabagh-Bannu Railway and cemented lorry road which are the side branches of road & railway, separating from main line at Kamar Mashani. The formations at Makarwal have been an important source of Coal in the Western part of Indo-Pak subcontinent for the last 60 years.

Key Words: Geology, coal, Makarwal.

J/44. Jan, M.Q., 1968a. Petrography of the emerald-bearing rocks of Mingora (Swat State) and Prang Ghar (Mohmand Agency) West Pakistan. Geological Bulletin, University of Peshawar 3, 10-11.

Emerald-bearing rocks are present near Mingora in Swat State, and Prang Ghar in Mohmand Agency. Rock containing fuchsite in addition to calcite and /or siderite are perhaps the most favorable for emerald, though some pegmatite and greenschists may also have emerald. The emerald and chrome-mica (fuchsite) probably have some genetic bearing on the chrome-bearing ultramafic intrusions of the two areas.

Key Words: Petrography, gemstone, emerald, Swat.

J/45. Jan, M.Q., 1968b. Pleistocene sandstone. Geological Bulletin, University of Peshawar 3, 34.

Pleistocene sediments are exposed on the northern slope of the Cherat Range, about 1 ½ miles south east of Jalozai village. The beds dip gently to the south, making an angular unconformity with the older rocks. The base of these sediments is composed of sandstone, which is overlain by friable shale, which in turn is overlain by grit stone. This note is written with the intention to introduce the sandstone that has interesting mineralogy, which shed some light on the provenance.

Key Words: Pleistocene, sandstone, Cherat Range.

J/46. Jan, M.Q., 1969. Preliminary geology of the Shilman area, Khyber Agency, with notes on a Copper-bearing Gabbro. Geological Bulletin, University of Peshawar 4, 92-93.

Reconnaissance geological work was carried out in Shilman, Khyber Agency, and traverses were made along roads and major streams. Low-grade metamorphic rocks, striking northeast and dipping northwest, occur in the northwest of the area. The rocks are generally of a grayish color, the phyllitic rocks having well-developed cleavages. Some rocks are greenish-gray to dark gray and contain carbonaceous material. The rocks are cut by abundant quartz veins and also by some basic and a few granitic intrusions. The intrusions in the phyllitic rocks are mostly small, concordant bodies, not more than a few tens of feet thick. The basic rocks are dark colored, medium-grained gabbros and dolorites. The gabbro near Bar Kili is composed of Plagioclase, abundant dark minerals and a little quartz. The gabbro contains various copper minerals – Chalcopyrite, bornite, cuprite, malachite, etc. either disseminated, in a pockets, or as incrustations, in a ten foot-thick brecciated zone along the contact.

Key Words: Reconnaissance, geology, metamorphism, Shilman, Khyber Agency.

J/47. Jan, M.Q., 1970. Petrography of the upper part of Kohistan and southwestern Gilgit Agency along the Indus and Kandia Rivers. Geological Bulletin, University of Peshawar 5, 27-48.

This paper presents a petrographic account of the common rocks of the previously unmapped area of Indus Kohistan and southwestern Gilgit Agency. The study is based on field observations and thin section of 55 rocks selected from over 200 samples quickly collected along the Indus Valley Road and Kandia River. The major rocks of the area are amphibolites (gneissose metaigneous; some banded ? metasedimentary) and norites-diorites (the former also having a clinopyroxene), and minor (?) alpine peridotites, granitic rocks, pegmatites, and low grade regionally metamorphosed schists in the Kandia valley. The norites-diorites are abundant in the north, the amphibolites in the south. Tentative ages have been assigned to the rocks; the various igneous rocks are considered to be related to the Himalayan orogeny and emplaced between Middle/Late Cretaceous and Early Tertiary.

Comparison of the rocks from various parts of the northern West Pakistan shows that the Hornblende Group of Martin et al. (1962) extending from Chilas in Gilgit Agency to at least Western Dir – a distance over 160 miles. There is a probability that the group may be extending in the adjacent eastern Afghanistan, which is covered by the Hindukush Range. North to south, the group may occupy a territory as wide as 60 miles.

Key Words: Petrography, amphibolites, norite, diorite, Indus valley, Kandia River, Kohistan.

J/49. Jan, M.Q., 1975. Notes on the igneous rocks of Spinkai and adjacent areas of Tirah, Khyber Agency. Geological Bulletin, University of Peshawar 7 & 8, 73-78.

A brief petrographic account of the most common igneous rocks of the Spinkai area (Tirah) is presented in this note. Reconnaissance survey reveals that like the adjacent Kohat district, much of the Tirah Tribal territory is free of igneous and metamorphic rocks. Traverses in Spinkai area indicate that crystalline rocks, mainly igneous, are confined to a narrow strip of country (only a few miles broad) extending along Afghanistan-Pakistan border. The country rocks on the southern contact are Paleozoic in age (Tahirkheli, et al., 1971). Tertiary and Mesozoic sedimentary rocks are exposed further south and east. This leads to think that in this part of the Safed Koh Range, the intrusive activity was either confined to the central part of the range, or that the main activity was older than the Tertiary (and even Mesozoic). Dolerite intrusions of probable Permian age (Tahirkheli, Personal Communication) are common to the northeast between Torkham and Jamrud. Ahmad et al., (1969) have also reported basic and acid igneous rocks of Late Mesozoic to Early Tertiary age from the Warsak area, farther northeast.

Key Words: Reconnaissance, petrography, Spinkai, Tirah, Khyber Agency.

J/50. Jan, M.Q., 1977a. The Mineralogy, Petrology and Geochemistry of Swat Kohistan, NW Pakistan. Ph.D. Thesis, University of London, 349p.

This is the first detailed petrological description of the southern part of the Kohistan island arc, supported by hundreds of whole rock and mineral chemical analyses. It describes the petrological aspects of the ultramafic rocks and garnet granulites of the Jijal complex sitting on the Indus suture, the southern amphibolites, gabbro-norites of the now called Chilas complex, and quartz diorites to the south of Kalam. It is shown that the amphibolites and gabbro-norites extend from Swat towards Chilas. Mineralogical aspects of pyroxenes, amphiboles, garnets and other minerals are elaborated.

Key Words: Mineralogy, petrology, geochemistry, amphibolites, gabbro-norites, diorites, Jijal complex, Swat Kohistan.

J/51. Jan, M.Q., 1977b. The Kohistan basic complex: A summary based on recent petrological research. Geological Bulletin, University of Peshawar 9&10, 36-42.

The central part of the Kohistan basic complex in the Swat district has been studied in detail petrographically and geochemically. The main rocks of the area—amphibolites, noritic rocks, and quartz diorites – do not appear to be directly related mutually or to the rocks of the Jijal complex (garnet granulites and alpine-type ultramafic rocks). Temperature pressure estimates suggest that the various metamorphic rocks of the area were formed under different geothermal gradients. It is recommended that the noritic rocks be henceforth called pyroxene granulites.

Key Words: Petrography, petrology, geochemistry, Swat Kohistan.

J/52. Jan, M.Q., 1979a. Petrography of the Jijal complex, Kohistan. Geological Bulletin, University of Peshawar 11, 31-49.

This paper presents a detailed petrography of the garnet granulites and garnet-free ultramafic rocks which constitute a > 150 sq. km tectonic block at Jijal, Indus Kohistan. The granulites are classified into 1) those with essential plagioclase, and 2) those with little or no plagioclase; the two types are a consequence of bulk chemical rather than environmental differences (Jan and Howie, in prep.). A total of 17 mineral assemblages have been identified, with garnet + clinopyroxene + plagioclase + quartz + rutile ± hornblende ± epidote being the most widespread. The plagioclase-free granulites are generally composed of two or three of the minerals garnet, clinopyroxene, hornblende, and orthopyroxene or epidote. The granulites were produced by high-pressure metamorphism of a series of hypersthene gabbros with some more and some less silicic rocks.

The ultramafic rocks have alpine-type features but, unlike most alpine-type ultramafic rocks, they are dominated by diopsidites (with or without olivine); dunite, harzburgites and websterites together make less

than 50 % of the > 40 km slab. The granulites and ultramafic rocks are considered to have originated in the Tethyan lower crust-upper mantle before they were metamorphosed during the collision of the Indian-Asian masses. The granulites were intruded in the granulites as plastic material after the main metamorphism but before the two were tectonically brought in their present surroundings.

Key Words: Petrography, garnet granulite, ultramafic rocks, Jijal, Kohistan.

J/53. Jan, M.Q., 1979b. Petrography of the amphibolites of Swat and Kohistan. Geological Bulletin, University of Peshawar 11, 51-64.

The amphibolites of Swat and Kohistan are mainly found in two belts. Those forming the southern belt are the prograde metamorphic products of basic to intermediate rocks, which were intruded into tuffs, with some volcanic flows; the tuffs now represented by banded amphibolites. The rocks are locally migmatitic and are essentially composed of hornblende, plagioclase and/or clino-epidote, with garnet and/or quartz in some places. Opaque minerals, rutile and/or sphene are the common accessory minerals, while white and dark micas, clinopyroxene, carbonate, k-feldspar, margarite, corundum, cummingtonite, zoisite, green spinel and staurolite are locally present. The amphibolites of the granulite belt are retrograde products of the pyroxene granulites, mainly due to an influx of water, and are essentially composed of hornblende and plagioclase.

Key Words: Petrography, amphibolite, Swat, Kohistan.

J/54. Jan, M.Q., 1979c. Petrography of pyroxene granulites from northern Swat and Kohistan. Geological Bulletin, University of Peshawar 11, 65-87.

The pyroxene granulites of Swat and Kohistan, formerly called norites, form a part of an extensive belt stretching between Nanga Parbat and central Dir. They are relatively uniform in composition and usually represented by leucocratic rocks essentially composed of plagioclase, orthopyroxene and clino-pyroxene, with subordinate amounts of quartz, opaque mineral(s), apatite, amphibole, biotite and, locally, garnet; but some of the rocks contain a higher proportion of amphibole and biotite. The proportion of quartz increases towards the intermediate members, which may also have essential K-feldspar. The rocks are gneissose (foliated) and layered/banded, with some of the layers being pyroxenitic or anorthositic. Some of the bands are due to metamorphic segregation whilst others are relict igneous layers modified by metamorphism.

This paper presents a detailed account of the petrography of the rocks together with a discussion on the nature of the foliation, layering, and other aspects (xenoliths, hornblende-pegmatite, etc), and details of the plagioclase in the granulite. Many of the features can be better explained by invoking metamorphism. It appears that the rocks crystallized plutonically from an andesitic basalt magma in an island arc or a continental margin, were metamorphosed (800°C, 7-8 kb) and finally intruded, as crystalline material capable of plastic flow, in the country rocks which were passing through amphibolite facies metamorphism.

Key Words: Petrography, gabbro-norites, pyroxene granulite, Swat, Kohistan.

J/55. Jan, M.Q., 1979d. Petrography of quartz diorites to the south of Kalam, Swat. Geological Bulletin, University of Peshawar 11, 89-97.

The quartz diorites of Swat Kohistan appear to be partial melting products of more mafic rocks during the collision of Asian-Indian landmasses and the Himalayan orogenic-metamorphic episodes. On the basis of texture and type of principal mafic mineral(s), at least four types of quartz diorites can be recognized in the area to the south of Kalam. One of these, with strongly pleochroic hypersthene relics, appears to be a retrograde type after pyroxene granulites. It is not clear whether or not the other types are a product of differentiation from a single parent magma; however, it is likely that they represent independent pulses of diorite (andesite) magma produced over a considerable length of time (Late Cretaceous to Middle Tertiary), the earlier ones having been metamorphosed.

J/56. Jan, M.Q., 1979e. Topaz occurrence in Mardan, North West Pakistan. *Mineralogical Magazine* 43, 175-176.

Colourless, purple, and pink topaz and transparent quartz crystals have been found in calcite veins (with or without milky quartz) in calcareous rocks near Katlang (34 ~ 24' N, 72 ~ 6' E), Mardan. The veins do not contain any fluorite nor the country rocks any topaz. The topaz and transparent quartz crystals are mostly broken and perfectly euhedral outlines are very rare. Refractive indices, 2V, specific gravity, and the fluorine (determined) and H₂O + (calculated) contents of two topaz crystals are suggestive of their high 100 OH/(OH+F) ratios (> 25). Rather than being derived, the topaz may have formed in situ by hydrothermal/pneumatolytic activity, followed by tectonic movements that fractured the crystals and resulted in their incorporation in later-formed vein calcite.

Key words: Gemstone, topaz, Mardan.

J/57. Jan, M.Q., 1980. Petrology of the obducted mafic and ultramafic metamorphites from the southern part of the Kohistan island arc sequence. *Geological Bulletin, University of Peshawar* 13, 95-107.

The ~ 36,000-km² Kohistan region is a well-defined tectonic zone with unusual lithology when compared to the neighboring regions. It is occupied mostly by plutonic and volcanic igneous rocks ranging from ultramafic to silicic. A few authors have suggested that some or the entire Kohistan zone represents a fossil island arc. Based on over 250 rock and minerals analyses, mainly from Swat, a petrological account of the mafic and ultramafic rocks of Kohistan is presented below, together with comments on their tectonic environments, metamorphism, and the duration of the presumed island arc.

The basic rocks occur in two NE-trending belts of amphibolite and pyroxene granulite stretching from Nanga Parbat to eastern Afghanistan, and in the wedge-like tectonically-emplaced Jijal complex (~ 200 sq. km) which comprises garnet granulites and alpine ultramafics. It is suggested here that most of the southern amphibolites (and the overlying metasediments of the Kalam group) represent the Tethyan oceanic crust and the alpine ultramafics the underlying upper mantle. The pyroxene granulites, some amphibolites and, probably, Jijal garnet granulites have been derived from a high alumina tholeiite (calc-alkaline) magma that was intruded into the oceanic crust during the early phases of arc-building.

J/58. Jan, M.Q., 1982. Chemical changes accompanying the granulite to amphibolite transition in Swat Kohistan, North West Pakistan. In: Sinha, A.K. (ed.), *Contemporary Geoscientific Researches in Himalaya* 2, 49-52. Singh, Dehra Dun, India.

In southern Kohistan, gabbros and norites (granulite facies) show retrogression to amphibolites on local as well as wide scale. This is a chemical study of the phenomenon. The transition is accompanied by fall in Ti and Fe²⁺, and rise in Fe³⁺, alkalies, H₂O, Ba, Cu, Ni, and Y.

J/59. Jan, M.Q. 1983. Further Data on ortho- and clinopyroxenes from the pyroxene granulites of Swat-Kohistan, northern Pakistan. *Geological Bulletin, University of Peshawar* 16, 55-64.

Microprobe analyses of pyroxenes from the pyroxene granulites of Swat-Kohistan are similar to their wet chemical analysis and the two sets of analysis yield similar temperature estimates. The pyroxenes are exsolved, but the exsolved pyroxene is similar in chemistry to its corresponding principal pyroxene, suggesting the attainment of physico-chemical equilibrium. The Mg/(Mg+Fe²⁺) ratios for the coexisting pyroxenes have been plotted and the implications of granulite facies metamorphosed noritic lenses in the amphibolite belt of Kohistan discussed.

Key words: Pyroxene, pyroxene granulite, Swat-Kohistan.

J/60. Jan, M.Q., 1984a. Chromian andradite and olivine-chromite relations in chromite layer from the Jijal complex. Abstracts, First Pakistan Geological Congress, Lahore, p.56.

Green chromian andradite associated with chrysolite occurs in a chromitite layer within dunite of the Jijal complex. The garnet contains over 10% Cr₂O₃ and has the formula Ca_{6.13} Cr₁₃₇ Fe⁺³_{2.53} Si_{5.94} O₂₄. The garnet formed during retrograde greenschist facies metamorphism of the Jijal complex. Analyses of chromite in the dunite and chromite, layers resemble those of high Cr-chromite but their total Fe is a little higher. In contrast, the olivine is highly magnesian, with a ratio 100 Mg/ (Mg + Fe²⁺) of about 96%. These features appear to have been caused by Fe ↔ Mg exchange between the two minerals down to a blocking temperature of about 800°C.

J/61. Jan, M.Q., 1984b. Some K/Ar ages from the Chilas complex in Swat. Geological Bulletin, University of Peshawar 17, 171-173.

K/ Ar dates (64-79 Ma) have been obtained on four samples from the Chilas complex in Swat Kohistan. Field studies and petrography suggest that hornblende in SH 37 grew secondarily at the expense of pyroxene mainly, whereas the pegmatite bodies have formed by metasomatic processes. The age of hornblende in SH 37 is younger than that of the whole rock but the two ages would not be significantly different at the 95 % confidence level if the error in potassium determination were in fact 2 %. Surprising is the younger age of the granulite (US14) sample compared to others. It can be attributed to a number of factors such as argon loss from the non-retentive sites in the whole rock sample, to overprinting caused by a later tectonic, intrusive or magmatic activity.

It has been noted by a number of workers that K/Ar ages of rocks that have gone through polyphase metamorphism and deformation usually record younger periods than the actual age of formation (cf. Le Fort et al., 1983). It seems that the four K /Ar determinations from Swat record cooling and uplift ages after the rocks had passed through pyroxene granulite facies metamorphism. Similar ages (70-80 m.y., according to Shams, 1980, and Maluski and Matte, 1983) were obtained on Shangla blueschists of the Indus suture zone. Hence Bard (1983) suggested that the high-P metamorphism may have taken place during obduction.

J/62. Jan, M.Q., 1985. High-P rocks along the suture zones around Indo-Pakistan plate and phase chemistry of blueschists from eastern Ladakh. Geological Bulletin, University of Peshawar 18, 1-40.

The Indo-Zangbo suture zone (IZS), the Indoburman suture zone and the Chaman Fault are the traces of major collisional boundaries between the Indo-Pakistan plate and Eurasian block, Gondwanic microcontinents or island arcs. These suture zones are characterized in several places by ophiolites and tectonic melanges. High-P metamorphic rocks, generally belonging to blueschist facies, have recently been discovered along the suture zones in Naga hills, southern Tibet, eastern and western Ladakh, Swat and Afghanistan. The high-P metamorphism probably occurred during the Late Cretaceous / Paleocene. In the IZS it is complemented by low- to medium-P metamorphism to the north, suggesting a northward dip for the subduction zone. Along the southern margin of the Kohistan arc near Jijal, immediately N of IZS, gabbroic rocks were metamorphosed to high-P garnet granulite at a depth of > 40 km about 100 m.y. ago.

Detailed investigations, based on whole rock and 188 point analyses in three sections, suggest that metabasites in the eastern Ladakh ophiolites melange are ocean floor basalts metamorphosed under blueschist facies conditions. They are mineralogically similar to high-grade blueschists of other areas and contain sodic, sodic-calcic and calcic amphiboles, epidote, chlorite, albite, phengite, paragonite, garnet, quartz, rutile, calcite, and magnetite. The PT trajectory suggests that the metamorphic conditions culminated around 370-480°C, 7-8 k-bar and subsequent retrogression, possibly during uplift, took place at similar temperature but lower (6-4) pressure.

Key words: Plutons, Chilas, Jijal, Kohistan arc.

J/64. Jan, M.Q., 1986b. Composition of the pluton core of the Kohistan island arc in NW Himalaya, Pakistan. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, 19-20.

The Kohistan island arc covers about 36,000 km² of N. Pakistan. It formed as an intra-oceanic arc in response to northward subduction of Neotethyan lithosphere during Late Jurassic-Cretaceous, and consists of arc volcanics, amphibolites, diorite-tonalite-granite plutons and minor sedimentary rocks. The base consists of the stratiform Chilas complex which stretches for >300 km with a width of about 40 km in the middle. It is composed of mildly layered gabbro-norites with subordinate Qz-Hyp diorites, pyroxenites and anorthosites of calcalkaline affinity. These contain variable amounts of Pg (An₆₄₋₄₃), Opx (En₆₆₋₅₁), Cpx (Fs₁₂₋₂₂, Wo₄₃₋₄₈), Mt, Il ± Qz ± K-spar ± Hbl ± Bio ± rare Scapolite. In the central part of the complex there are small (up to 5 sq. Km), seemingly intrusive bodies of dunite-peridotite-pyroxenite-troctolite gabbro-norite-anorthosite. -ol/pxn pegmatite association displaying excellent layering, graded bedding, slump breccia and syn-depositional faults. These rocks may be derived from a picritic melt or may be remobilized deeper-level cumulates. This association contains Ol (Fo₈₅₋₇₃), Opx (En₈₃₋₆₆), Cpx (Fs_{5.4-12.5}, Wo₄₅₋₄₉), Pg (An₉₈₋₈₃), Chr or Cr-Sp, Hbl and vermicular pleonaste. Association of other arc-related rocks, absence of oceanic rocks, and the chemical and mineralogical features suggest that the Chilas complex is not an ophiolite. It is similar to plutonic rocks from deeper parts of island arcs and analogous to the Border Ranges complex, Alaska. It was re-equilibrated under pyroxene granulite facies conditions (750-850°C, 5-6.5 kb) about 110 mybp. A portion of this complex, subducted to >40 km along the Indus suture was metamorphosed to garnet granulite facies 104 mybp.

J/65. Jan, M.Q., 1988a. Relative abundance of minor and trace elements in mafic phases from the southern part of the Kohistan arc. Geological Bulletin, University of Peshawar 21, 15-25.

Many pyroxenes, garnet, hornblende, epidote, biotite, and one each of olivine and chromite from amphibolites, gabbro-norites and ultramafic rocks were analysed for up to 21 minor and trace elements. Like major elements, many of these also are systematically distributed between the coexisting mineral pairs and trios. Orthopyroxene contains higher amounts of MnO, Co, Ni, Zn, and lower TiO₂, Na₂O, Li, Pb, Cr, V, Zr, Sr, Ba, Y, Nd and La as compared to clinopyroxene. Biotite contains more Cr, Cu, Li, Pb, and Ni than pyroxenes and hornblende. The amounts of TiO₂, Na₂O, K₂O, Fe₂O₃ and Ni are higher in hornblende than in pyroxenes and garnet. Garnet is impoverished in Li, Ni, V and Zn as compared to clinopyroxene and hornblende.

Key words: Geochemistry, ultramafics, mafic phases, Kohistan arc.

J/66. Jan, M.Q., 1988b. Geochemistry of amphibolites from the southern part of the Kohistan arc, N. Pakistan. Mineralogical Magazine 52, 147-159.

The southern part of the Cretaceous Kohistan island arc is occupied by an extensive belt dominantly comprised of amphibolites. These include banded amphibolites of partly meta-volcanic parentage, and non-banded amphibolites derived from intrusive rock. In addition to being relict, banding has also been produced by shear deformation, metamorphic/metasomatic segregation and, possibly, by lit-par-lit injection of plagiogranitic material. Non-banded amphibolites also occur as retrograde products of noritic granulites forming the lopolithic Chilas complex. The chemistry of 37 rocks has been compared with those of known

tectonic environments. The amphibolites have chemical characteristics similar to volcanic rocks found in island arcs and most of the analyses apparently support affinity with the calc-alkaline series. The amphibolites consist essentially of hornblende, plagioclase and/or epidote. Garnet and clinopyroxene have developed locally in rocks of appropriate bulk composition. Metamorphism may have taken place during the mid-Cretaceous under conditions of 550 to 680 °C and 4.5 to 6.5 kbar p_{H2O}. The metamorphic grade appears to increase from the centre of the southern belt toward the Chilas complex to the north and Indus-Zangbo suture (IZS) to the south. In the vicinity of the IZS, garnet-clinopyroxene + amphibole assemblage developed locally in response to high P-T.

J/67. Jan, M.Q., 1990. Petrology and geochemistry of the southern amphibolites of the Kohistan arc, N. Pakistan. *Physics and Chemistry of the Earth* 17, 71-92.

The southern part of the Cretaceous Kohistan island arc is made up of amphibolites and a variety of other rocks. These constitute a more than 350 km long belt extending from eastern Afghanistan to Nanga Parbat. The amphibolites can be divided into banded and non-banded varieties. Despite a minor quantity of associated metasediments, the banded amphibolites are not metasedimentary themselves; they were derived from volcanic and plutonic precursors, whereas the non-banded amphibolites are after plutonic rocks. In addition to being relict, banding was produced by shear deformation, lit-per-lit injection of trondhjemitic material and possibly, other processes discussed in the paper. The amphibolites consist essentially of hornblende, intermediate plagioclase and/or epidote ± quartz. Almandine-rich garnet developed preferentially in rocks with low Mg/Fe ratios and diopside-salite in those with high CaO. Metamorphism took place before late Cretaceous at 550-680 °C 4.5-6.5 kbar p_{H2O}. Locally, however, higher PT conditions operated and the two minerals grew more abundantly over a wider range of rock composition. Metamorphic conditions were locally suitable for extraction of trondhjemitic and granitic melts from the amphibolites. The chemical characteristics of the amphibolites are similar to volcanic rocks found in island arcs and most of the analyses apparently support affinity with the calc-alkaline series.

J/68. Jan, M.Q., 1991. High-P metamorphic rocks from the Himalaya and their tectonic implication - a review. *Physics and Chemistry of the Earth* 18, 329-343.

The suture zones bordering the Indian subcontinent on the E, N and W are characterized in several places by the occurrence of ophiolitic complexes and tectonic melanges. High-P metamorphic rocks have recently been discovered in the melanges in Burma, Naga Hills, southern Tibet, eastern and western Ladakh, Kohistan (Jijal, Allai, Shangla) and Khost (Afghanistan). The development of these rocks has an important bearing on the plate tectonics of the Himalaya.

The High-P metamorphic rocks belong to prehnite-pumpellyite, blueschist and high-P greenschist facies but extensive garnet-granulites have developed at 35 km depth in Jijal. In the Indus-Zangbo suture zone (IZS) the high-P metamorphism is complemented to the N by low- or medium-P metamorphism and calc-alkaline magmatism in Tibet, Ladakh as well as Kohistan. High-P metamorphism in Jijal has been dated at 104 Ma, in Shangla at 70-100 Ma and in western Ladakh during mid-Cretaceous. Elsewhere, the timing of the high-P metamorphism is not known but a Cretaceous age is inferred. Since collision along the IZS occurred during Eocene, the high-P metamorphism is therefore related to the northwards subduction of the neo-Tethyan lithosphere under Tibet or late Mesozoic magmatic arcs. The timing of high-P metamorphism coincides with the breakup of India from Gondwanaland and its rapid northwards movement, whereas the tectonic melanges may principally have formed during Eocene collision and obduction.

J/69. Jan. M.Q., 1992. Highly aluminous hornblende-cummingtonite coronas in gabbro-norites of the southern amphibolite belt, Kohistan. *Geological Bulletin, University of Peshawar* 25, 127-131.

The gabbro-norites of the Chilas complex and southern amphibolites belt locally contain thin (<0.2 mm) amphibole coronas around pyroxene. These consist of an inner shell of fibrous, colourless to pale cummingtonite, and an outer shell of bluish green aluminosilicate, with or without a discrete growth of epidote + vermicular quartz on the edges of the plagioclase. The coronas represent the initial stage of amphibolite facies metamorphism, which prevailed in the southern part of the Kohistan arc during mid Cretaceous. The tschermakite, with 19.2 % Al_2O_3 , is one of the most aluminous calcic amphiboles thus far reported. The primary amphibole in the gabbro-norites is brown ferroan pargasite containing much higher Ti and K than the coronitic tschermakite.

J/71. Jan, M.Q., 1998. 13th Himalaya-Karakoram-Tibet International Workshop (Conference Report). Episodes 21, p.106.

This workshop was held at the National Centre of Excellence in Geology, University of Peshawar from April 20-22,1998. It was convened by M. A. Khan and M. Q. Jan, and was attended by more than 160 participants, 89 of them from 13 countries outside Pakistan. The workshop consisted of two field excursions and paper presentation.

The workshop was preceded by a field excursion (April 17-19) to the sedimentary sequence of the Himalayan foothills, covering the Islamabad-Salt Range-Kohat-Peshawar section.

The workshop was followed by a week-long excursion along the KKH (April 23-29). The KKH joins China with Pakistan and follows the course of the Hunza and Indus rivers before splitting at Besham into a westerly branch (passing through Swat to Peshawar and an easterly branch (through Hazara to Islamabad). The excursion followed the westerly route on the way up and ended in Islamabad via Hazara. This trip provides a wonderful opportunity of examining a section across the NW Himalaya, Kohistan arc, and central Karakoram and the suture zones between them. Unfortunately, due to unexpected rain storm and landslides, the trip was terminated at the Shyok Suture southwest of Hunza and not much of the Karakoram section could be examined. Each of the 70 participants was supplied a 131 -page field guide edited by R D Lawrence and M A Khan.

There was a brief inaugural session chaired by RAK Tahirkheli, It consisted of introductory remarks, note of thanks, and a summary of the major contributions to the geology of the Himalaya-Karakoram region of Pakistan during the last 50 years by the Chief Guest (S H Gauhar, Geol. Surv. Pakistan).

Technical papers consisted of over 50 poster; and 80 oral presentations, covering eleven sessions:

- 1) NW Himalaya (Chairman: M P Searle, UK).
- 2) Karakoram and Hindukush (M Gaetani, Italy),
- 3) Suture zones and ophiolites (J P Burg, Switzerland),
- 4) Western Himalaya (J DiPietro, LISA),
- 5) Central Himalaya (B Grasemann, Austria).
- 6) Eastern Himalaya and Tibet (K Arita, Japan),
- 7) Tibet (Xian: Xuchang, China).
- 8) Foreland basins (V C Thakur, India),
- 9) Kohistan (P Le Fort, France),

10) Neotectonics and Quaternary (E Appel. Germany),

J/72. Jan, M.Q., Ahmad, I. & DiPietro, J.A., 1999. Mineralogy of a carbonatite-related fenite in Lower Swat, Northern Pakistan. Geological Bulletin, University of Peshawar 32, 71-75.

The Precambrian-Cambrian Manglaur formation contains several small bodies of carbonatite and fenite to the SE of Mingora. Their composition and close association with late Paleozoic granitic rocks is similar to these of the Naranji Kandao area in Buner. The entire suite may be related to Late Paleozoic rifting. The carbonatite is sugary sovite comprising calcite and clinopyroxene, with minor amounts of primary (?) clinozoisite, cancrinite- vishevite, apatite, sphene, opaques and zircon. The fenite consists of pure albite (abundant) calcite, biotite with > 3 % MgO and minor magnetite.

J/73. Jan, M.Q. & Arif, M., 1996. Chemistry of chromite in the ophiolite complexes of Pakistan. Abstracts, 30th International Geological Congress, Beijing, p.662.

The northwestern boundary of the Indian plate in Pakistan is demarcated by a series of ophiolitic complexes and, locally, high-pressure rocks. The Indus suture in northern Pakistan contains, from east to west, Sapat, Jijal, Shangla, and Skhakot-Qila complexes, of which the latter two occur in tectonic melange zones. In addition, a lopolithic body of mafic-ultramafic rocks – the Chilas complex - also occurs in a Cretaceous magmatic arc to the north of the Indus suture. The suture on the western margin of the Indian plate contains, from north to south, the Waziristan, Zhob valley and Bela ophiolites, the latter extending for about 400 km from the coast of the Arabian sea northwards. These three are examples of megamelanges; in Bela, blocks measuring more than 100 km have been reported. The tectonic settings of these complexes have been the subject debate, mainly because of a lack of sufficient geological data.

Ultramafic and mafic plutonic rocks, ranging from residual peridotites to cumulate peridotites and gabbros, constitute large parts of these complexes. Disseminated and segregated chromite (in some economically exploitable) occurs in these complexes, and displays field and textural features similar to those reported from other parts of the world. Chemical data on composition of the chromite is available from all the eight occurrences. On the basis of chromium number [$Cr \# = 100Cr/(Cr+A1)$], the complexes can be divided into three groups: (1) the Sapat, Jijal and Waziristan complexes contain high Cr chromites with $Cr \# > 60$; (2) the Shangla, Skhakot-Qila, Zhob and Bela rocks contain chromite which displays a wide range of composition with $Cr \#$ varying from 15 to 90; and (3) rocks of the Chilas complex are characterized by low Cr chromites ($Cr \# < 65$). The petrogenetic importance of chromite chemistry has been discussed by several authors. It is interesting to note that the chromite compositions from Pakistan appear to indicate different tectonic settings for the origin of the complexes under consideration. Those with high Cr chromite have been regarded to represent island arc type origin. Opinion differs on the origin of group (2) chromite-bearing complexes; they may well be of complex origin with components which originated in different tectonic settings. The Chilas complex of group (3) containing low Cr chromite has been considered to have formed in a rift-related set up (intra-arc rifting or back arc basin). The present compilation lays emphasis on the importance of detailed mineral-chemical data to understanding the petrogenesis of ophiolite complexes.

J/76. Jan, M.Q. & Asif, M., 1981. A speculative tectonic model for the evolution of NW Himalaya and Karakoram. Geological Bulletin, University of Peshawar 14, 199-201.

The Himalaya are commonly considered to be the product of collision between the Asiatic and Indo-Pakistan plates. A number of plate tectonic models have recently been proposed for the NW Himalayas. Tahirkheli et al. (1979), Klootwijk et al. (1979), and Viridi (1981) suggested the formation of Kohistan Ladakh Island arc between the two plates. Coward et al. (in press, 1982) found that the structure of the Kohistan zone is much complex for such a simple interpretation. Complicated models, involving north- and south- facing subduction zones have been envisaged by Andrews-Speed and Brookfield (1982) and Windley (pers. Comm.).

We present here a model supported by new radiometric ages. The major sequence of events during the evolution of NW Himalaya and Karakoram of Pakistan and Kashmir is tentatively proposed here to be as follow:

Early to Mid Cretaceous: N-facing subduction of the Neo-Tethyan oceanic crust to produce volcanic and plutonic rocks (Dras, Chalt, Shyoke, Kohistan amphibolites) resulting in the formation of the Kohistan – Ladakh Island arc.

Late Cretaceous: Intrusion of the Chilas, Jijal, Kargil basic complex(es); and development of blueschists.

Paleocene to very Early Eocene: Collision of the Island arc with India (Powell, 1979); obduction of ophiolites and blueschist; simultaneous N- and S- facing subduction of the oceanic crust intervening between a Gondwanic microcontinent and the Island arc to produce the earlier phases in the Karakoram- and Kohistan-Ladakh granitic belts, regional metamorphism. Eocene to Early Miocene: Eruption of Eocene Kalam volcanic; younger intrusions (some derived from continental crustal material?) in the two granitic belts (Jan et al., 1981). Post-Early Miocene: Crustal thickening and production of the youngest granitic rocks in the Karakoram belt. The tectonic position of the Khunjerab-Tirich Mir granitic belt (115-84 m. y.) is not clear to us. These rocks might be a product of N-facing subduction N of the microcontinent (? Reshun Fault or Chitral- Upper Hunza Fault of Desio, 1979, however no ophiolitic rocks have so far been found in this area. An alternative of this is to think that the granites are of Late Cimmerian tectonic phase (Desio, 1979), related to Wakhan and Pamir granites and produced by a S- facing subduction zone further north.

Key words: Tectonics, evolution, Himalaya.

J/77. Jan, M.Q. & Asif, M. 1983. Geochemistry of tonalites and quartz diorites of the Kohistan-Ladakh (Trans Himalayan) granitic belt in Swat, N. Pakistan. In: Sham F.A. (ed.), Granites of Himalayan, Karakorum and Hindu Kush. Institute of Geology, Punjab University, Lahore, 355-376.

The Transhimalayan Kohistan-Ladakh granitic belt in the Swat district, NW Pakistan, is mostly represented by plutons of intermediate composition; granites are less abundant while basic bodies are rare. This paper presents a brief account of the petrography and a detailed discussion of the geochemistry of 38 tonalites, (quartz) diorites and related rocks, analysed for up to 25 elements. The chemistry suggests that the rocks are principally calc-alkaline in nature, many of those having island arc affinities. However, chemical variation for some elements is considerable and erratic. It is concluded that the rocks are the product of independent pulses of magma, generated by partial melting of subducted crust or the overlying upper mantle wedge over a long period from Middle Cretaceous to post-Eocene.

J/78. Jan, M.Q., Asif, M. & Tahirkheli, T., 1981. The geology and petrography of the Tarbela “alkaline” complex. Geological Bulletin, University of Peshawar 14, 1-28.

The Tarbela complex comprises gabbroic rocks (oldest), dolerites, melteigites, albitites, normal and sodic granites, albite-carbonate rocks / breccia, and carbonatites (youngest), together covering an area of about 4 sq. km. The rocks have been intruded along a fault zone between the Salkhala and Tanawal formation. Some of the gabbroic intrusions display in situ differentiation with one intrusion grading from pyroxenitic outer margin in leucogabbroic/dioritic interior with a core of intrusive albitites.

Amongst typical alkaline minerals, sodic pyroxenes are restricted to the sodic granite, and nepheline to the melteigite. However, trace elements in albite-carbonate rocks, the high quantity of albite $\pm$ carbonate along with consistent presence of zircon, and rutile / sphene in most albitites are indicative of their alkaline affinity. The gabbroic rocks might also be alkaline, as suggested by the abundance of amphiboles (hornblende, kaersutite, hastingsite), low An-content of plagioclase, clinopyroxene composition, the general absence of primary quartz and the possibly high Ti-content reflected in amphibole, sphene and ilmenite. These observations, coupled with the close field association point towards an overall alkaline nature of the complex. The rocks show a considerable degree of alteration (autometasomatism) with widespread development of scapolite, carbonate, amphibole, mica, sphene, rutile, etc. The country rocks have been metasomatised in the vicinity of the intrusion and scapolite, albite, carbonate, ? quartz, pyrite have been produced. Some of the albitized sedimentary rocks resemble adinoles. This paper presents a detailed account of the petrography of the complex together with optical details of the minerals and a geological map. The petrogenesis of the complex is yet not clearly understood and hypothetical schemes based on differentiation under variable PCO₂ and liquid immiscibility are presented.

J/79. Jan, M.Q., Asif, M., Tahirkheli, T. & Kamal, M. 1981. Tectonic subdivision of granitic rocks of north Pakistan. Geological Bulletin, University of Peshawar 14, 159-182.

The granitic rocks of north Pakistan can be divided into five types on the basis of available radiometric, petrographic, geochemical, tectonic and geographic data. (The granitic gneisses in the Nanga Parbat, Mansehra, and Swat areas are Late Precambrian (?) to Cambrian, S-type and possibly related to the Pan-African orogeny. The peralkaline to alkaline granites of Tarbela, Shewa-Shahbazgarhi, Ambela, Malakand proper, and Warsak were originated in extensional environments (rift / graben-related) during Eocene (50 to 40 m. y. ago). Dominantly calc-alkaline, Cretaceous-Tertiary granitic rocks constitute three, several hundred kilometer long belts in the Himalaya-Karakoram-Hindukush region.

The Khunjerab-Tirich Mir belt is the oldest (~ 115 to 86 m. y.) of the three and produced in continental margin environment in response to the subduction of the Paleotethys during the Cretaceous. Radiometric ages in the Karakoram granitic belt (continental margin) ranges from 65 to 5 m. y. whilst those in the Ladakh-Kohistan granitic belt (continental margin or island arc) from 63 to 19 m.y. It is possible that both these belts are a product of simultaneous subduction along the MMT and (?) MKT. It is likely that the more basic plutons in these two belts were produced by the partial melting of a predominantly oceanic crust, whilst in the rest of the rocks of the two belts both oceanic and continental crust contributed to the magma formation.

Key words: Tectonics, granitic rocks, Himalaya, Karakoram, Hindukush.

J/80. Jan, M.Q., Banaras, M., Ghani, A. & Asif, M. 1983. The Tora Tigger ultramafic complex, southern Dir District. Geological Bulletin, University of Peshawar 16, 11-29.

The ultramafic rocks of Tora Tigger near Munda are emplaced in amphibolites of the Kohistan tectonic zone along the Main Mantle Thrust. The amphibolites are represented by metamorphosed gabbros and norites of the Chilas layered complex, and garnet-bearing mafic to intermediate plutons. The ultramafic include dunites and a variety of peridotites, pyroxenites, and hornblendites. The hornblendites are the most abundant of these, are coarse-grained to pegmatite, and contain deformed felsic dykes and veins. The origin

of the olivine- and pyroxene ultramafics is not clear; they might be alpine-type or, more probably, cumulates of the Chilas complex and related to the metamorphosed gabbros and norites. Field relations and textural features suggest that the hornblendites have formed by metasomatism of the various rocks in the area.

Key words: Ultramafic complexes, Tora Tigga, MMT.

J/81. Jan, M.Q., Colback, P.S.B. & Ahmad, M. 1985. Low-temperature secondary minerals from Tarbela. *Geological Bulletin, University of Peshawar* 18, 189-197.

Several types of sulfates and other minerals, believed to have formed at low temperatures, were found in a remedial excavation site overlooking Tunnel 3 and 4 on the right bank of the Tarbela Dam. Identified with the help of optical properties, XRD and chemical analyses, these include gypsum, pickeringite, potassium alum, hydrated iron sulphate, epsomite, locontite, natroalunite, buntite, halloysite, (?) leonite and (?) starkeyite. Optical and chemical data for most of the samples studied are presented in the paper. The sulphates are thought to have formed in connection with the weathering and alteration of pyrite commonly present in the metasediments of the host Salkhala formation. The huntite has formed by the action of ground water on dolomitic rocks, or gabbros and pyroxene / hornblende peridotites, and the halloysite from alkali feldspar-rich intrusive rocks of the Tarbela "alkaline" complex compressive phases. It seems more plausible that the two sets of fractures and faults represent a conjugate set of wrench faults with a maximum stress axis of roughly E-W orientation. This also coincides with the orientation suggested by the folding (Durrani, 1980). I would like to bring the author's attention to the fact that the major faults also show a substantial amount of dip slip (normal) component (Durrani, 1980). This normal component of the faults and the gentle nature of the folds suggest that the compressional phase responsible for the folding and presumably coeval wrench faults was followed by a tensional phase. This tensional phase caused reactivation of earlier faults, now with dip slip movements, and was also responsible for the gentleness (partial unfolding) of early tighter folds. Discordance of the strike of the strata (N-S trend from the rest of the axial belt (roughly NE-SW trend) suggests that these tensional structures are probably related to some sort of rotation of the Indian craton causing subsequently tensional regime. In the light of above it is suggested that the tectonic history of the Dilband area occurred in following steps:

Folding and faulting due to compression (E-W trend).

Reactivation and dip-slip movements of the pre-existing faults and flattening of the original tighter folds due to tensional forces.

The fluorspar deposits are lacking elsewhere, including the type locality of the Chiltan Limestone (near Quetta). It seems that fluorspar deposits formed by late stage hydrothermal activity (Schcheglov, 1969), more likely in a tensional regime. Further study on the morphology and petrology of veins and, especially, new techniques in the field of fluid inclusions have substantial scope to determine the genesis of fluorspar deposits of Dilband area.

J/82. Jan, M.Q. & Howie, R.A., 1980. Ortho- and clinopyroxenes from pyroxene granulites of Swat Kohistan, northern Pakistan. *Mineralogical Magazine* 43, 715-726.

This paper presents wet chemical analyses of forty-one pyroxenes (thirty-nine of them new) from pyroxene granulites and a few neighbouring rocks from Swat Kohistan and the adjoining Indus Valley. The granulites, considered to be derived from plutonic norites of an island arc tholeiitic nature, constitute one of the most extensive belts of its kind in the world. The pyroxenes are not unusual in any respect but they bear a closer resemblance to metamorphic than to igneous pyroxenes crystallized from deep-seated tholeiitic magmas. The distribution of Mg, Fe, and Mn (average $K^{MgFe}_D = 0.57$) and the tie-line intersections on the Wo-En join (generally from Wso.5 to Wov6.5) between the coexisting eighteen pyroxene pairs from the granulites are discussed. Based on eight different methods of geothermometry and other considerations, it is concluded that the pyroxene granulites were metamorphosed at around 800 °C and 7 to 8 kbar.

Key words: Pyroxene granulite, Swat Kohistan.

J/83. Jan, M.Q. & Howie, R.A., 1981a. The mineralogy and geochemistry of the metamorphosed basic and ultrabasic rocks of the Jijal complex, Kohistan, NW Pakistan. *Journal of Petrology* 22, 85-126.

The Jijal complex, covering more than 150 sq. km in the extreme north of Pakistan, is a tectonic wedge of garnet granulites intruded in the south by a 10×4 km slab of ultramafic rocks. The granulites are divisible into plagioclase-bearing (basic to intermediate) and plagioclase-free (ultrabasic to basic) types, the two types reflecting differences in bulk chemistry. Garnet + plagioclase + clinopyroxene + quartz + rutile $\pm$ hornblende $\pm$ epidote is the most common assemblage. The plagioclase-free rocks are composed mainly of two or three of the minerals garnet, amphibole, clinopyroxene and epidote. Orthopyroxene occurs in websteritic rocks devoid of epidote. Much of the amphibole and some epidote appear to be prograde products. Although variation diagrams do not reveal a genetic link between the two types of granulite, it is considered that they are comagmatic rather than the products of two or more unrelated magmas. The compositions of garnet ($\text{Py}_{28-46} \text{Alm}_{27-43} \text{Gro}_{16-28}$), clinopyroxene ($\text{Mg}_{44-34} \text{Fe}_{5-17} \text{Ca}_{51-49}$, Al_2O_3 3.0–9.9 per cent), orthopyroxene (with up to 5.5 per cent Al_2O_3), amphibole (with up to 16.3 per cent Al_2O_3 and high $\text{Al}^{\text{vi}}/\text{Al}^{\text{iv}}$), and the abundance of garnet suggest a high-pressure origin for the granulites. The rocks appear to have differentiated from a tholeiitic magma of oceanic affinity or they may be genetically related to the pyroxene granulites of Swat considered to have originally crystallized from a calc-alkaline magma of island arc or continental margin affinity. They probably crystallized in the ancient Tethyan crust/upper mantle (or less likely in a continental margin), later to be metamorphosed to granulites (670–790 °C, 12–14 kb) during the collision of the Indian-Asian landmasses, and carried upwards during later Himalayan orogenic episodes. The ultramafic rocks are alpine-type in nature and devoid of garnet. They are dominated by diopsidites; dunites, peridotites, and harzburgites together form <50 per cent of the area of outcrop. The chemistry of the rocks, and their olivines (Fo_{92-89}) and clinopyroxenes ($\text{Mg}_{49.5-48} \text{Fe}_{2.8-5.2} \text{Ca}_{47.4-46.8}$) are similar to those of alpine complexes of the harzburgite subtype. It is not clear whether they represent a faulted slab of suboceanic crust/upper mantle, mantle diapirs in deep orogenic roots, or dismembered ultramafic rocks differentiated from a basaltic magma. They seem to have a complex history; their present mineralogy is suggestive of high grade metamorphism (800–850 °C, 8–12 kb). They are magmatically unrelated to the garnet granulites and were probably intruded into the latter as plastic crystalline material after both had been independently metamorphosed, but before the entire complex was carried tectonically into its present surroundings. The abundances of the diopsidites is in marked contrast to other alpine-type complexes and the possibility of Ca and Si metasomatism during or before their metamorphism should not be totally ruled out.

J/84. Jan, M.Q. & Howie, R.A., 1981b. Petrology of minor olivine gabbros and ultramafic rocks from upper Swat, N.W. Pakistan. *Geological Bulletin, University of Punjab* 16, 1-10.

Small bodies of ultramafic and olivine gabbroic rocks have been reported from a number of places in the amphiboles and pyroxene granulites of Swat. Most of these rocks are inconsistent in texture, mineralogy, chemistry and the extent of metamorphism. They have probably been emplaced at different times and do not seem to be directly related mutually or to their host rocks. As an illustration, the petrography and chemistry of two olivine gabbros, two pyroxenites, one bahiaite, and a two-pyroxene-two amphibole-olivine-plagioclase-spinel rocks is presented, together with comments on the relationship between various rock types of the area.

J/85. Jan, M.Q. & Howie, R.A., 1982. Hornblendic amphiboles from basic and intermediate rocks of Swat-Kohistan, northwest Pakistan. *American Mineralogist* 67, 1155-1178.

Chemical analyses for 21 elements together with physical data are presented for 38 amphiboles (34 of them new) from garnet granulites, pyroxene granulites, amphibolites, and quartz diorites constituting the southern half of the Kohistan Cretaceous-early Tertiary arc. The metamorphic hornblendes are rich in alumina and some of them have high Al^{vi}/Al^{iv} ratios. The influence of metamorphic conditions is not important except on A-site occupancy and, possibly, on Ti and Mn contents. Refractive indices, birefringence, and density display a systematic increase (and 2V a decrease) with decrease in the ratio $(Mg + Al^{vi})/(Mg + Al^{iv} + Al^{vi} + Ti + Fe^{3+}) + Fe^{2+} + Mn$. Pleochroic colors and amount of absorption are controlled by Fe^{3+} , Ti, Fe^{2+}/Ti , and Mg/Fe^{2+} , while Z:c appears to increase with $Fe^{3+} + Ca$.--Modified journal abstract.

Key words: Amphiboles, basic rocks, Intermediate rocks, Swat Kohistan.

J/86. Jan, M.Q. & Howie, R.A., 1987. Some garnets, epidotes, biotite, micas and feldspars from the southern part of Kohistan, NW Pakistan. *Acta Mineralogica Pakistanica* 3, 5-25.

Partial or complete analyses of 52 mineral (with trace elements for 22) from amphibolitic rocks, mafic granulites and quartz diorites are presented. Garnet development in the amphibolite belt is sporadic and controlled by bulk chemistry, especially low Mg/Fe, but in Lilauni area of the amphibolite belt and in the garnet granulites of Jijal, abundant garnet has developed in response to high pressures. The amphibolite facies garnets are distinctly richer in almandine+spessartine and poorer in pyrope and grossular components as compared to the high-pressure granulite. The epidote is mostly monoclinic with Ps content ranging from 0 to 32-mole %. Epidote composition is controlled by the Fe^{3+}/Al ratios of the environment and by fO_2 but other factors might also exert some influence. No obvious difference is seen in the epidote compositions from the amphibolites and Jijal granulites.

The biotites in granulites generally have higher Ti, and lower Mn, Al and Na than those in amphibolites and diorites, which are considered to have equilibrated at lower temperatures than the granulites. Four of the biotites are altered to varying extent and show a loss in K (and Si) and gain in H_2O and to a lesser extent, in Ca. The feldspar analyses in some cases have excess Si and Al over Ca and alkalis. The plagioclase in a calc-silicate rock within the amphibolite terrain is albitic, it's abnormally low An content reflecting the peculiar bulk chemical and mineralogical composition of this rock.

Key words: Garnets, epidotes, biotite, micas, feldspars, Kohistan.

J/87. Jan, M.Q. & Jabeen, N., 1990. A review of mafic-ultramafic plutonic complexes in the Indus suture zone of Pakistan. *Physics and Chemistry of the Earth* 17, 93-117.

Several small to large bodies of mafic-ultramafic rocks have recently been studied in the Indus Suture Zone of Northern Pakistan. These occur in tectonic melanges along the suture, as klippe over-riding the Indian plate, and as cumulate/intrusive bodies in the Kohistan arc sequence. In this paper we present the salient petrological features of six well studied and prominent complexes. The Jijal (granulite), Chilas and Tora Tiggia complexes are closely associated with rocks of the Kohistan arc and have petrographic and chemical features similar to plutonic rocks from deeper levels of island arcs. The Jijal, Dargai, Shangla and Allai ultramafic bodies are found along the Indus suture. The Shangla serpentinized peridotites and Dargai klippe represent segments of the Neotethyan oceanic crust/upper mantle. The Jijal and Allai Kohistan dunite-peridotite-diopside association appears to have complex origin.

Key words: Mafic-ultramafic complexes, Indus suture.

J/88. Jan, M.Q., Kamal, M. & Khan, M.I. 1979. Tectonic control over emerald mineralization in Swat. *Geological Bulletin, University of Peshawar* 14, 101-109.

Emerald and chromian tourmaline occur in carbonate-talc / serpentine / chlorite rocks, carbonate-bearing talc schists, and associated quartz veins near Mingora, Charbagh, and Shangla. The rocks are altered ultramafics found in a discontinuous belt of volcanic, volcano-sedimentary, and sedimentary rocks that have undergone high P – low T metamorphism. The belt is a thrust slice overlying Gondwanic sialic metasediments and underlying the Kohistan (? oceanic) amphibolites both of which display Barrovian

metamorphism in the almandine amphibolite facies. It appears that the emerald-bearing belt represents a marginal basin or trench rocks of (?) Mesozoic age with tectonically incorporated lenses of ultramafic rocks from the upper mantle.

J/89. Jan, M.Q., Kamal, M. & Qureshi, A.A., 1981. Petrography of the Loe Shilman carbonatite complex, Khyber Agency. Geological Bulletin, University of Peshawar 14, 29-43.

The Shilman complex comprises sill-form bodies emplaced along a fault zone in Palaeozoic to Precambrian metasedimentary rocks. The largest outcrop is 2.5 Km long with a width of 170m in the central part. The rock-type of the complex include altered (meta) gabbros / dolerite, followed by amphibole-apatite-, biotite / phlogopite-, and dolomitic carbonatites, syenites and lamprophyric rocks, and Fe-rich hydrothermal veins. The syenitic rocks have locally been intruded and brecciated by light-coloured sovitic veins. It is suggested that the basic rocks might be related to the rest of the complex.

The country rocks (slates, phyllites, mica schist, recrystallized limestone and quartzite) have been regionally metamorphosed up to the biotite zone of Barrovian. They display, locally, considerable fenitization with development of alkali pyroboles, phlogopite and alkali feldspars. The complex is westward extension of the over 200km arcuate belt of alkaline complexes found around the northern half of the Peshawar plain and intruded during Early Tertiary along faults resulting due to the collision of the Indo-Pak plate with Eurasia.

J/90. Jan, M.Q. & Karim, A., 1990a. Continental magmatism related to Late Paleozoic-Early Mesozoic rifting in northern Pakistan and Kashmir. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 22-23.

For details consult the following account.

Key words: Continental magmatism, Paleozoic, Mesozoic, rifting, northern Pakistan, Kashmir.

J/91. Jan, M.Q. & Karim, A., 1990b. Continental magmatism related to Late Paleozoic-Early Mesozoic rifting in northern Pakistan and Kashmir Geological Bulletin, University of Peshawar 23, 1-25.

During the Late Paleozoic and very Early Mesozoic, three groups of igneous rocks originated in the present day northwestern part of the Indo-Pakistani subcontinental landmass: 1) The Peshawar plain alkaline igneous province (PAIP), 2) The Panjal volcanics and associated intrusive rocks of Kashmir and Kaghan, and 3) The dolerite dykes in Peshawar, Hazara and Kashmir regions. The PAIP comprises the Tarbela complex (gabbros, albitites, granites), the batholithic Ambela granitic complex (AGC: granites, syenites, carbonatite, dolerites), the Shewa-Shahbazgarhi and the Warsak granites (some alkaline), gabbros and dolerite, the Malakand granite, and the carbonatite complexes of Sillai Patti (Malakand) and Loe Shilman (Khyber). The Panjal volcanics consist of flows (basalt, andesite, rhyolite and alkaline types), agglomerates and tuffs, dolerites, gabbros and norites. The Panjal igneous activity spans from Carboniferous to Triassic, but it were most extensive and voluminous during Permian. Dolerite dykes of the Peshawar, Hazara and Kashmir regions are quartz-hypersthene normative in character and have a Permian stratigraphic age.

Reliable age data are lacking for most of the PAIP, but the Koga alkaline rocks within the AGC have Rb-Sr isochron ages of 297-315 Ma, the U-Pb systematics of zircon in the Malakand granite suggest a Carboniferous age, and the Shahbazgarhi porphyries have a Carboniferous stratigraphic age. The Panjal volcanics and the dolerite dykes have similar (essentially Permo-Carboniferous) stratigraphic ages. Based on the available geochemical data in combination with the ages of the three groups of rocks, it is suggested that the present day northwestern margin of the Indo-Pakistani landmass experienced a major episode of swelling and rifting, with associated magmatism which culminated during Late Carboniferous to Early Triassic.

J/92. Jan, M.Q. & Karim, A., 1992. High-pressure veins in corona gabbros of Khwaza Khela Kohistan. *Geological Bulletin, University of Peshawar* 25, 47-50.

Gabbroic rocks of Khwaza Khela in the southern amphibolite belt of the Kohistan island arc preserve a record of thermal history from magmatic crystallization to high-pressure vein formation. The rocks formed from arc-related magma at about 1000 °C, 3-4kb, probably during the Early Cretaceous, subsequently calcic plagioclase and olivine reacted to form orthopyroxene + clinopyroxene + spinel ± tschermakite coronas at 800 °C, 6-8kb. The corona formation may have occurred in the early stages of the closure of the arc with the Karakoram plate (~ 95-102 Ma ago). Finally the rocks were subjected to high-pressure metamorphism, which is reflected in thin quartzofeldspathic veins containing garnet, zoisite, paragonite and kyanite were formed at 500-600°C, 10-12 kb. This paper presents petrography of these rocks and discusses the tectonic implications of the coronas and high-pressure veins, which developed in response to cooling and crustal thickening.

Key words: Gabbros, amphibolite belt, Khwaza Khela, Kohistan.

J/93. Jan, M.Q. & Karim, A., 1994. Crustal thickening observed through Coronas and high-P veins in metagabbros of Kohistan island arc, N. Pakistan. *Journal of Nepal Geological Society* 10, Abstract Volume, 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu, Nepal, 70.

The southern margin of the E-W trending Kohistan magmatic arc in the NW Himalaya-Karakoram ranges is made up of amphibolites and a variety of other lithologies ranging from peridotite to granite. The amphibolites are derived from volcanic and plutonic rocks of Early Cretaceous age. Gabbroic relics in the amphibolites are common both in Swat and Indus valleys. They display calc-alkaline character and their mineralogy is similar to low-pressure island arc plutonic rocks. During cooling and crustal thickening, olivine and anorthite in the gabbroic relics near Khwaza Khela (Swat) reacted to produce coronas consisting of two pyroxenes+pleonaste+tschermakitic hornblende at about 800°C, 5.5-7.5 kbar. Later these rocks were locally traversed by veins containing high-P assemblages: garnet, kyanite, zoisite, paragonite, corundum, chlorite, plagioclase and quartz. These formed in the range of 510-600°C, 10-12 kbar, either due to India-Kohistan collision in Eocene or earlier. This paper presents microprobe data on the minerals and discusses the tectonic implications of the coronitic and vein assemblages in the gabbros, which appear to have formed during cooling and crustal thickening.

Key words: High-P veins, metagabbros, Kohistan island arc.

J/94. Jan, M.Q. & Karim, A., 1995. Coronas and high-P veins in metagabbros of the Kohistan island arc, northern Pakistan: evidence for crustal thickening during cooling. *Journal of Metamorphic Geology* 13, 357-366.

The E-W-trending Kohistan terrane in the NW Himalaya is a sandwich of a magmatic arc between the collided Karakoram (Asian) and Indian plates. The southern part of the Kohistan arc is principally made up of amphibolites derived from volcanic and plutonic rocks of Early Cretaceous age. Gabbroic relics in the amphibolites display calc-alkaline character, and their mineralogy is similar to low-P plutonic rocks reported from modern and ancient island arcs. The largest of these relics, occurring along the southern margin of the amphibolite belt near Khwaza Khela, is subcircular in outline and is about 1 km across. It consists of cumulate gabbros and related rocks displaying a record of cooling and crustal thickening. Primary olivine and anorthite reacted to produce coronas consisting of two pyroxenes +Mg-Fe²⁺-Al spinel ± tschermakitic hornblende at about 800° C, 5.5–7.5 kbar. This thermotectonic event is of regional extent and may be related to the overthrusting of the Karakoram plate onto the Kohistan arc some 85 Ma ago, or even earlier. Later the gabbros were locally traversed by veins containing high-P assemblages: garnet, kyanite, zoisite, paragonite, oligoclase, calcite, scapolite and quartz ° Chlorite ° Corundum ± diopside. Formed in the range 510–600° C, and 10–12 kbar, these suggest further thickening and cooling of the crust

before its uplift during the Tertiary. This paper presents microprobe data on the minerals, and discusses the tectonic implications of the coronitic and vein assemblages in the gabbros.

J/95. Jan, M.Q. & Kempe, D.R.C., 1970a. Recent researches in the geology of Northwest West Pakistan. Geological Bulletin, University of Peshawar 5, 62-89.

The northwest part of the West Pakistan has seen detailed geological investigation in several areas during the past ten years. In this paper, an attempt has been made to give a brief account of the research work (much of which has already been published) carried out in Peshawar and Malakand Divisions, and Gilgit Agency since 1974. A summary of economic investigations is given and a detailed account of the bibliography has been presented in the end to provide an easy source of references for future workers.

The important conclusion that the authors have reached from this work is that many of the more or less regionally metamorphosed rocks, previously considered Precambrian, are mainly Siluro-Devonian, to a lesser extent, Carboniferous in age, with a relative abundance of reef complexes. Many of these rocks were intruded by various types of igneous (mainly granites), mostly during the Late Cretaceous and Early Tertiary periods.

J/97. Jan, M.Q. & Kempe, D.R.C., 1973. The petrology of the basic and intermediate rocks of Upper Swat, Pakistan. Geological Magazine 110, 285-300.

A series of metamorphosed (amphibolite facies) basic and intermediate igneous rocks from upper Swat, Pakistan, is described, with seven chemical analyses. The rocks intrude Palaeozoic metasediments and are partially bordered by other, later, intrusive and volcanic rocks. The group, now represented by, from S-N, epidote amphibolites, amphibolites, noritic and hypersthene gabbros, and quartz diorites, is considered to be derived from a series of plagioclase hypersthene, norites, hypersthene gabbros, and hypersthene diorites. Variation diagrams are used to show that the series forms a differentiated sequence; FMA and lime-alkali diagrams suggest that it is similar to the rocks of the Garabal Hill-Loch Fyne area of Scotland. Some of the mineralogy of the group is briefly discussed, with five chemical analyses. A K/Ar age determination gives 67 Ma; thus the rocks probably derive from an early Himalayan (Alpine) tholeiitic basalt magma.

J/98. Jan, M.Q., Kempe, D.R.C & Symes, R.F., 1971. A green chrome-tourmaline from Swat, West Pakistan. Abstracts, 23rd Pakistan Science Conference, Peshawar, p.3.

Traces of a green, chrome-tourmaline occur in calcareous rock in contact with serpentinite, near Alpurai, Swat. The mineral is thought to be produced by silica-rich hydrothermal solutions, which have crystallized as thin quartz veins in the calcareous rocks. The petrography of the rock, and the optical properties of tourmaline along with its chemistry paragenesis and comparison with other such tourmaline occurrences is presented. Beside other constituents the Alpurai tourmaline has about 7.3 per cent Cr₂O₃ and 0.2 per cent V₂O₃ as revealed by electron microprobe analysis.

Key words: Tourmaline, Swat.

J/99. Jan, M.Q., Kempe, D.R.C & Symes, R.F., 1972. A green chromian tourmaline from Swat, West Pakistan. *Mineralogical Magazine* 38, 756-759.

Traces of a green chromian tourmaline occur in calcareous rocks in contact with serpentinite near Alpurai, Swat, West Pakistan. The petrography of the rocks and the optical properties of the tourmaline are presented along with its chemistry (it contains over 8 % Cr_2O_3 and about 0.2 % V_2O_3). The mineral is compared with other chromian tourmalines and its paragenesis discussed: it is thought to have been produced by silica-rich hydrothermal (or gaseous) solutions, which have crystallized as thin quartz veins in the calcareous rocks, introducing boron and other constituents.

Key words: Tourmaline, Swat.

J/100. Jan, M.Q., Kempe, D.R.C. & Tahirkheli, R.A.K., 1969. The geology of the corundum-bearing and related rocks around Timurgara, Dir. *Geological Bulletin, University of Peshawar* 4, 83-89.

The geology of the Timurgara, Dir area has been mapped, largely because of the occurrence of ruby corundum associated with some ultramafic bodies intruding the regional hornblende gneisses, quartzofeldspathic gneisses, and minor phyllites.

The most abundant intrusive rocks are diorites, themselves intruded by granites. The ultramafic bodies include serpentinites, pyroxenites and the corundum-bearing amphibolites. The relationship of the other intrusive rocks is not clear.

Key words: Mapping, geology, ultramafics, ruby, corundum, Dir.

J/101. Jan, M.Q., Kempe, D.R.C. & Tahirkheli, R.A.K., 1971. Corundum, altering to margarite, in amphibolites from Dir, Pakistan. *Mineralogical Magazine* 38, 106-109.

Pink to pale purplish corundum crystals, generally less than 15 mm but occasionally reaching 6 cm in length, sometimes idiomorphic, are found sparsely disseminated in a dark grey tremolite rock (amphibolite) associated with small ultrabasic intrusions (?sills) at Timurgara, Dir, West Pakistan (34° 48' N., 71° 50' E.). The corundum bearing amphibolites form bands in contact with pyroxenites and serpentinites intruded into banded hornblende gneisses (Jan et al., 1969); rarely, the amphibolites themselves have a gneissose texture. The banded gneisses are composed of plagioclase, hornblende, epidote (up to 50 % in some rocks), garnet, and minor quantities of iron ore and rutile. The rocks are veined, wedged, and tongued, and are mainly metasedimentary in origin. Other intrusions of granite and, most commonly, dioritic and noritic rocks are found in the area. The latter are composed of plagioclase, bronzite, clinopyroxene, hornblende, quartz, biotite, iron ore, and apatite; such rocks are abundant to the north-east of the area in upper Swat.

Key words: Corundum, amphibolite, Timurgara, Dir.

J/102. Jan, M.Q., Khan, A. & Windley, B.F., 1983. The Waziristan ophiolite complex: Chemistry of chromites and some other minerals. *Proceedings, 2nd National Seminar on Development of Mineral Resources, Peshawar* 1, 16p.

The Waziristan complex covering over 500 sq. km area, was tectonically emplaced during Paleocene - Early Eocene. It consists of ultramafics, gabbros, sheeted dykes, pillow lavas and pelagic sediments rock constituting type ophiolite complexes. However, a complete sequence with all the members intact does not occur in any single locality due to dismemberment and tectonic slicing. This paper presents an account of the petrography of the complex and the mineral chemistry of the podiform chromitites. The chromites consists of aluminochromite ($\text{Cr}_2\text{O}_3 = 49\text{--}61\%$) with subordinate chromian chlorite and/or chromian serpentine+ magnetite / on Cr-Al-Fe³⁺ + Ti diagram the chromites plot in the area of alpine chromite but on the other conventional diagram they occupy the overlapping fields of those from alpine and stratiform complexes. Many of the chromites are zoned with ferrite-chromite margin richer in the Cr/(Cr+Al) and poorer in Mg/(Mg+Fe) ratio than the unaltered cores. The chlorites are generally rich in SiO_2 and MgO

and poor in Al_2O_3 . It is suggested that during greenschist-facies metamorphism diffusion of Mg, Al and some Cr from the chromite margins towards the silicate matrix resulted in the development of ferri-chromite and chlorite.

Key words: Ophiolites, chromite, chemistry, Waziristan.

J/103. Jan, M.Q., & Khan, M.A., 1991. Petrologic evaluation of the mafic-ultramafic complexes in the lower levels of the Kohistan magmatic arc. Abstracts, 1st Postgraduate Training Course in Plate Tectonics, Punjab University, Lahore, p.6.

Synthesis of petrographic and geochemical data presented in the past three decades suggests that the Indian and Asiatic (Karakorum) Plates in northern Pakistan are separated from each other by a sandwich of an island arc. This, subduction related Cretaceous arc, consists predominantly of igneous rocks showing various degrees of metamorphism. Our detailed investigations on three mafic-ultramafic complexes from Kohistan not only corroborate the idea of the arc but also throw light on the growth of the lower crust.

The Chilas complex is a huge mass, more than 200 km in length and up to 40 km in width. It consists of a gabbro-norites into which are emplaced small bodies of ultramafic-mafic –anorthositic rocks showing excellent layering. Mineralogical and geochemical data support a subduction-related origin for the complex which has remarkable similarities with plutonic rocks of the island arc. The complex may have developed from a mantle diapir during early arc rifting or it may represent the plutonic base for the arc volcanics.

The Jijal complex is a 100 km block of ultramafic rocks and garnet granulites along the MMT. The ultramafic rocks range from pyroxenite through peridotite to dunite with chromite segregations. The granulites range from plagioclase + Garnet + clinopyroxene + quartz + rutile + hornblende + epidote assemblage to those consisting of granulites, hornblendites, pyroxenites and epidotites (meta-anorthositic). These rocks have preserved magmatic layers despite high-pressure granulite facies metamorphism. Geochemical and mineralogical data suggest that the complex represents arc cumulates metamorphosed at 800°C, 10 kbar about 100 m.y. ago.

The small (5 km²) Tora Tigga Complex is emplaced in amphibolites just north of the suture in southern Dir. It consists of hornblendites, olivine-rich and pyroxene-rich ultramafic rocks, and plagiogranite closely associated with metagabbroic rocks probably belonging to the Chilas Complex. These rocks have calc-alkaline magmatic signatures and may be cumulates to hydrous arc magma.

J/104. Jan, M.Q., & Khan, M.A., 1995. Potential for ruby mineralization in upper Kaghan, NW Himalaya. Geological Bulletin, University of Peshawar 28, 1-7.

The Precambrian to Early Paleozoic basement of the upper Kaghan has a cover of metamorphosed sedimentary and volcanic rocks of Late Paleozoic-? Early Triassic age. About 3 km NE of Naran, the cover rocks contain a few tens of meters thick marbles containing thin (mostly <1 cm) micaceous bands one of which hosts tiny (up to a millimeter) grains of pinkish red corundum. The occurrence of the ruby corundum is similar to the Hunza and Azad Kashmir ruby deposits, thereby necessitating further search in the area.

The marbles consist of calcite + muscovite + biotite & quartz + pyrite. The micaceous bands consist of the two mica + pyrite I- opaque oxide + calcite ± rutile ± quartz plagioclase ± chlorite ± garnet. Microprobe analyses are presented for the common phases. Petrography and preliminary geothermobarometry suggest that the marbles were metamorphosed at 450-500°C, 6 kbar, followed by a lower temperature (~280 °C) overprinting of chlorite-epidote grade during retrogression. Considerable inter- and intra-granular variations in the Cr content of peen mica and ruby suggest a lack of mobility of Cr during metamorphism. The abundance of micaceous minerals and pyrite, and local occurrence of garnet and corundum suggest that the thin bands associated with the marbles were highly aluminous and iron-rich (?lateritic), and that reducing environments prevailed during their diagenesis.

Key words: Ruby, metamorphism, Precambrian, Paleozoic, Kaghan.

J/105. Jan, M.Q. & Khan, M.A., 1996. Petrology of gem peridot from Sapat mafic-ultramafic complex, Kohistan, NW Himalaya. *Geological Bulletin, University of Peshawar* 29, 17-26.

A large quantity of peridot has recently been marketed from the Parla Sapat area to the NE of Nara. The peridot occurs in pockets and veins located in shear zones in partially serpentinized dunitic host rocks. The latter constitute basal cumulates of the Kohistan magmatic arc thrust onto the Indian plate during Early Paleocene. The peridot is associated with serpentine (essentially chrysotile), minor magnetite, and local magnesite and talc. It is mostly yellowish green, takes good polish, and suitable specimens are faceted into brilliant stones of highest quality. It occurs in euhedral to subhedral crystals, but most stones are broken due to crude methods of recovery. The stones are mostly <3 cm in length, but up to 15 cm long crystals weighing 2 kg have been recovered. The largest faceted stone is reported to measure about 310ct.

The peridot is pleochroic from pale green ($\alpha=\gamma$) to yellowish green or olive in greenish yellow variety ($\beta=Z$). Refractive indices ($\alpha = 1.644$ to 1.653 , $\gamma = 1.682$ to 1.684 ± 0.003), density (3.26 to 3.44) and EPMA data suggest that most specimens range in composition from Fo89 to Fo92, but some are more magnesian (up to Fo97). The depth of color increase from light green to yellowish green with increase in the Fe content, but the greenish yellow color may partly be related to a higher Ti content. Some peridot contains tiny inclusions of magnetite and hairy to acicular, brownish black ludwigite [(Ti_{0.011} Cr_{0.041} Fe³⁺_{0.947}) (Mg_{1.085} Fe²⁺_{0.897} Mn_{0.004} Ni_{0.013}) BO₅]. The paragenesis may be related to hydrothermal activity with also introduced CO₂ and B. The undeformed nature of the peridot suggests that the solutions may be related to the late phases of Himalayan metamorphism or leucogranites of the underlying Indian plate, both of which are of Eocene age.

Key words: Petrology, gems, peridot, ultramafics, Sapat, Kohistan, NW Himalaya.

J/106. Jan, M.Q. & Khan, M.A., 1997a. Mineralogy of gem olivine (peridot) from Kohistan-Kaghan watershed. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad 2 p.

A large quantity of peridot has recently been marketed from Parla Sapat area to the NE of Naras. The peridot occurs in pockets and veins located in shear zones in partially serpentinized dunitic host rocks. The latter constitute basal cumulates of the Kohistan magmatic arc thrust onto the Indian plate during the Early Paleocene. The peridot is associated with serpentine (essentially chrysotile), minor magnetite and local magnesite and talc.

Physical constants and chemical composition of the peridot were studied in detail during the present investigation. It is mostly yellowish green takes a good polish and suitable specimens are faceted into brilliant stones of highest quality. The mineral occurs in euhedral to subhedral crystals but most stones are broken due to crude methods of recovery. The stones are mostly < 3 cm in length, but larger stones have been recovered including a 10-15 cm long crystal weighing 2 kg. The largest faceted stone is reported to measure about 310 ct.

The peridot is pleochroic from pale green ($\alpha=\gamma$) to yellowish green or olive in greenish yellow variety ($\beta=Z$). Refractive indices range from $\alpha=1.644$ to 1.653 and $\gamma=1.682$ to 1.684 ± 0.003 , and density from 3.26 to 3.44. The refractive indices and electron microprobe analyses suggest that most peridot ranges in composition from Fo89 to Fo92 but some compositions are more magnesian (up to Fo97). The depth of colour increases from light green to yellowish green with increase in the Fe content, but the greenish yellow colour may partly be related to higher Ti content.

Some peridot contains tiny inclusions of magnetite and hairy to acicular inclusions of a brownish black substance, locally forming mats. XRD and probe data suggest that later to be ludwigite (Ti_{0.011} Cr_{0.041} Fe₃+0.097) (Mg_{1.085} Fe₂+0.897 Mn_{0.004} Ni_{0.013}) BO₆ a mineral not reported previously in peridot. It is thought that the paragenesis developed along shear zones and is related to hydrothermal activity, which also introduced CO₂ and B. The undeformed nature of the peridot suggests that the solutions may be related to the late phases of regional metamorphism or leucogranites of the underlying Indian plate, both of which are of Eocene age.

J/107. Jan, M. Q., Khan, M.A., 1997b. A review of the geology and tectonics of N. Pakistan. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, 1-2.

North Pakistan is significant for its geographical position at the junction of world's three major mountain ranges; Hindukush, Karakoram and Himalayas. Several lines of evidence based on diverse geological studies including lithological and structural mapping, petrography, geochemistry, fossil findings and radiometric age determinations, have led to realization that N. Pakistan comprises three, previously discrete and distant apart, plates named Karakoram, Kohistan and India. These plates accreted to Eurasia during Jurassic-Early Tertiary to form the present-day landmass of south-central Asia.

The Karakoram plate incorporates much of the Karakoram-Hindukush ranges and adjacent areas of south-central Asia. Northern Baltistan (including K2) and upper reaches of the Hunza, Ishkuman, Yasin, Yarkhun and Chitral valleys are parts of northern Pakistan which occur in the Karakoram plate. The plate is divisible into three tectonic units; (1) a metamorphic complex, comprising metapelites with subordinate marbles of probable Precambrian-Palaeozoic age in the south. (2) an Andean-type batholith (granodiorites, diorites and granites) of Late Cretaceous-Tertiary age in the middle and (3) a succession of intact stratigraphy (predominantly carbonates and pelites with subordinate sandstones and conglomerates) from Ordovician to Triassic in the north with rare remnants of a Precambrian basement (metapelites) near the Baroghil Pass. A series of discontinuous plutons of Late Cretaceous age, stretching from Wakhan-Trich Mir to Khunjerab and beyond, intrude this tectonic unit. The Karakoram plate is a lateral equivalent of the Lahasa block in the east, and the Afghanistan and Iran microcontinents in the west. All these microplates are Gondwanic in their faunal affinity and are considered to have been separated from the Gondwana during Permian. The paleotethys closed to the north of these microplates in Jurassic (150-145 Ma) at the site of the Rushan-Pashart-Bangong-Nujiang Suture Zone, accreting these microplates with Eurasia. The southern contact of the Karakoram plate is with the Kohistan island arc terrane at the site of the Shyok suture.

The Kohistan terrane in north Pakistan is a fossil island arc of Cretaceous-Early Eocene age. This is an east-west trending belt of 30-60 km width, encompassing the Kohistan region of north Pakistan, i.e., middle Indus, Swat and Dir valleys. It was formed in an intraoceanic setting in the Neotethys. Basalts, gabbros and ultramafic rocks predominate the early phases of arc growth giving way to the intermediate to felsic (mainly granitic) igneous rocks in the later states. The earliest rocks in the Kohistan terrane are about 120 Ma old. This coincides with the age of the separation and northward drift of the Indian plate from the eastern Gondwana independently deduced from the ocean-floor magnetic anomaly data. The Kohistan terrane suffered two collisions; firstly it collided with the southern margin of previously accreted Karakoram-Eurasia at about 90-80 Ma (Chalt suture), when it became an Andean-type continental margin. Finally the terrane was sandwiched when the Indian plate collided with its southern margin during Early Tertiary at the site of the Main Mantle Thrust or Indus Suture. These multiple tectonic events have exposed the deepest parts of the arc crust, including Moho, attracting considerable attention from petrologists for the study of deep-arc crustal structures and composition.

The Himalayas, in essence, represent the deformed northern part of the Indian plate involved in continent-continent collision. They are regionally divisible into internal (or hinterland) and external (or foreland) zones. The internal zone occurs immediately to the south of the MMT. It comprises crystalline rocks tectonically stacked in such a way that deep-crustal (hence higher grade) rocks occur on the top of shallower, lower-grade rocks successively in the south. Polyphase deformation and metamorphism, accompanied by partial melting and granite gneisses, are characteristic of the internal zone. The external zone, which in essence, is a type foreland thrust-fold belt, comprises successions of stratified sedimentary rocks of Hill Ranges (e.g., Margala, Kalachita and Kohat), Potwar-Kohat plateau, and Salt Ranges. The classical division of the Himalayas into Tethyan, higher, lesser and sub Himalayas is not strictly applicable to the west of the Nanga Parbat Syntaxis, roughly, the Internal zone includes higher and inner part of the lesser Himalaya, while the outer part of the lesser Himalaya and sub-Himalaya occur in the external zone.

A simplistic scenario of the origin of Himalaya includes (1) subduction of the leading oceanic part of the Indian plate from about 120 Ma to about 65 Ma in the north-west, and up to 50 Ma elsewhere, (2) partial subduction of the basal parts of the Indian-plate continental crust leading to Eocene peak metamorphism including the high-P metamorphism responsible for the 49 ± 5 Ma eclogites in the upper Kaghan valley, (3) rapid uplift and shifting of deformation front from the MMT successively southwards to the thrusts in the interiors of the Indian plate; Shontargali and Batal Shears at about 40 Ma, Main Boundary Thrust (MBT) at about 10 Ma and Main Frontal Thrust at the Salt Range in geologically recent past, (4) north-verging

folding of the Himalayan thrust sheets into dome and basin structures (e.g., Hazara-Kashmir, Besham, Indus and Nanga Parbat syntaxial bends and Hazara and Swat arc). Whereas the youngest of these structures are still active (e.g. Raikot fault at the western limb of the Nanga Parbat syntaxis), the older structure (e.g. MBT) have been frequently reactivated.

Key words: Tectonics, Karakoram, Kohistan arc, Himalaya.

J/108. Jan, M.Q. & Khan, M.A., 2000. A Petrological overview of the Kohistan magmatic arc, NW Himalaya, N Pakistan. Abstract Volume, 15th Himalaya-Karakoram-Tibet Workshop, (Chengdu) China, 5-6.

The Kohistan Terrane in N. Pakistan occupies the suture zone between the collided Indian and Asian Plate. It formed primarily as an intra-oceanic crust between 125 and 90 Ma prior to its accretion with the Asian plate along the Shyok Suture. The final obduction of the Kohistan onto the Indian plate in Early Eocene ensued the principal phase of the Himalayan orogeny.

A two-fold subdivision of the rocks forming the Kohistan crust is now well established. Much of the ultramafic-mafic component of the arc crust developed in the intraoceanic setting prior to collision with Asia. Mafic-ultramafic plutonic complexes (Jijal and Sapat), together with gabbroic-basaltic amphibolites (Kamila belt), at base of the arc crust, and basaltic-boninitic volcanics (the Chalt Formation) and Jaglot-Yasin metasediments, in the upper arc crust are representative lithologies of this tectonic setting. Post Shyok suture lithologies include ca.80~45 Ma Kohistan Batholith, Early Eocene utror-Shamaran volcanics and sedimentary rocks deposited in Early Eocene Dir and Drosh basins in Andean-type setting. The Chilas gabbro-norite-ultramafic complex was magmatically emplaced in the waning stages of intraoceanic phase but preceded the onset of the Andean-type magmatism.

Earlier models suggested that Kohistan is a simple island arc tilted on an end with its base at the Indus suture and top at the Shyok Suture. Later, more detailed studies reported several complexities including large-scale folding of the arc crust, existence of Kamila shear zone and metamorphic ages spanning 95~85Ma. Most tectonic models from the Kohistan Terrane Indus Suture. But several aspects of the terrane are still under discussion and need further investigations. These include: (1) Nature and extent of the oceanic basin consumed at the Shyok Suture and the palaeolatitude position of Kohistan in Late Early Cretaceous; (2) Existence and polarity of subduction zone at the site of the Shyok Suture and facing direction of Kohistan in terms of location of the fore-, and back-arc basins; (3) Timing of emplacement for the Chilas Complex, i.e., pre- or post Shyok Suture; (4) Nature of the Kamila Amphibolite belt, i.e., a stack of gabbroic-ultramafic magma chambers or a metabasalt basement with intrusive gabbroic plutons, both metamorphosed to amphibolites; (5) Nature of the mafic plutonic rocks in the Jijal Complex; garnet granulites, garnet gabbros, or both; (6) Nature of the ultramafic rocks in Jijal and Chilas Complexes: mantle peridotites, or cumulates at the base of an island arc crust or ophiolite.

Lack of rocks in Kohistan crust with a clear continental basement affinity negates possibility of its origin as a continental margins offshore the Karakoram plate. This implies that models suggesting a Sea of Japan type origin for the Shyok Ocean are invalid. Several pieces of evidence, including isotope systematics, palaeomagnetic studies and laterization favor an equatorial palaeolatitude position for Kohistan in Late Early Cretaceous. This implies that the Shyok ocean was a sizeable entity, which closed at the site of the Shyok suture after producing subduction-related 110~90 Ma Karakoram Batholith. The Suggestion that the Shyok ocean was additionally bounded by a subduction zone to its south with southerly dips that gave birth to intraoceanic Kohistan island arc is currently under debate. But the presence of boninites in Chalt Volcanics at the northern margin of the terrane certainly lends supports to this model. The mid-crust levels Chilas intrudes the interface between the Kamila amphibolites and overlying metasediments of the Jaglot group. A lower state of deformation in the Chilas Complex compared to the host Kamila Amphibolite and the Jaglot metasediments and a U-Pb zircon age of 84Ma indicates a post- or syn-Shyok Suture origin for the Chilas Complex. The 110Ma Rb-Sr whole-rocks age contradicts this interpretation warranting further geological and geochronological investigations.

The Kamila Amphibolite belt is composite in nature. It consists of predominantly pillowed metabasalts (both MORB and arc) together with metagabbros. Burial of the Kamila pillowed metabasalts from a surface level to that of lower crust is attributed to (1) mid-crustal magmatic overloading by the Chilas Complex and (2) tectonic burial beneath the folded Chilas Complex and Jaglot Group along the Kamila shear zone. This highlights role of combined tectonics and magmatism in crustal growth in island arc.

The Jijal Complex, exposed at the base of the Kohistan Crust directly above the Indus Suture, is the most studied yet least understood unit in the Kohistan. Workers in the recent past have preferred to place petrological MOHO directly at the Indus Suture implying that the overlying 4-km thick ultramafic unit, together with garnet gabbros/granulites constituted cumulates at the base of the Kohistan Island Arc Crust. Alternatively, petrological MOHO is placed at the contact between the ultramafic and the gabbroic units implying that the ultramafic unit in the Jijal Complex is part of the infra-arc mantle. Another controversy relates with the garnetiferous mafic rocks in the Jijal Complex. These have been interpreted to have directly crystallized as such are a product of high pressure metamorphism imprinted on what were originally gabbroic rocks or pyroxene granulites. Coherently in continuous magmatic layering with both in the ultramafic and garnet gabbros preclude Jijal Complex is a part of mantle. The structure ascribed to upper mantle can equally commonly in ultramafic cumulates. A mineral chemical data of a large number of samples, both from Chilas and Jijal do not favor a mantle nature for the ultramafic rocks of these two complexes.

Key words: Kohistan arc, orogeny, Himalaya.

J/109. Jan, M.Q., Khan, M. A. & Qazi, M.S. 1992. The Sapatgali mafic-ultramafic complex, Kohistan arc, N Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 44.

The Sapatgali complex is one of the several mafic-ultramafic complexes occupying the bottom of the Cretaceous Kohistan island arc. It occurs in the immediate hangingwall of the Indus suture zone along the drainage divide between the Kohistan and Kaghan terrains. Previously undescribed, much of the complex consists of gabbroic rocks, but in the central part, there are basal ultramafic cumulates emplaced onto the Indian plate. It displays well developed layering which may be disrupted, folded, pinched and swelled. The basal ultramafics, attaining a maximum width of 1.5-km, extend for 15-km. In the central part, these can be divided into the following zones, from base to top:

Homogeneous serpentinitized dunites (350 m thick), dunites with thin chromite layers (350 m), thinly layered dunites-pyroxenites (30 m), Layered dunites-pyroxenites-gabbros (170 m) with chromite layers in the lower part, and gabbros. The gabbroic rocks may be amphibolitised and consist of a variety of lithologies ranging from troctolites to anorthosites, with local pyroxenite ($\pm$ olivine) layers and horizons of olivine-rich ultramafics. These rocks are at places cut by pyroxene-rich pegmatites containing upto 45 cm long pyroxene crystals.

Preliminary microprobe studies on the ultramafic rocks show that the clinopyroxene is Mg-Ca-rich diopside, and olivine has a forsterite content of 92 to 78, but in rare cases >95 . The chromite displays high Cr# (75-67) and low Fe³⁺/R₃⁺ (<10). These data, especially the chromite analyses, are akin to those of ultramafic rocks of island arcs, including the Jijal Complex, 80 km to the west. The huge Chilas complex, which occurs in the central part of the Kohistan arc, contains Cr-oxides with Cr# typically <60 .

Key words: Ultramafics, Sapat Complex, Kohistan arc.

J/110. Jan, M.Q., Khan, M. A. & Qazi, M.S. 1993. The Spat mafic-ultramafic complex, Kohistan arc, north Pakistan. In: Treloar, P.J. & Searle, M.P. (Eds.), Himalayan Tectonics. Geological Society, London, Special Publications 74, 113-121.

The Sapat layered complex occupying the tectonic base of the Cretaceous Kohistan island arc, occurs in the immediate hanging wall of the Indus suture zone north of the Kaghan valley. Previously undescribed, much of the complex consists of gabbroic rocks, but in the basal part there are ultramafic cumulates (15 x 2 km) in direct tectonic contact with the Indian plate. In the central part, the complex can be divided into five zones. From the base these are: (1) homogeneous serpentinitized dunites (350 m thick), (2) dunites with thin chromite layers (100 m), (3) thinly layered dunites-pyroxenites (30m), (4) layered dunites-pyroxenites-gabbros (170 m) with chromite layers in the lower part, and (5) gabbros. The gabbroic rocks are amphibolitized and consist of a variety of lithologies ranging from troctolites to anorthosites, with local pyroxenite (+ olivine) layers and horizons of olivine-rich ultramafics. These rocks are locally cut by pyroxene-rich pegmatites containing up to 45 cm long pyroxene crystals. Preliminary microprobe studies on the ultramafic- rocks show that the clinopyroxene is Mg-Ca-rich diopside, and olivine has a forsterite

content of 92 to 78, but in rare cases > 95. The chromite displays high Cr No. (75 to 67) and low $\text{Fe}^{3+}/\text{R}^{3+}$ (<10). These data, especially the chromite analyses, are akin to those of ultramafic rocks of island arcs, including the Jijal complex, 80 km to the west. We suggest that the Sapat complex formed the basal part of the Kohistan terrain and is related to arc magmatism. It has been metamorphosed under epidote amphibolite facies conditions.

Key words: Ultramafics, Sapat Complex, Kohistan arc.

J/111. Jan, M.Q., Khan, M.A. & Windley, B.F., 1989. Mineral chemistry of the Chilas mafic-ultramafic complex, Kohistan island arc, N. Pakistan: oxide phases. *Geological Bulletin, University of Peshawar* 22, 217-239.

The Chilas Complex contains a great variety of Fe^{3+} , Al, Cr, and Ti oxide phases. The principal gabbro-norite association (PGA), which forms much of the complex, and the amphibolite dykes which represent a younger magmatic event in the Chilas Complex, contain magnetite-ilmenite pair exsolved from an initially single phase; no Cr-Al spinel occurs in these rocks. The ultramafic-mafic-anorthosite association (UMAA) of rocks, which appears to be emplaced in the PGA, contains oxides covering the entire range from pleonaste through Al-Cr- Fe^{3+} spinel (with a maximum of 39 wt. % Cr_2O_3) to magnetite. These display complete ranges for Cr / (Cr + Al) and $\text{Fe}^{3+} / \text{R}^{3+}$ ratio which decrease with increase in Mg / (Mg+ Fe^{2+}) ratio (0.7 to 0.0). The composition of the UMAA spinel varies from one to another samples and in some cases from grain to grain within a single specimen. The variations are attributed to subsolidus re-equilibration with adjacent silicate grains and to exsolution. The exsolved pairs define a complete solvus similar in shape to those reported elsewhere. The UMAA also contains pleonaste formed in reaction coronas between calcic plagioclase and olivine, and in few cases, ilmenite formed during exsolution of Cr-Al- Fe^{3+} spinel. Exsolved oxide phases in both the associations of rocks have re-equilibrated under low oxygen fugacity during cooling of the complex at temperature ranging from >800 to 500°C. The detailed microprobe analytical data for the oxide phases discussed in this paper support our earlier view that the Chilas Complex is related to the Kohistan arc probably formed during intra-arc rifting in initial stages of development of a back-arc basin.

Key words: Ultramafics, Spinel, Chilas Complex, Kohistan arc.

J/112. Jan, M.Q., Khan, M.A. & Windley, B.F. 1992. Exsolution in Al-Cr- Fe^{3+} spinels from the Chilas mafic-ultramafic complex, Pakistan. *American Mineralogist* 77, 1074-1079.

The Chilas complex contains accessory and segregated spinels that display a complete range from Cr-poor pleonaste through Al- Fe^{3+} -rich chromite to Cr-poor magnetite. Microprobe data reveal complete ranges for the Cr/(Cr + Al) and $\text{Fe}^{3+}/\text{R}^{3+}$ ratios, whereas the Mg/(Mg + Fe^{2+}) ratio ranges from 0.7 to 0.0; the former two ratios increase as the latter decreases. Grain to grain compositional variation within a thin section is common.

It is particularly drastic in tiny spinel grains and is mainly because of subsolidus re-equilibration with adjacent grains of olivine, pyroxenes, and amphibole. Many samples also contain aluminum chromium spinel with blebs and lamellae of exsolved Fe^{3+} -rich spinel.

The exsolved grains define a complete solvus, the shape of which is similar to those of other documented examples of exsolved spinels in the system $(\text{Mg-Fe})\text{Fe}^{3+}_2\text{O}_4$ -(Mg- Fe^{2+}) Cr_2O_4 -(Mg- Fe^{2+}) Al_2O_3 . Exsolution probably took place during cooling at <600 °C.

J/113. Jan, M.Q. & Khan, M.J., 1992. Precambrian sequence of Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, 17-18.

Precambrian rocks in NW Pakistan can be classified into a basement (Salkhala Group) and overlying slates (Hazara, Attock Formations), quartzite (Tanawal Formation) and conglomerate (Tanaki Formation). The Salkhala Group consists of metamorphosed pelites with significant graphitic, quartzitic and carbonate

components, and associated gneisses, pegmatites and dolerite dykes at many places. There is a general increase in the grade of metamorphism towards north, with varying types of schists, migmatites and paragneisses. Radiometric studies in the Nanga Parbat Haramosh area and Besham suggest that the oldest rocks are at least 1850.1950 M.Y. in age.

The slate sequence is overlain by the Tanawal Formation and comprises quartzite, quartzitic schist, phyllite and some conglomerate. It is intruded by granitic rocks. Major pluton intruding these quartzites is the Mansehra Granite, with Rb/Sr isochron age of 516 ± 16 MY. The upper most part of Precambrian sequence in NW Pakistan is formed by a conglomeratic unit, the Tanaki Formation.

Key words: Precambrian, Pakistan.

J/115. Jan, M.Q. & Khattak, M.U.K., 1983. Petrology of a hornblende-rich pegmatite and host amphibolites near Matta, upper Swat. Geological Bulletin, University of Peshawar 16, 31-41.

The 500×30 m pegmatite near Matta consists of hornblende + epidote + garnet lithology and hornblendite, with a small proportion of leucocratic, deformed dykes and veins. It is hosted by epidote amphibolites derived from gabbroic rocks and belonging to the southern amphibolite belt of the Kohistan zone. The hornblende-epidote lithology of the pegmatite is chemically identical to the amphibolites and is, therefore, neither a younger intrusion in nor a metasomatic product of the amphibolites. The coarse-grained fabric of the pegmatite may have developed locally in response to a higher concentration of fluid phase, mainly water but some fluorine. The hornblendite, which is coarser grained (with up to 35 cm long crystals) and may cut the hornblende-epidote lithology, may be a product of metamorphic differentiation or, more likely, metasomatism. The amphibolites are tholeiitic in affinity and probably represent the Tethyan oceanic crust.

J/116. Jan, M.Q., Khattak, M.U.K., Parvez, M.K. & Windley, B.F. 1984. The Chilas stratiform complex: field and mineralogical aspects. Geological Bulletin, University of Peshawar 17, 153-169.

The Chilas complex in northern Pakistan stretches for about 300 km from Astor to western Dir and attains a width of 40 km in the middle. It was probably emplaced during the early stages of development of the Cretaceous Kohistan island arc. Field observations, supported by petrography and mineral chemistry, suggest that the complex is composed of two groups of rocks. Group A consists predominantly of noritic rocks with subordinate pyroxenites, anorthosites and hypersthene-quartz diorites. These cover most of the complex, are generally strongly foliated and display some layering. The mineral composition of these rocks varies as follows: orthopyroxene En75 to En51; clinopyroxene Mg=43 to 27, Fe=9 to 22, Ca= 42 to 50; plagioclase An62 to An43.

Group B rocks occur in the form of lenses (upto 5 km²) and smaller bodies showing complex contact relations, ranging from concordant to discordant, with their host (group A) rocks. These comprise dunite, peridotites, pyroxenites, troctolites, norite, anorthosite, and pyroxene pegmatites; of these the former two are the most abundant. The principal outcrops of these rocks are found in Chilas area but isolated, small bodies occur as far to the west as Swat. The range in the mineral composition of these rocks is: olivine Fo88 to An77; orthopyroxene En90 to En62; clinopyroxene Mg=46 to 37; Fe= 5 to 17, Ca= 49 to 45; plagioclase An98 to An77. Characteristic features of this group of rocks are the development of excellent layering and corona structure.

The group A association may have evolved from a high-alumina basaltic (calc-alkaline) magma. It is not clear whether the group B rocks represent magmatic cumulates of this magma or younger intrusions of a

more basic (picritic) magma. Both groups were probably metamorphosed under pyroxene granulitic facies, to be followed by amphibolite dykes and hornblend-plagioclase pegmatites.

J/117. Jan, M.Q., Khattak, M.U.K. & Tahirkheli, R.A.K. 1983. A comparison of chemistry of chromites from Zhob valley, Harichand and Waziristan ophiolite complexes of Pakistan. Proceedings, National Seminar on Development of Mineral Resources, Peshawar 3, 13p.

Chromian spinels from Zhob, Harichand and Waziristan are essentially aluminos-chromites generally rich in Cr_2O_3 . Different variation diagrams have been used to compare the chemistry of chromites on the basis of 73 analyses from Zhob (15 of them new), 27 from Harichand and 9 new analyses from Waziristan. On $\text{Mg}/(\text{Mg}+\text{Fe}^{2+})$ vs $\text{Cr}/(\text{Cr}+\text{Al})$ and $\text{Fe}^{3+}/(\text{Cr}+\text{Al}+\text{Fe}^{3+})$ and Cr_2O_3 vs. total FeO and mol % Al_2O_3 / $(\text{Cr}_2\text{O}_3 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3)$ diagrams they generally plot in the overlapping fields of chromites from stratiform and alpine complexes.

Their alpine (or ophiolitic) nature is not obvious on TiO_2 vs. Fe^{2+}/Mg diagram either, although the Waziristan chromites plot only in the alpine field on this diagram. However, on $\text{Cr}-\text{Al}-\text{Fe}^{3+}+\text{Ti}$ diagram chromite analyses from all the three complexes are restricted to the field of those from alpine complexes.

The Zhob chromites display a greater range in composition due probably to a higher number of analyses from this area. In general, the Zhob chromites have a higher range in the ratio $\text{Mg}/(\text{Mg}+\text{Fe}^{2+})$ and $\text{Fe}^{3+}/(\text{Cr}+\text{Al}+\text{Fe}^{3+})$ whilst the Harichand ones have a higher range in the ratio $\text{Cr}/(\text{Cr}+\text{Al})$.

J/118. Jan, M.Q., Malik, R.H. & Ahmad, K.H., 1995. Gem garnet in pegmatites from Neelum valley, Azad Kashmir. Geological Bulletin, University of Peshawar 28, 9-14.

The upper Neelum valley is occupied by a group of basement rocks of Precambrian to early Paleozoic age and a cover of younger rocks. Both the basement and cover contain Late Paleozoic (?) mafic sheets. There are at least two sets of pegmatites, one we-dating and the other post-dating the mafic sheets. A few of these contain green tourmaline, pink beryl, and colourless topaz, one of the pegmatites near the village of Phullawai contains bluish green tourmaline and gem garnet. The garnet is well-formed and reaches up to 30 g in weight. It is clear, transparent, takes a good polish, and ranges from yellowish red to tangerine and crimson red. Many spots analysed in two tiny ($\sim 0.5 \text{ cm}^2$) grains are uniform in composition. The garnet is rich in spessartine (79.9 mole %), with small amounts of almandine (15.3 mole %) and grossular (4.4 mole %) components.

J/119. Jan, M.Q., & Mian, I., 1971. Preliminary geology and petrography of Swat, Kohistan. Geological Bulletin, University of Peshawar 6, 1-32.

Regional survey, covering 1400 square miles of area, was carried out in Swat Kohistan to prepare a preliminary geological map and investigate the structure, petrography and economic geology of the region. The area is covered by various types of plutonic and a lesser quantity of sedimentary and volcanic rocks. Quartzite, siliceous schist, phyllite, siltstone/shale, and limestone of the Kalam Group (Carboniferous to? Siluro-Devonian) are exposed in the Matiltan-Kalam area. Norites, diorites, and the associated rocks of the Kohistan Basic Complex (Late Cretaceous) cover a large area to the south of Kalam. They form a northeast trending belt that extends to the east in Indus Kohistan and to the west in Dir. To the northwest, the Kalam Group is overlain by a thick sequence of silicic to intermediate lavas, tuffs and agglomerates (the Utror Volcanic Rocks) of probable Cretaceous-Eocene age. These, and the sedimentary rocks, have been cut by various types of plutonic rocks, mainly quartz diorites and granites, in Gabral and Ushu Valleys. The plutons are thought to be emplaced during Early to Middle Tertiary period. Quaternary alluvium and glacial deposits occur in small quantity in all parts of the region.

J/120. Jan, M.Q., Parvez, M. K. & Khattak, M.U.K., 1984. Coronites from the Chilas and Jijal-Patan complexes of Kohistan. Geological Bulletin, University of Peshawar 17, 75-85.

This paper describes coronites from the Jijal-Patan and Chilas complexes of northern Pakistan. In Jijal, plagioclase and orthopyroxene reacted under high P - high T metamorphic conditions (~ 8500C, 12-14 Kbar) to produce garnet + clinopyroxene coronas. These rocks occur along the MMT suture zone and were metamorphosed at > 40 km depth due to subduction / sinking. In the Chilas complex, orthopyroxene / clinopyroxene / hornblende + spinel coronas developed due to reactions between highly calcic plagioclase and mafic minerals under medium P- high T conditions (750-8500C, 5-7 kbar). These coronas may have formed due to slow cooling, either during uplift or pyroxene granulite facies metamorphism of feldspathic peridotites, troctolites, olivine gabbros, and related rocks. At higher levels during uplift, when the Chilas complex had access to water, labradorite-andesine reacted with mafic minerals to produce thin amphibole and epidote ± quartz coronas in noritic granulites. These medium to low P - low T epidote amphibolite facies coronas are mostly very thin but quite common. In rare cases the rocks are more severely affected, thus bridging the gap to epidote amphibolites.

J/121. Jan, M.Q. & Rafiq, M., 1999. Highly unusual chloritoid-ilmenite-rich rocks in the Indus suture melange north of Peshawar, North West Pakistan. Terra Nostra 99 (Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany), 75-76.

The Indus suture to the north of Peshawar, along which are juxtaposed the Indian plate and the Kohistan magmatic arc, is characterized by a tectonic melange. It consists of ophiolitic ultramafic rocks, greenstone, and a variety of sedimentary rocks: metamorphosed under greenschist facies conditions (up to garnet grade) (Hussain et al., 1984). The component lithologies in the mélangé may extend for tens of kilometers. Within the greenstone, there occur sparse, up to 200 m long and 1 to 3.5 m thick, lenticular bodies consisting of abundant chloritoid (31 to 59 modal per cent), ilmenite + subordinate, oxidized pyrite (12 to 25 %), quartz (8 to 31%), variable amounts of white mica (up to 3.9 Wt % FeO), and chlorite (pseudoturningite to ripidolite).

The analyses of these rocks consist essentially of SiO₂, TiO₂, Al₂O₃ and iron oxide. Such compositions have neither been reported for igneous nor sedimentary rocks. Although extremely rare, similar compositions have, however, been proposed for weathered and lateritized basaltic rocks and their metamorphosed equivalents (Liou and Chen, 1978; Singer, 1975; La Tour et al., 1980). Major, trace and rare-earth element analyses of three greenstone samples show some transition towards the chloritoid-ilmenite rocks. This, coupled with the presence of local chloritoid in the greenstone, and the close association of the chloritoid-ilmenite rich rocks with greenstone suggest a common parentage for the two. The greenstone analyses contain high TiO₂, Fe₂O₃, and P₂O₅. They show an enrichment in light REE and depletion in heavy REE, a negative Eu and positive Yb anomaly, and their chondrite normalized patterns resemble those of basaltic rocks from some island arcs and oceanic islands (Kay, 1984). Their Hf-Th-Ta (Wood, 1980), Ti-Zr-Y (Pearce and Cann, 1973), and Nb-Zr-Y (Meschede, 1986) relations suggest that the greenstone may be derived from oceanic islands alkali basalt.

Due to inaccessibility of the area, detailed field studies have not been performed to work out the relations of the chloritoid-ilmenite-rich rocks with their host greenstone. The former may represent shear zones in the basaltic precursors of the greenstone along which extensive alteration took place due to passage of water. More likely, the chloritoid-rich rocks may be weathered/lateritized soils whose relations with their host basalt (greenstone) have been exacerbated during melange formation, metamorphism and emplacement during the Paleocene.

J/122. Jan, M.Q. & Shah, M.T., 1987. Ni, Cr, Cu, Zn, Co, Ag and Au content of some Talc-carbonate rocks from NWFP, Pakistan. Geological Bulletin, University of Peshawar 20, 215-216.

The principal ophiolite complexes of northern Pakistan (i.e., Waziristan, Skhakot Qila, Jijal, Shangla-Mingora) are characterized by the occurrences of talc-carbonate rocks ($\pm$ quartz, chlorite, serpentine, fuchsite, epidote, oxide and sparingly, emerald and Cr-tourmaline). These rocks occur along the margins of and in shear zones, within ultramafic rocks and have been considered as the product of alteration. In the southern part of the Malakand pass, there are several small lenses of talc-carbonate-quartz rocks in greenschist facies metapelites. Carbonate-bearing ultramafic rocks bordering alpine-type peridotites may contain various mineralization such as Hg, As, Co-Ni arsenides; several occurrences of gold have also been reported. The carbonate-bearing rocks, termed listwaenite, are light grey-green rocks consisting mainly of carbonates with accessory quartz, talc, serpentine, chlorite, fuchsite, hematite, magnetite, pyrite, and Cr-spinel. These grade into serpentinized peridotite through a talc-carbonate zone.

J/123. Jan, M.Q. & Symes, R.F., 1977. Piemontite schists form upper Swat, northwest Pakistan. *Mineralogical Magazine* 41, 537-540.

The piemontite schist is a fine grained rock with a distinct purplish colour and a silver-grey lustre associated with the schistosity. In thin section it is composed of quartz, albite, muscovite, margarite, tourmaline, piemontite, spessartine garnet, a Mn-rich chlorite (MnO = 2.24%), rutile, and magnetite. A crude segregation of quartz and albite from the muscovite, piemontite, tourmaline laminae occurs in the plane of the schistosity. The quartz grains are anhedral, interlocking and of even grain-size up to 0.25 mm in diameter and constitute modally 40 % of the rock. They commonly contain inclusions of small euhedral piemontite and magnetite crystals. Albite occurs as broadly twinned poikilitic patches up to 1 mm across and containing abundant inclusions of the associated minerals, which form a distinctly crenulated schistose fabric. The albite poikiloblasts often show rotational features suggestive of syntectonic growth. Muscovite occurs as bundles of colourless or slightly rose-coloured grains. Margarite and the manganese-rich chlorite both occur in blebs of small colourless, radiating brushes.

Both the piemontite and the tourmaline occur as euhedral, elongated crystals subparallel to the dominant schistosity, the former being strongly pleochroic whereas the latter is colourless, or a very dull yellow dravite, showing some pleochroism in shades of pink. In the quartz-poor areas of the schistose fabric piemontite constitutes up to 15 % of the rock, some crystals being elongated up to 0.4 mm in length and 0.1 mm broad. The piemontite grains almost always carry tiny magnetite inclusions concentrated in their cores. Spessartine garnet is not common but forms occasional idioblastic crystals the habit of which seemingly indicates a late metamorphic growth, enclosing piemontite and tourmaline. Microprobe studies show that the disseminated magnetite is often intimately associated poikiloblastically with minute rutile grains. The piemontite crystals in orientation suitable for optical examination consist mainly of 0.05-0.1 mm prisms elongated along [010]. Twinning on {100} was only rarely observed. However, two crystals twinned on {100} and lying parallel to the optic plane (010) were measured for u , y , and for the extinction angles. Dispersion of the indicatrix is strong and values are for NaD only: CY 1.748, canary yellow, /1 1.770, amethystine pink, y 1.795, deep rose pink, γ -a 0.047, $2V_y$ calc = $87^\circ 29'$.

An XRF analysis of the whole rock, using pressed-powder discs, was carried out for major, minor, and a range of trace elements. H₂O⁺ was determined by the Penfield method and FeO by Wilson's method. Accuracy should be within $\pm 2\%$ of the amounts present for the major elements. The values quoted in Table I for Co, Ga, Y, and Zr are expected to be correct to within ± 5 ppm, Cr, Ni, and Sr to within 20 ppm, and those for Ra, Cu, and Zn within 40 ppm. Owing to the over-all small grain-size and presence of magnetite inclusions the piemontite was not separated for chemical analysis, but analysed by electron-microprobe. The reported analysis of the piemontite is the average of three homogeneous grains free of inclusions and large enough to allow ten spot counts per grain. Total Mn has been expressed as Mn₂O₃ and total Fe as Fe₂O₃ following Deer *et al.* The analysis shown in Table I is expected to be accurate to $\pm 2\%$ of the amounts present for the major elements.

Compared to an average Palaeozoic shale, from which the piemontite schist is probably formed (Clarke, 1924), the rock has higher SO₂, MgO, CaO, and K₂O and lower TiO₂, Na₂O, and P₂O₅. The values for Ba, Cr, Ga, and Zr are lower, and those for the other trace elements higher than those given for an average shale by Turekian and Wedepohl (1961). The significant difference of the Swat rock from the average values is in its nickel (2 x the average content), copper (> 11 times that of the average), and especially Mn (20 x).

The high manganese value reflects special circumstances, which precipitated abundant manganese at the time of the deposition of the shale horizon. Local volcanic or hydrothermal activity may have been the contributory factor.

The manganese content of the piemontite ($\text{Mn}_2\text{O}_3 = 12.55\%$) is high for this mineral although Bilgrami (1956) has reported up to 17.78 % Mn_2O_3 from a piemontite in a pegmatite from Chikla, India. The analysis has been recalculated on the basis of twelve oxygens in Table I. From this it appears that all the Mn^{3+} and Fe^{3+} are in octahedral co-ordination. However, a survey of the analysed epidote group minerals in the literature suggests that the Mn occurs in different oxidation states, most of it being octahedral but some also occupying some of the large cation sites (Hutton, 1942; Bilgrami, 1956; Cooper, 1971; Marmo et al., 1959; Short, 1933). This also seems to be the case of the Swat piemontite, if the formula is recalculated on the basis of 13 (O, OH) after adding 1.84% H, O to the analysis to give 1 (OH) in the formula $(\text{Ca}_{1.4}\text{Mg}_{0.01}\text{Mn}_{0.16}\text{K}_{0.01})(\text{Al}_{1.88}\text{Fe}_{0.50}\text{Mn}_{0.62}\text{Si}_{3.00012}(\text{OH})_{1.00})$. In this formula Mn is about four times as abundant in the octahedral site as in the large cation site and is in accordance with most of the earliest piemontite analyses (see Short, 1933). Cooper (1971) argues that bulk chemistry (especially oxidation state) rather than the metamorphic conditions controls the occurrence of piemontite. Further determinations of Mn_2O_3 and MnO contents of the piemontite-bearing rocks are needed to verify this, because, as pointed out by Cooper, most metamorphic occurrences of piemontite are in high-pressure or in high-pressure to intermediate-facies series terrains. The Swat rock seems also to have formed under high-pressure conditions. Apart from its closeness to the thrust fault and the glaucophane schist it occurs in a belt of schists that in places contain chloritoid, garnet, staurolite, and kyanite.

J/124. Jan, M.Q. & Tahirkheli, R.A.K., 1969. The geology of the lower part of Indus Kohistan (Swat), West Pakistan. Geological Bulletin, University of Peshawar 4, 1-13.

An area of over 450 square miles in Indus Kohistan, Swat, has been mapped and the detailed petrography of the rocks is presented. The area investigated is bounded by latitudes $35^{\circ} 15'$ to the north, and $34^{\circ} 45'$ to the south, by the Indus River to the east, and by the drainage divide of the Indus and Swat Rivers to the west. The predominant rocks in the southeast and south belong to the Lower Swat-Buner Schistose Group (Siluro-Devonian or possibly Ordovician). The Schistose Group is commonly represented by low grade quartzite, quartz-mica schists, amphibolites, marbles, calcareous schists, phyllitic schists, graphitic schists, and greenschists. These were intruded by ultramafic rocks (pyroxenites and dunites near Jijal; serpentinites near Alpurai, Jijal etc.) during the earlier phases of the Himalayan orogeny (middle to late Cretaceous). During later orogenic phases (early Tertiary), the area was intruded by the abundant Swat Granites and Granite Gneisses (generally leucocratic, two feldspar-bearing rocks) and pegmatite, and major gneissic granodiorites near Shang and Dubair. These events were followed by overthrusting of the (?Precambrian) Upper Swat Hornblendic Group which covers the northern and northwestern part of the investigated area. The Hornblendic Group is represented mostly by diorites, metadiorites, hypersthene gabbros, and garnet-amphibole gneisses.

J/125. Jan, M.Q. & Tahirkheli, A.Z., 1990. The Tora Tigga complex, southern Dir, NW Pakistan; an example of mafic-ultramafic rocks in the bottom of an Island arc. Geological Bulletin, University of Peshawar 23, 231-251.

The Tora Tigga complex comprises dunite, peridotites, pyroxenites, hornblendites, metagabbros and plagiogranite covering over 6 km area. It is located in the north of the Indus-Zangbo suture, in an extensive terrain of amphibolites that form the southern part of the Cretaceous Kohistan island arc. The ultramafic rocks are closer to those found in stratiform complexes than to oceanic peridotites and the metagabbros are calc-alkaline island arc-type. Chemical variation suggests that the rocks are magmatically related. They probably represent amphibolites facies metamorphosed cumulates in a magma chamber of the Kohistan arc. The hornblendites are medium-grained to pegmatitic, and range from small dykes, patches and pools to large bodies over 2.5 km in length. There are gradational lithologies to pyroxenites and peridotites in which

hornblende is replacive in texture; however, chemical data do not support a metasomatic origin for such rocks and the hornblendites.

J/126. Jan, M.Q., Weaver, B.L. & Windley, B.F., 1997a. Summarized petrology of the garnet granulites of the Jijal complex, Kohistan Himalaya. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, 28-29.

For more details consult the following account.

Key words: Petrology, garnet granulites, Jijal, Kohistan.

J/127. Jan, M.Q., Weaver, B.L. & Windley, B.F., 1997b. General petrology of the garnet granulites of the Jijal complex, Kohistan Himalaya, Pakistan. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 75-76.

The Indus Suture in northern Pakistan is the trace of the collisional boundary between Indian Plate and the Cretaceous Kohistan magmatic arc. A series of mafic-ultramafic rocks occurs in the hanging wall of the Suture. Of these, the Jijal complex (73°E, 35°N) is unique in several ways. This 150 km² tectonic block consists of a wide range of ultramafic to mafic rocks. The southern part of the complex is occupied by a 10x4 km slab comprising chromite-bearing dunite, peridotites and pyroxenites that are layered in many places. To the northeast of these, the main mass of the complex consists of garnet granulites derived from gabbros, tracholites, pyroxenites and anorthosites that too are locally well-layered. The mineral assemblages in these record granulite facies conditions at 10-15 Kbar, which may be, related to subduction of the complex some 105 Ma ago.

The garnet granulites display many assemblages, of which the most abundant is Grt-Cpx-Pl-Qtz-Rt±Hbl±Ep. Other include hornblendites (commonly with garnet±Cpx), garnetites (±Cpx±Hbl±Pl), garnet pyroxenites (±Hbl), garnet anorthosites (±Cpx±Scp), and retrograde assemblages some of which contain Zo+Ky+Pg. Thousands of mineral analyses have been performed with EPMA. In the ultramafic rocks, the olivine is Fo98-83, orthopyroxene is En91-78, clinopyroxene is diopside with low Al and Na, and chromite has a Cr/(Cr+Al)>0.6[1]. In the granulites, the phases show a wide variation, reflecting variation bulk chemistry.

Garnet consists of 14 to 68 mole% Prp, 23 to 58% Alm, 15 to 45% Grs, and low Adr (<5%) and Sps (<1.5%). Clinopyroxene ranges from Mg50Fe2Ca48 to Mg32Fe17Ca51, with up to 11.3 wt% Al₂O₃ and <2.5% Na₂O. Plagioclase ranges from An50-22, but a few more calcic compositions (up to An87) may be pre-metamorphic. Olivine (Fo85-75) and orthopyroxene (En86-67) occur in a few ultramafic members. Hornblende amphibole contains 14-20% Al₂O₃, moderate Na₂O (typically 2 to 3%), and low TiO₂ (mostly <1%). Paragonite ranges from P99-87, Epidote from Ps0-33, and scapolite from Me72-62.

Major and trace-element analyses of many dozen garnet granulites have been performed. A mantle-normalized multi-element diagram for some of the mafic members shows positive anomalies for Ba, Sr, P and Ti, and negative for Nb, Ce and Zr. These characteristics, especially the Nb and Sr contents and the overall shape of the spidergram, are typical of the subduction-related magmas. The peak and small Ce trough may be reflection some crustal input to the mantle derived magmas. The granulites display rather complex REE pattern but all show a positive Eu anomaly against chondrite. The mutual relationship of the ultramafic rocks and garnet granulites has not been deciphered as yet, but both display layering and probably represent cumulates related to the Kohistan arc.

In the upper structural levels near Patan, the granulites contain blocks of gabbro-norites apparently equilibrated in hornblende granulite facies (Pl-Opx-C0x-Hb). The blocks are traversed by dyke-like bodies of garnet granulite; however, the two lithologies show a gradual passage within a couple of centimeters. There is a perfect match in the major and trace element contents of the and we regard the gabbro-norite as precursor of the garnet granulite. It appears that the development of the garnet granulites due to increased pressure in lower crust accompanied the loss of H₂O (and addition of CO₂) along fractures.

J/128. Jan, M.Q., Wilson, R.N. & Windley, B.F., 1982. Paragonite paragenesis from the garnet granulites of the Jijal complex, Kohistan, N. Pakistan. *Mineralogical Magazine* 45, 73-77.

Chemistry of six white micas from the high-pressure garnet granulites of Jijal is presented, together with trace elements, refractive indices, and 2V, for one. The micas are rich in the paragonite component (over 93%), with one analysis having the highest 100 Na/(Na + K) ratio (98.5) so far reported. The paragonite is not a stable mineral of the granulites but was overprinted on the granulites at about 505-540 °C and 8-9 kbar (suggesting a depth of 30 km).

Key words: Garnet granulites, Jijal, Kohistan.

J/129. Jan, M.Q. & Windley, B.F., 1990. Chromian spinel-silicate chemistry in ultramafic rocks of the Jijal complex Northwest Pakistan. *Journal of Petrology* 31, 667-715.

The approximately 150 km² Jijal complex occupies a deep-level section of the Cretaceous Kohistan arc obducted along the Indus suture. The complex consists of mafic garnet granulites, and a > 10 km × 4 km slab of pyroxenites (diopsidite > websterite; ± olivine), dunite, and subordinate peridotite, all of which are devoid of plagioclase. These contain chromite either in lenses, layers, and veins or as disseminated grains. The chromite is mostly medium grained, subhedral to euhedral, shows pull-apart texture, and may contain inclusions of associated silicates. Chromite grains within thin sections of chromitite are generally homogeneous in composition, but dunite and pyroxenite samples commonly contain chromite grains of variable composition. The segregated chromite has higher Cr₂O₃ wt%, *cr*-number, and *mg*-number, and lower *fe*-number than the accessory chromite. These variations are mainly attributed to subsolidus exchange of Mg and Fe between chromite and associated olivine or pyroxene, and to inheritance from a magmatic source, but other factors may also be responsible. In general, the chromite grains are altered along margins and fractures to ferritchromite that is enriched in *cr*-number (and generally Fe³⁺, Mn, and Ti) and impoverished in *mg*-number compared with the parent grains. Chromian chlorite (clinochlore, penninite, with up to 7.3 wt.% Cr₂O₃) is commonly associated with the alteration, as is serpentine in most silicate rocks and some chromitites. The chlorite shows considerable compositional variation from grain to grain and in some cases within a single grain. Clinopyroxene is low-Al, -Na and high-Ca diopside. Orthopyroxene ranges from En₉₁ to En₈₂ and olivine from Fo₉₈ to Fo₈₄ (ignoring one analysis each). The *mg*-number of these minerals is higher in chromitites than in dunites and pyroxenites. Several aspects of the petrogenesis of the ultramafic rocks (e.g., the abundance of diopsidite) are not clear, but they seem to have passed through a complex history. The high *cr*-numbers (>60) in the chromite indicate that the rocks may have originated from some form of oceanic lithosphere-island arc interaction. Petrography and mineral compositional data suggest that the rocks are ultramafic cumulates derived from an arc-related (?primitive) high-Mg tholeiitic magma, possibly at pressures in excess of 8 kb. There also are small ultramafic bodies in the form of conformable layers and emplaced masses within the garnet granulites. These contain magnetite and pleonaste with < 10 wt.% Cr₂O₃, and less magnesian olivine and pyroxene than the principal ultramafic mass. These also have the characteristics of island arc plutonic rocks, but it is not clear whether the garnet granulites constitute a continuous sequence or are cumulates with the principal ultramafic mass or the two are produced from different source magmas.

Key words: Ultramafics, chromite, spinels, Jijal, Kohistan.

J/130. Jan, M.Q., Windley, B.F. & Khan, A. 1985. The Waziristan ophiolite, Pakistan, general geology and chemistry of chromite and associated phases. *Economic Geology* 80, 294-306.

The Waziristan complex, covering over 500 km², was tectonically emplaced during the Paleocene to early Eocene. It consists of ultramafic rocks, gabbros, sheeted dikes, pillow lavas, and pelagic sediments--a typical ophiolite suite. However, a complete sequence does not occur in any single locality due to tectonic dismemberment. The podiform chromitites consist of aluminochromite (Cr₂O₃ :49-61%) with subordinate

chromian chlorite and/or chromian serpentine + magnetite. In Cr-Al-Fe (super +3) + Ti space the chromites plot in the area of alpine chromites, but on other diagrams they overlap the fields of chromites from alpine and stratiform complexes. Many chromites are zoned with "ferrit-chromit" margins richer in Cr/(Cr + Al) and poorer in Mg/(Mg + Fe²⁺) than the unaltered cores. The chlorites are generally rich in SiO₂ and MgO and poor in Al₂O₃. It appears that during greenschist facies metamorphism (or alteration) diffusion of Mg, Al, and some Cr from the chromite margins toward the silicate matrix resulted in the development of ferrit-chromit and chlorite.

Key words: Ophiolites, chemistry, chromite, Waziristan.

J/131. Jan, M.Q., Windley, B.F. & Wilson, R.N. 1984a. Chromian andradite and associated phases in a chromitite layer in dunite from the Jijal Complex. Abstracts, First Geological Congress, Lahore, p.55.

Green chromian andradite associated with chrysotile occurs in a chromitite layer within dunite of the Jijal complex. The garnet contains over 10 % Cr₂O₃ and has the formula Ca_{6.13}Cr_{1.37}Fe_{3+2.53}Si_{5.94}O₂₄. The garnet formed during retrograde greenschist facies metamorphism of the Jijal complex. Analyses of chromite in the dunite and chromitite layers resemble those of high Cr chromite but their total Fe is a little higher. In contrast, the olivine is highly magnesian, with a ratio 100 Mg/(Mg + Fe²⁺) of about 96%. These features appear to have been caused by Fe - Mg exchange between the two minerals down to a blocking temperature of about 800° C.

Key words: Chromite, dunite, Jijal, Kohistan.

J/132. Jan, M.Q., Windley, B.F. & Wilson, R.N. 1984b. Chromian andradite and olivine-chromite relations in a chromitite layer from the Jijal Complex, NW Pakistan. Canadian Mineralogist 22, 341-345.

Green chromian andradite occurs associated with chrysotile in a chromitite layer within the dunite of the Jijal alpine ultramafic complex (northern Pakistan). The garnet contains on average 10.1 wt. % Cr₂O₃ (range 9.2-11.6%) and has a formula Ca_{3.04}(Cr_{0.67}Fe_{3+1.29}Al_{0.02})Si_{2.9}O₁₂. The garnet formed during retrograde greenschist-facies metamorphism of the Jijal complex.

Keywords: Chromian andradite, dunite, retrograde metamorphism, Jijal complex.

J/133. Jankovic, S., 1984. Metallogeny and mineral potential of northern Pakistan (North of Indus Suture Zone), A preliminary assessment. Geological Survey of Pakistan, Record 65, 25p.

The area of northern Pakistan situated north of the Indus Suture zone 9the Main Mantle Thrust – Tahirkheli, 1980) is a part of a global metallogenic belt - the Tethyan Eurasian Metallogenic Belt, formed at the southern margin of the Eurasian plate (Jankovic, 1976).

Owing to its remoteness and inaccessibility, the ore mineralization of Northern Pakistan has not so far been systematically investigated, either from a geological or a specifically metallogenic viewpoint. A previous tentative assessment of the mineral potential of the Northern Pakistan, predominantly south of the main Mantle Thrust, did not consider this part of Pakistan as particularly promising. 9Sillitoe, 1978). But recent discoveries of very significant lithium deposits of pegmatite type in Afghanistan, very close to the Pakistani border and tin and boron deposits (skarn type) in southern Pamir, USSR, as well as a regional metallogenic analysis, clearly indicates that the mineral potential of Northern Pakistan may be very promising.

The aim of this brief report is to draw attention to and emphasize the importance which Northern Pakistan, north of the Main Mantle Thrust, may have as a potential source of Li, Ta, Nb, Sn, W, Mn and Be as well as base metals and gold, and to point out the need and justification for a detailed and systematic investigation of this part of Pakistan.

J/134. Jaswal, T., 1990. Structure and evolution of the Dhurnal oil field, Northern Potwar Deformed Zone, Pakistan. M.Sc. Thesis, Oregon State University, Corvallis, 62p.

Key words: Structure, hydrocarbon, Potwar, Dhurnal.

J/135. Jaswal, T.M., Lillie, R.J. & Lawrence, R.D., 1997a. Structure and evolution of the Northern Potwar Deformed Zone, Pakistan. American Association of Petroleum Geologists Bulletin 81, 308-328.

The northern Potwar deformed zone (NPDZ) is part of the active foreland fold and thrust belt of the Salt Range and Potwar Plateau in northern Pakistan. About 500 km of seismic reflection profiles are integrated with surface geologic and drilling data to examine the deformation style and structure of the NPDZ with particular emphasis on history of deformation of the Dhurnal oil field. The seismic lines suggest that the overall structure of the eastern NPDZ is a duplex structure developed beneath a passive roof thrust. The roof thrust is generated from a tipline in the Miocene Murree Formation, and the sole thrust is initiated from the same Eocambrian evaporite zone that extends 80 km southward beneath the Soan syncline and Salt Range. The Dhurnal oil field structure is a pop-up at the southern margin of the NPDZ, and developed beneath the passive roof thrust. The passive roof thrust crops out just north of Dhurnal on the steep, northern limb of the Soan syncline. An overstep passive roof thrust (Sakhwal fault) is interpreted west of Dhurnal; this fault developed due to southward progression of the deformation front beneath the earlier passive roof thrust.

Very gentle basement dip and almost zero topographic slope in the NPDZ suggest that the Eocambrian salt provides effective decoupling at the present position of the NPDZ. The strong deformation in the NPDZ appears to have developed farther north, in an area where the evaporites may be lacking. Since 2 Ma, the NPDZ moved farther south over the evaporites without further deformation, whereas erosion removed any former topographic slope. Restoring a balanced cross section suggests that the minimum shortening across the NPDZ is more than 55 km. Assuming that this shortening occurred between 5.1 and 2 Ma, the shortening rate is about 18 mm/yr.

J/138. Jaume, S.C. & Lillie, R.J., 1988. Mechanics of the Salt Range-Potwar Plateau, Pakistan: a fold and thrust belt underlain by evaporates. Tectonics 7, 57-71.

The Salt Range and Potwar Plateau are part of the active foreland fold-and-thrust belt of the Himalaya in northern Pakistan. In this region the distance from the Main Boundary Thrust (MBT) to the front of the fold-and-thrust belt is very wide (100-150 km) because a thick evaporate sequence forms the zone of decollement. Recent studies have combined seismic reflection profiles, petroleum exploration wells, Bouguer gravity anomalies, and surface geology to construct cross sections in the eastern, central, and

western Salt Range-Potwar Plateau areas. In this study the sections are compared with a model that considers the mechanics of a fold-and-thrust belt to be analogous to that of a wedge of snow or soil pushed in front of a bulldozer (Chapple, 1978; Davis et al., 1983; Dahlen et al., 1984; Dahlen, 1984). Models which include the effects of evaporites at the base (Chapple, 1978; Davis and Engelder, 1985) suggest that these thrust belts will have (1) narrow ($< 1^\circ$) cross-sectional tapers, (2) larger widths than areas not underlain by evaporites. (3) Symmetrical structures, and (4) changes in deformational style at the edge of the evaporite basin. The section across the eastern Potwar Plateau most closely resembles this latter model, having (1) a taper of $0.8^\circ \pm 0.1^\circ$, (2) a width of 100-150 km, (3) thrust faults that verge both to the north and south, and (4) structures rotated 30° counterclockwise with respect to the Salt Range. From the observed taper and pore fluid pressures of the eastern Potwar Plateau, estimates of the values for the yield strength of the evaporites (τ_o) and the coefficient of internal friction of the overlying wedge (μ) are calculated as $\tau_o = 1.33\text{-}1.50$ MPa and $\mu = 0.95\text{-}1.04$, which are then applied to the other cross sections. In the central and western sections, a basement uplift, the Sargodha High, interferes with the front of the fold-and-thrust belt. This feature causes the ramping of the Salt Range Thrust end produces a relatively steep basement slope ($2^\circ\text{-}4^\circ$) beneath the Potwar Plateau. This dip, in the presence of the weak evaporite decollement, is sufficient to provide critical taper; no topographic slope is necessary, and the thrust wedge of the southern Potwar Plateau is pushed over the decollement without significant internal deformation.

The northern Potwar Plateau is strongly folded and faulted, yet the topographic slope remains flat. Although the deformation suggests that evaporites are not present there, the observed taper in the northern Potwar Plateau is best fitted by the model with evaporites at the decollement. Combining this with published paleomagnetic and geologic constraints, a model for the evolution of the northern Potwar Plateau suggests that the area deformed as a steeply tapered ($3.5^\circ\text{-}5.5^\circ$) thrust wedge until approximately 2 million years ago, when the southward propagating decollement encountered the evaporites. Between 2 Ma and the present the northern Potwar Plateau has been pushed along the salt decollement without deformation, and erosion has reduced its original steep topographic slope to a nearly level surface.

J/139. Javaid, A.R., 1984-86. The geology and mapping of Muzaffarabad area from Chehla Bandi to Chattar Kalas with special emphasis on building settlement and consolidation in Muzaffarabad City. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 63p.

Nearly 100 sq. km area has been mapped mainly East and East--West of Muzaffarabad (A.K.), at the scale of 1:10,000. This thesis is prepared with the aim to study the area in detail and to explore the reasons of building settlement and consolidation in Muzaffarabad. The stratigraphic succession has been established, lithological and structural discontinuities are marked. Structurally the area is complex. Since the area is on the core of Hazara-Kashmir syntaxis, some units of the rocks have been separated due to major thrust faults, among these Jhelum fault (between Hazara Formation and Murree Formation) and Muzaffarabad fault (between Abbottabad Formation and Murree Formation) are the biggest. An attempt has been made to evaluate and put forth the generalized idea about the bearing capacity on different terraces of Muzaffarabad city. The samples of different localities are taken for laboratory tests. The purpose of laboratory test is to evaluate the strength parameters which are responsible for settlement and consolidation. In this report, an attempt is made to explore the reasons of settlement in the area as well as remedial measures were suggested.

J/140. Javaid, M., 1992-94. Geology of Dubran Area, District Haripur with microfacies study of Langrial algal limestone. M.Sc. Thesis, Punjab University, Lahore, 131p.

Geological mapping of some 64 sq. Km area around Dubran in District Haripur has been carried out at the scale 1: 12500. The geomorphology, stratigraphy, structure, palynology and micropaleontology have been described. Stratigraphically a Mesozoic Tertiary sedimentary cover is overlying a Precambrian to Eo-cambrian basement of Hazara group now metamorphosed in the lower green schist facies. Numerous faults, high angle, reverse and normal have now disrupted the sequence. High angle north dipping Nathia Gali

Thrust is the main fault that passes through the area and has thrust the Precambrian Hazara Slates over the younger sedimentary sequence. Dubran syncline lying on top of a major anticlinorium makes an interesting structure.

J/141. Javed, H.J., 1985-87. Litho-structural mapping and Geology of Baragali-Kundla Area, District Abbottabad, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 183p.

This report gives an account of geological studies and lithostructural mapping carried out in Kundla-Bara Gali area. The prescribed area lies on both side of the road leading from Murree to Abbottabad. It is a mountainous region with fairly high relief. Litho-structural mapping of approximately 29 km² was carried out. The stratigraphic succession ranges from Hazara Formation (Precambrian) to Kuldana Formation (Eocene) with absence of Cambrian to Jurassic rocks. The lithology is mainly limestone, sandstone and shale. Extensive sampling was carried out and micro structural studies along with petrography of various rock units under the microscope from thin section of certain rock samples was also carried out in the laboratory.

A geological map is prepared on a scale of 1:7060 and two cross sections (AA' and BB') were drawn in order to interpret the regional structure and tectonic history of the area. The report also included the brief study of the rock units exposed in the project area. Major structures (folds and faults) lies in the project area are also discussed. Finally there is a general discussion about the source rocks, reservoir rocks (Hydrocarbon) and the economic importance of the rock units present in the project area.

Key words: Mapping, geology, Baragali, Abbottabad.

J/142. Javed, K., 1983-85. Litho-Structure studies of Fini-Bhirina-Paniali and Haddo Bandi Area, District Mansehra. M.Sc. Thesis, Punjab University, Lahore, 162p.

There is a specific relationship between the geological structures, landforms and the climate. This relationship can be worked out by qualitative as well as quantitative analysis of the topographic map. The most commonly exposed lithologies in the project area, are schist from chlorite to garnet grade, Susalgali granite gneiss, Mansehra granite, quartzites and hornfelses. The rocks of the project area have been classified into nine lithologic units for the sake of mapping purposes at a scale of 9.2 cm to km on 5.8 inch to a mile.

The area is deformed by different deformation phases, among which three are recognize on mesoscopic as well as microscopic scale and area is characterized by heterogeneous deformation. The rocks have been folded isoclinally and later being refolded into open folds.

The area lies in the zone of brittle deformation and show extensive fracturing instead of folding. Mesoscopic and microscopic deformational features are well developed in the area. The rocks exhibit effects of polymetamorphism. The thermal metamorphism is superimposed on the regional metamorphism.

J/145. Jawaid, A., Javed, A. & Pervaiz, M., 1983. Mineralogy petrology & economic geology with emphasis on mineral deposits of Besham-Lahor area Swat Kohistan. *Kashmir Journal of Geology* 1, 120.

Igneous and metamorphic rocks of the project area (longitude (E) 72° 50' to 72° 54' latitude (N) 34° 54' to 34° 58') represent the leading edge of the Indian continent underthrusting the Kohistan Island Arc. The mineralization described in this work are related to igneous and metamorphic rocks. Granite/pegmatite complex are of Pre-Cambrian age. Metamorphics of the area are correlated with Salkhala Formation, Tanawal Formation and poorly defined Thakot metasediments. In mapped area metamorphism of pelitic rocks ranges from chlorite to biotite grade, and rocks are named as biotite-chlorite-graphite schist, while quartzite and amphibolites are also present. They are folded metasediments and uplifted due to stresses during Himalayan orogenies. Sequences of folded metasediments was followed by the intrusion of Lahor granite/pegmatite. The Lahor granite/pegmatite has been assigned a mixed origin and is result of the processes of intrusion, anatexis and palingenesis of the country rock. The formation of this granite involves more than one phase of magmatic activity and granatization of the country rocks.

Oxides (magnetite, haematite) and sulphides (galena, sphalerite, molybdenite, pyrites) mineralization are associated with Lahor granite/pegmatite complex and metasediments. Oxides occur in skarns which were originated by the igneous/metamorphic activity (metasomatism). Late stage hydrothermal activity formed disseminated and vein mineralization of sulphides. The study covers the petrographic and ore-microscopic aspects. The evaluation of petrographic and ore-microscopic data of Besham Lahor area, shows its economic importance.

The lives of millions of people in most parts of the developing world remain at risk due to ruthless mining practices. Pakistan is not an exception. Asbestos occurs in association with talc and magnesite in the dunites and serpentinites of the Main Mantle Thrust (MMT) melange north of Peshawar Basin, in Mohmand and Malakand agencies and District Charsadda (longitude 71°35' to 71°55'E and latitude 34°25' to 34°30'N; Noor Jehan, 1996). It has formed as a result of metamorphic transformation of olivine in the presence of CO₂ (Hamidullah, 1984). It is mined, transported and crushed in the local crushing plants and sold as pure asbestos or as powder for the production of talcum powder and other industrial products to industries through out the country. In the primitive crushing plants, asbestos is crushed in the same or the nearby (5 feet away) grinder used for grinding grains for flour (Fig. 1).

A variety of studies were carried out on the geology, mineral chemistry, fibre size economics and environmental impacts of this asbestos and related minerals and rocks in the study area and its surroundings. Electron microprobe data (SiO₂=51.69%, MgO=45%, Al₂O₃=1.33%, FeO=1.33%, CaO=0.06%), XRD data (Table 1) and petrographic observations classify these asbestos minerals as chrysotile, antigorite and tremolite, with the former as the dominant type, and highly carcinogenic. The diameter (<0.3 micrometer) and length (>0.8 micrometer) of individual fibers also indicate these to be carrying sufficient inhalation properties. Enhanced occurrences of allergies of lungs, eyes and skin have been noted in the surroundings of the local mines and relevant industries in the area. Worker in these crushing plants are at the highest risk. Little or no precautionary measure are taken (Fig. 1). More than 200 patients were suspected for asbestos-related lung fibrosis in the Government Lady Reading Hospital, Peshawar. Among these, 50 were followed up and confirmed as suffering from malignant mesothelioma (99% due to asbestos). Several are dead now. Sixty seven percent of these patients belong to northern districts of the province from where asbestos comes (Dr. Arshad Javed, Personal Communication). We still have to sort out relationship between these patient and the local asbestoses.

The asbestos-bearing zone (MMT) extends west across the boarder to Afghanistan. Fine quality asbestos is found at Logar in Afghanistan. The MMT also extends east, through Pakistan and across the border through India (as the Indus Tzangbu Suture Zone), ending at Nepal. Thus the problem is regional and if not well taken care of in time, Afghanistan, Pakistan and India may be engulfed by the epidemic of asbestos related diseases in the near future. Some of the important recommendations suggested for mitigation of asbestosis and other related ailments in the light of the data obtained are: adoption of ventilation and water spraying procedures in all processes of mining, transportation and industrial use of asbestos; personal protection of labor and skilled worker; restriction on use of asbestos in the manufacturing of talcum powder; awareness, training and health and safety monitoring of the employees; implementation of international compensation laws and ultimately abandoning asbestos mining and industrial uses in the region.

J/153. Jehan, N., Hamidullah, S. & Ahmad, I., 1997. Economic and environmental study of asbestos from Skhakot-Qila ultramafics complex, N. Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

Economic growth must be accompanied by environmental assessment to ensure sustainable development. This paper describes the economics and environmental impacts of asbestos from Skhakot Qila ultramafic complex in the agencies of Malakand and Mohmand and the district of Charsadda at the northern and north western extremities of Peshawar valley. Asbestos is mined at Narai Ohe, Newe Kili, Behram Dheri, Qila Hero Shah and Bucha, and crushed and milled at Tangi, Newe Kili and Berlin, both in primitive and relatively modern crushing plants. From 35 mines in this area, only 15 were found in operation, each producing a truck of raw asbestos and other minerals weighing 10 metric tonnes and sold for Rs. 3000/- per truck. This process daily generates a total 150 metric tonnes of raw stuff and Rs. 45000/- as income in the area. Similarly the 8 crushing plants in the area crush 4 trucks of asbestos: each one sold for Rs. 6000/- and thus generating a total income of Rs. 24000/- per day. Asbestos from the study area has been, however, analysed and proved to be the carcinogenic variety (Noor Jehan & Hamidullah. 1997). No precautionary measures are, however, taken for protection from asbestos dust. (grains and asbestos are ground in the same or closely situated (5 feet apart) crushing machines. These machines dissipate dust to the village population in the surrounding and whole mining and crushing process has therefore, created a considerable environmental chaos in the area. People around the crushing plants have begun suffering from skin and eye allergies as well as asthma. The crushed asbestos is utilised in the production of talcum powder which is another environmental dilemma recently about 100 cases of mesothelioma have been registered in the Lady Reading Hospital. Peshawar, among these 60 are from the asbestos bearing areas. The paper recommends strict environmental laws to control the mining, crushing and industrial use of asbestos.

Repeated terrestrial stereophotogrammetric surveys have been used to make various maps. The glacier example quoted shows basic data requirements and presents standard techniques to study height variations of the surface, the terminus mass and ice movement. The results show that the system is a good method to determine glacial variations. However, when applying this techniques the orientation of each photo should be identical. In order to obtain reliable data, a combination of methods is necessary.

J/158. Jianming, C., Crompton, T.D., Walton, J.L.W. & Bilham, R., 1984. The survey work of the International Karakoram Project. In: Miller, K.J. (ed.), *The International Karakoram Project*, Volume 2, 124-139. Cambridge University Press. Cambridge University Press.

In 1913 a triangulation network was set up to connect the survey systems of Russia and India. This chain crosses the Karakoram a region of intense tectonic deformation. The southern section of the 1913 link was remeasured by the survey party of the International Karakoram Project with a view to detecting continental movement over the intervening 67 years. The fieldwork was completed successfully despite a number of setbacks including the death of one the team. The network has been analyzed in number of ways in order to find the best method for the analysis of possible deformation. Figural distortions have been detected and geophysical interpretation of these has been essayed.

The tills of the upper Hunza region include both lodgement and meltout types. Particle size analysis shows them to be relatively coarse-grained and somewhat positively skewed. There is evidence of modification of the particle size distribution by meltwater eluviation, especially in the case of the Ghulkin and Pasu glacier deposits but the role of bedrock lithology and glacier size is also discernible. Tills currently being deposited are predominantly of meltout type: these have diffuse fabrics, rather granular matrixes and contain evidence of eluviation and collapse. Re-deposition of the abundant coarse supraglacial debris by sliding under gravity is common. The thickest exposures of compact and sheared lodgement till, on the other hand, are of pleistocene age, especially those of the main valley (t 2), diffuence col (t 3) and expanded foot (t 4) stages. There is no evidence of direct deposition of till by viscous flow either during or since the Pleistocene although the abundant debris flows do contain glacial material. It appears likely that the present combination of high-activity glacial regimes and arid to semi-arid valley floor climatic conditions have prevailed since at least the beginning of the late Pleistocene. The distribution of the dense, jointed lodgement tills of Pleistocene age is consistent with their deposition in a generally free-draining environment beneath thick glaciers. The genetic classification of tills based on field relationships is generally confirmed by laboratory-derived data on particle size, particle shape, stone orientation and fabric.

Magnetic reversal stratigraphy and sedimentary tectonic history of the Upper Siwalik Group, eastern Salt Range and southwest Kashmir. In: Farah, A. & DeJong, K.A., (Eds.), *Geodynamics of Pakistan*. Geological Survey of Pakistan, Quetta, 149-165.

The upper Pliocene or lower Pleistocene interval of the Siwalik (Himalaya) molasses exposed in the Jhelum area, Pakistan, has been examined for lateral variation in depositional environment and rate of fluvial sedimentation. Stratigraphic sections measured through this interval at various localities in the Jhelum area are constrained by a magnetic reversal stratigraphy. Variations in the rate of molasses sedimentation appear to be related to large-scale tectonics in the northwestern Himalaya. Sedimentation rates increase towards the axis and apex of the recent structure indicating that the tectonic feature controlled the focus of molasse sedimentation during the sedimentation time. Sediments exposed in the Pabbi hills, Rohtas anticline, Chambal ridge, and the Mangla-Samwal anticline, each display variation of sedimentary/tectonic style as a function of their placement within the overall basin contour of the Himalayan foredeep.

Key words: Stratigraphy, magnetic polarity, Potwar, Siwaliks, Himalaya.

J/163. Johnson, G.D., Rey, P., Ardrey, R.H., Visser, C.F., Opdyke, N.D. & Tahirkheli, R.A.K., 1981. Paleoenvironments of the Siwalik Group, Pakistan and India. In: Rapp, G. & Vondra, C.F. (eds.), *Hominid sites: their geological settings*. American Association for the advancement of Science, Selected Symposia Series 63, 197-254.

This is a detailed account of the magnetostratigraphy, sedimentology and structure of the Siwaliks of central Potwar Plateau and a portion of adjacent Kashmir. Particular emphasis is placed on the alluvial character of the Chinji through upper Siwalik formations of the Siwalik Group. Descriptions are given for paleoenvironmental rationale; fluvial character of the stratigraphic succession; lateral variation in sedimentary style; fluvial cycle recurrence rate; development of the floodbasin stratigraphy; evidence of pedogenesis affecting the floodbasin stratigraphy; interpretation of the Siwalik paleosols; application to the Siwalik Miocene record; and Late Miocene Siwalik geochronology, environmental change, faunal implications and habitat. It is speculated "that sites recording favourable hominoid habitat from latest Miocene, Paleocene and Pleistocene age strat should lie to the east of in a more equitable portion of the environmental cline. As such, sites from the contemporary Nepali Siwaliks and further east may record the equitable hominoid habitat which was lost in the Potwar Plateau about six million years ago".

Key words: Paleoenvironments, Nagri, Siwaliks, Potwar, Kashmir.

J/164. Johnson, G.D., Zeitler, P.K., Naesser, C.W., Johnson, N.M., Summers, D.M., Frost, C.D., Opdyke, N.D. & Tahirkheli, R.A.K., 1982. The occurrence and fission-track ages of Late Neogene and Quaternary volcanic sediments in Siwalik Group, Northern Pakistan. *Paleogeography, Paleoclimatology, Paleoecology* 37, 63-93.

Volcanic sediments, now mostly bentonites and bentonitic mudstones, occur throughout the Late Neogene and Quaternary Siwalik Group of northern Pakistan. A number of these deposits have been dated by the fission-track method, utilizing zircon phenocrysts from these deposits, and provide the chronometric constraints upon which a paleomagnetic stratigraphy is developed for the Siwalik Group. Notable in the

occurrence of these altered tuff horizons is an apparent mode in their stratigraphic development from approximately 3.0 to 1.5 m.y. B.P. which coincides with the period of activity of the Dacht-e-Nawar volcanic complex of east-central Afghanistan. Fission-track ages of certain tuffs for critical areas of northern Pakistan are reported herein.

Key words: Fission-track ages, Neogene, Quaternary volcanics, Siwaliks.

J/165. Johnson, M.R.W., 1994. Volume balance of erosional loss and sediment deposition related to Himalayan uplifts. *Journal of Nepal Geological Society* 10, Abstract Volume, 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu, Nepal, 70.

The volume of sediment in the foreland basins, deltas and fans which are a consequence of the collision of India and Asia appears to require the removal of a vertical section ~35 km high if the sediments were entirely derived from the Himalaya. It is argued that this is implausible and that it is likely that the Himalayan hinterland (e.g. Karakoram and Tibet) was an important source of sediment prior to -20 Ma when significant Himalayan uplift commenced.

Key words: Sedimentology, erosion, deposition, Himalayan uplift.

J/166. Johnson, N.M., Opdyke, N.D., Johnson, G.D., Lindsay, E.H. & Tahirkheli, R.A.K., 1982. Magnetic polarity, stratigraphy and ages of Siwalik Group rocks of the Potwar Plateau, Pakistan. *Palaeogeography, Palaeoclimatology, Palaeoecology* 37, 17-42.

Six magnetic polarity sections have been established over the Potwar Plateau region of Pakistan, including the major stratotypes of the Siwalik Group. In all six sections the dominant feature of the magnetic polarity stratigraphy is a long normal polarity zone, which is contained within the Nagri Formation. This conspicuous normal polarity zone has been radiometrically dated at 9.5 ± 0.6 m.y., which identifies it as magnetic Chron 9. Radiometric dates for the Upper Siwalik Formation have also been used to identify the Chron 2-3 boundary in two of the sections. The magnetic polarity stratigraphy of three of the sections has been correlated securely with the accepted magnetic polarity time scale, so that the ages of the local stratigraphy are indexed accordingly. Based exclusively on data from stratotype sections, the Chinji Nagri and Dhok Pathan Formations have nominal age ranges of 13.1-10.1, 10.1-7.9 and 7.9-5.1 m.y. Age fluctuations on the order of 105 years may be anticipated for these formational boundaries within a radius of some 20 km of the designated stratotype. Mean sediment accumulation rates during the Chinji, Nagri and Dhok Pathan interval range from 13 to 52 cm/103 yr.

Essentially linear sediment accumulations are locally maintained over time intervals of several million years. The Chinji-Nagri lithofacies boundary marks a transition from slow to faster sediment accumulation over much of the Potwar Plateau, indicating a fundamental sedimentary-tectonic change at this time.

J/168. Johnson, N.M., Stix, J., Cervený, P.F. & Tahirkheli, R.A.K., 1985. Paleomagnetic chronology, fluvial processes, and tectonic implications of the Siwalik deposits near Chingji Village, Pakistan. *Journal of Geology* 93, 27-40.

A 2800-m section of Siwalik strata containing the stratotypes for both the Chinji and Nagri formation has been dated by magnetic polarity stratigraphy, and the observed polarity zonation has securely been correlated with the Chron 17-7 segment of the time scale. The base of the section is the base of the Kamlial formation, which occurs near the top of Chron 17 (18.3 m.y.). The Kamlial-Chinji formation boundary

occurs in the middle of Chron 15 (14.3 m.y.), the Chinji-Nagri boundary near the bottom of Chron 10 (10.8 m.y.) and the Nagri-Dhok Pathan boundary at the Chron 8-9 boundary (8.5 m.y.). The Siwalik deposits near Chinji Village consist of four distinct classes of fluvial cycles, each with a characteristics periodicity: a first order of 107 years, a second order of 106 years, a third order of 104-105 years, and a fourth order of 100 – 104 years. The river system responsible of Siwalik sedimentation flowed from west to east and had properties much like the modern Ganges River system. Sedimentation rates in the Chinji Village area increased gradually through time, going from 0.12 mm/yr in the Lower Siwaliks to 0.30 mm/yr in the Middle Siwaliks. At about 11 m.y. blue-green hornblendes suddenly appear in abundance in channel sands. The appearance of these hornblendes, accompanied with accelerated sedimentation, is the effect of uplift in the source area, specifically the Nanga Parbat region. The modern Chinji Village area is no longer a depositional site, but instead is involved in overthrusting, uplift, and erosion. As the Indian Plate has drifted north during the past 18 m.y., the Chinji Village area has been gradually transformed from a subdued karst topography into a major depositional center for Himalayan sediments and finally back into a sediment source area to complete a sedimentary cycle that has spanned some 20 m.y.

J/169. Jones, C.L. & Israrullah, 1968. Potential for potash and other evaporite mineral resources in West Pakistan. US Geological Survey/Geological Survey of Pakistan (IR) PK-46, 17p.

Reconnaissance examination of marine evaporites in West Pakistan has revealed a highly favorable resource situation with respect to anhydrite, and a potentially favorable position for potash and sulfur. Further work is needed to evaluate the preliminary interpretations made during the present study. The establishment of a potash resource organisation within the Mineral Resource Directorate of the geological Survey of Pakistan is proposed. The organisation would be concerned exclusively with the investigation of potash deposits in the Salt Range and adjacent parts of the Potwar and Indus Plains.

K/8. Kakar, S.K., Mian, S.B. & Khan, J., 1971. The geology of Jandul valley, Western Dir. *Geological Bulletin*, University of Peshawar 6, 54-73.

The geology of Jandul Valley consists of Palaeozoic metamorphic rocks of amphibolite facies, intruded by igneous rocks in Jurassic-Cretaceous times. The plutonic rocks consist of an earlier phase of diorites, granodiorites, and granites and an apparently later phase of norites, hornblendites, pyroxenites and peridotites.

The Mesozoic magmatism was followed by volcanic activity in the Tertiary times. These, consisting of andesitic and dacitic tuffaceous rocks, are intimately inter-bedded with fossiliferous metasedimentary rocks of phyllite grade. This phase is characterised by the intrusion of porphyry dykes, which were probably the main feeds at the time. This was followed by a phase of granite and diorite dyke intrusions. Next quartz and pegmatite veins formed, followed by a final stage of dolerite dyke intrusions. Extension sporadic copper-mineralization is associated with the volcanism.

Structurally, the region is complexly folded and faulted. The main bodies of the intrusive and extrusive rocks seem to be located along a thrust zone. At least three tectonic stages are discernible in the area.

Proceedings of the First South Asia Geological Congress, Islamabad, 1992. Hydrocarbon Development Institute of Pakistan, Islamabad, 354-357.

Tarbela Dam on the Indus River is a unique case for the Himalayan regions as a whole in that high quality pre- and post-impoundment seismicity data are available. A recently published analysis of post-impoundment data for nine years suggests that earthquakes in 20 km radial zone centered on the reservoir are suppressed when the reservoir levels are high and they reappear again during periods of low water stand in the reservoir. In this rectangular lake. We find that upper crustal faults deduced from published composite fault plane solutions for pre-impoundment earthquakes in the same radial zone could also be the seats of the earthquakes observed during periods of low water level in the reservoir. The importance of this case history for the possibility of reservoir induced seismicity at future sites of high dams in the Himalaya cannot be over emphasized.

K/15. Kaneda, H., Karim, T., Yoshida, M., Ahmad, M.N. & Ali, M., 1996. Ore mineralogy and geomagnetic anomaly of Kaldam Gol skarn-type copper ore, Chitral, northern Pakistan. Extended Abstracts, International Seminar on Paleomagnetic Studies in Himalaya-Karakoram Collision Belt and Surrounding Continents, November 20-21, 1996, Islamabad. Geosciences Lab, Geological Survey of Pakistan, Islamabad, 128-129.

The Kaldam Go1 copper orebody is located at Chitral district, northern Pakistan. Geology around the ore showing consists of alteration of shale and limestone belonging to Gawuch formation of Cretaceous age. At the southern area bordering on the Gawuch formation, acidic to intermediate igneous rocks are distributed widely. The ore mineralized zones occur along the boundaries between limestone and shale. Judging from the geologic feature and mineralogical observation of ore specimens, the copper ore showing can be considered to belong to a skarn-type deposit. Detailed mineralogical studies have been carried out by means of XRD, optical ore microscopy, and rock-magnetic method (Table 1).

Mineral species are divided into two groups, that is, one is primary minerals and another is secondary minerals: The primary minerals are classified into the following three assemblages: (1) magnetite-andradite-chalcopryrite-quartz, (2) clinopyroxene- quartz-calcite-chalcopryrite-pyrite, and (3) epidote-clinopyroxene-quartz-calcite-pyrite-sphalerite. In addition, the volcanic rocks which weakly skarnized and mineralized and highly silicified, show the mineral assemblage quartz-epidote-calcite-pyrite-chalcopryrite- sphalerite. These mineral assemblages and their zonal distribution reveal the feature of typical skarn-type ore. Secondary minerals occur replacing magnetite, chalcopryrite and occasionally pyrite. Maghemite and goethite are the most common minerals of supergene alteration after magnetite. Goethite also occurs replacing chalcopryrite.

Secondary minerals after chalcopryrite are covellite, chalcocite, cuprite, malachite and brochantite. Primary magnetite and secondary (supergene) maghemite are the main source generating strong geomagnetic anomaly around the ore mineralization zone, which makes possible to model the subsurface structure.

Dolerite dikes around the Peshawar plain intrude a sequence of rocks, ranging in age from Precambrian to Permian. It is implied that they were intruded during a regional episode of crustal distention in Permo-Triassic times. A study of dikes in Attock-Cherat range, in an area of about 80 km² shows that the dolerites are oriented E-W. The dikes reach upto 10x1000 meters in size and are locally more abundant. They are variably altered, and are classified into (a) sheared, (b) medium grained and (c) Coarse grained dolerites.

Chemically the rocks are quartz and hypersthene normative theollites of continental flood basalt affinities. The rocks are dominantly composed of plagioclase (An₄₈₋₇₁) enclosed ophitically in clinopyroxene. Quartz, magnetite and ilmenite are accessory phases whereas alteration in many rocks has led to the development of abundant epidote, calcite, clay, chlorite, and biotite. Complex grains of clinopyroxene containing domains of augite, ferroaugite, and pigeonite have been studied in detail. A temperature estimate within the range of 1050-1270° has been made for these rocks.

About 100 sq. Km area including the landslided parts was mapped to find out the possible solution of this hazard. The study was carried out to understand the landslide problems in the area. The Abhal landslide was studied in detail based on its large size and proximity to foot-tracks, residential buildings and land property. Presence of MBT, heavy rain fall, toe-cutting by river Jhelum, steep slopes and water seepages contribute to landsliding in the area. The principal types of failure in the area have been recognized as slumps, earth flows, rock fall or combination of these three types. Soil samples were collected from the slided areas to evaluate the engineering properties of soil that contribute the failure. It includes Atterberg limits, natural water content, specific gravity, plasticity character, compaction and swelling. To establish the causes of landslides all the information and field data were collected. The results suggested that the failure occur due to high swelling potential of soils, steep slopes and presence of active fault (MBT).

K/23. Karim, T., 1995. Preliminary results of study on genesis of Kumhar magnesite, Hazara, Pakistan. Proceedings of Geoscience Colloquium (Geoscience Lab, Geological Survey of Pakistan, Islamabad) 11, 181-188.

Out of fourteen lenticular bodies of magnesite ore in Kumhar, lens 1 and 2 are the biggest and have been studied in more detail. Total reserves are 6.2 million tons, (mt) and proved reserves of lense 1 and 2 are 2.98 mt with an average of 45% MgO. The magnesite may have formed due to hydrothermal activity. Solutions rich in Mg replaced Ca in the host dolomitic limestone of the early Cambrian Abbottabad formation and which resulted in formation of magnesite. Homogenization temperature of fluid inclusions, varying from 150° C to 350° C, suggests closed relationships of hydrothermal activity with magnesite mineralization.

Key words: Magnesite, Abbottabad..

K/24. Karim, T. & Kaneda, H., 1994. Kumhar magnesite ore mineralization, Abbottabad, NWFP., Pakistan. Proceedings of Geoscience Colloquium (Geoscience Lab, Geological Survey of Pakistan, Islamabad) 8, 5-36.

The stratigraphy of the Abbottabad area is given with brief descriptions of various rock formations. Kumhar magnesite deposit is composed of 14 lens shaped ore bodies. One of these has been studied in the field as well as by petrography, XRD, and DTA/TG analytical techniques. Fluid inclusions and geochemical studies have also been performed.

Based on fluid inclusion studies and the field evidence, it is concluded that the Kumhar ore deposit was formed by hydrothermal activities which caused the replacement of the host dolomitic rocks. In addition, the mineralogical features are as follow: (1) ore is consisted of magnesite, calcite, talc and small amount of quartz, (2) dolomite, the host rock, is weakly disseminated with secondary calcite, quartz and talc, and (3) talc usually occur at the marginal parts of magnesite ore body and in the dolomite near the magnesite body. The geochemistry of ore-forming fluids of the Kumhar deposit is quite similar to the one of hydrothermal vein type deposits based on the fluid inclusion studies. This suggests that the related igneous rocks exist necessarily in the near area. In this area, a lot of mineralized showings such as barite, soapstone, gypsum and Pb-Zn sulphides in addition to magnesite have been observed. In order to examine the mineralization in this area, the study of ore-forming fluids and related-igneous rocks should be carried out in more detail through the fluid inclusion studies.

K/32. Kausar, A.B., 1994a. Alteration study of Ca-Fe skarn at Markoi, Kohistan island arc, Gilgit, northern Pakistan. Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad 8, 37-56.

In the Kohistan arc, Northern Pakistan, small lenses of skarn formed in Jurassic (?) limestone and clastic sediments adjacent to the Cretaceous to Tertiary Kohistan batholith. This composite batholith includes the Barite monzonite pluton that hosts porphyry copper mineralization. The Markoi skarn replaces limestone and volcanic rocks in a zone 180 meters by 40 meters along the contact with the potassically altered pluton. The units enclosing the limestone and calcareous sandstone were extensively metasomatized, as were outlying intrusion of Kohistan batholith.

Skarn alteration is divided into eight mineralogical zones away from the pluton to limestone: (1) epidote-amphibole-chlorite zone (2) magnetite-quartz zone (3) epidote-biotite zone (4) epidote-amphibole (actinolite)-magnetite zone (5) epidote-amphibole zone (6) pyroxene-amphibole zone (7) feldspar zone (8) garnet-calcite zone. Alteration zonation is dominantly controlled by faults (?), fractures and sedimentary bedding and composition. The garnet-calcite and magnetite-quartz zones are exoskarn formed in limestone and calcareous sandstone, and the other six zones are endoskarn formed in intermediate volcanic rocks. The andradite molecule of garnet increases in the limestone side. The zoning in exoskarn is in part the result of decrease in the chemical potential of A_{12O3} towards the limestone, where the zoning endoskarn is attributed to a decrease of the chemical potential of CaO towards the pluton. Comparison of bulk chemical compositions in altered and unaltered limestone and calcareous sandstone indicates that alteration was accompanied by overall addition of SiO_2 , A_{12O3} , FeO and MnO and depletion of CaO and CO_2 ; addition of Cu, Pb, and Zn in the garnet-calcite zone. Skarn and ore minerals were formed in the sequence skarn minerals - magnetite - chalcopyrite - pyrite sulfides, and occur in the garnet - calcite zone.

K/36. Kausar, A.B., 1995b. Rare Earth Elements variation across the Kohistan batholith, Gilgit area: Their implications for batholithic petrogenesis. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

During a time span of approximately 70 to 80 Ma beginning in Upper Cretaceous / Lower Jurassic a sequence of plutonic rocks was formed in the middle to northern part of the Kohistan terrane known as the Kohistan batholith. Commonly arranged in elongate, arcuate batholithic belts along the southern margin of the Asian plate, these rocks are generally interpreted as the products of intra-oceanic island arc (?) which formed during episodes of convergence between the Asian and Indian plates. It is analogous to the Ladakh batholith in northwest India and the Gangdese batholith in the south Tibet (Heim and Gansser, 1939; Allegre et al., 1984; Searle et al., 1987). Investigations of how these batholithic rocks formed are fundamental to our understanding of the growth and evolution of the Kohistan terrane and of Kohistan batholith crust in general.

Individual plutons of Kohistan batholith range in lithology from gabbro to granite, which is also a characteristic feature of I-type granitoid batholith. There have been fewer attempts, however, to look at the origins of diversity among different intrusions within the same batholith. An important objective in the study of the Kohistan batholith is to establish how their characteristics are related to the tectonic environments in which they are formed. Extensive early studies (Pettersson and Windley, 1985; Pettersson and Windley, 1991) examined the systematic petrological and geochemical characteristics of these batholiths and established the plutonism and volcanism in a generally arc-related environment, but the exact relationships between components of the sequence are still speculative. Using our data and other published information we evaluate the relationships between the different rock units and this have revealed remarkable regularities of longitudinal trends and persistent regional asymmetries in petrological, geochemical, isotopic and geochronological characteristics from north to south in Gilgit area (Pettersson and Windley, 1985; Treloar et al., 1989; Pettersson, 1984; Pettersson and Windley, 1991). The asymmetries have gradients transverse to the structural axis of the batholith and therefore appear to bear some fundamental relationship to its origin. The purpose of this paper is focussed on the REE geochemistry of the major rocks of Kohistan batholith and Rakaposhi volcanics and is used to provide insights into the sources, generation and evolution of the batholithic magmas.

Regional Geology

The Kohistan block of northern Pakistan has been recognized as a Mesozoic intra-oceanic island arc and is sandwiched between the Asian and Indian plates (Fig. 1; Tahirkheli et al., 1980; Bard et al., 1980; Coward et al., 1982). During the collision, this arc was partially thrust under the Asian plate during 75 to 102 Ma, based on Rb-Sr ages of syn-collisional granitoids and then obducted onto the Indian plate. The resulting terrane exposes a virtually complete section from its ultramafic at the deepest to surface volcanic rocks through the crust of an oceanic island arc. The terrane is rimed on the north by the Main Karakoram Thrust (MKT) and is bounded on the south by the Main Mantle Thrust (MMT). South of the MKT are the metasediments of Yasin Group and then volcanic and

volcaniclastic rocks dominate the prebatholithic section along the northern flanks of the Kohistan block. The plutons of the Kohistan batholith were emplaced into thick metavolcanics to the north and metasediments to the south in the Gilgit area, which comprises the focus of this research. The Kohistan batholith followed by a succession of massive diorites and layered gabbros that comprise the Chilas lower crustal mafic cumulate complex. To the south of Chilas complex is the belt of banded amphibolite, amphibole schists and pelitic schists of the Komila amphibolites and are associated with intrusions of hornblende, diorite and anorthosite (Coward et al., 1987). South of the Kamila amphibolites is the deepest levels, basic intrusives occur with garnet-granulite facies assemblages indicating conditions of 670-790 °C 12-14 kbar (Jan and Howie, 1981) and they are considered to be either, a tectonic block from the deeper part of Chilas complex or a lower crustal fragment from an arc distinct from the Kohistan arc (Coward et al., 1987). The Jijal complex is bounded on the south by the MMT, marked in places by a mélange of blueschists, greenschists, piedmontite schists and serpentinites probably derived from the Kohistan arc.

Brief Review and Setting of Kohistan Batholith.

The Kohistan batholith, an arcuate-shaped intrusion measuring 2700 km along the southern margin of the Asian plate, is part of the Trans-Himalayan batholith. The batholith is a composite body made up of a juxtaposition of large plutonic units displaying major differences in age, mineralogical-chemical composition and tectono-metamorphic history. Plutons are generally a few kilometers to a few tens of meters in dimension, although internal intrusive units have only been well defined in a few detailed studies of specific bodies. The intrusions also vary in composition, e. g., tonalite to granodiorite (Matum Das pluton), quartz diorite (Jutal pluton), and monzonite (Barst, Dainyor, Manu Gah and Sakwar plutons). Lithological zonation was not observed in the portion of the complex observed in Gilgit area. The presence of internal boundaries on most outcrops is interpreted as the successive intrusion of relatively small batches of magma of varying composition. Petterson and Windley (1985) described at least 20 separate, discrete plutons in the Kohistan batholith. Their geochronology indicates a 70 Ma time span for the intrusions in the Kohistan batholith approximately from 100 to 30 Ma. Magmatic activity started during the Early Cretaceous (Rb-Sr whole rock isochron age of 102 ± 12 Ma for the early, deformed Matum Das pluton), and the last magmatic phase occurred in Neogene (muscovite K-Ar age of 20 Ma for the last Parri aplite/pegmatite). Petterson and Windley (1985) proposed that the batholith can be divided into three stages: first stage plutons, referred to as earlier deformed plutons; second stage plutons, referred to as undeformed plutons; and late stage plutons, referred to as layered aplite-pegmatite sheets which have been intruded into the first and second stage plutons. Based on paleogeography, petrology, and chemical composition, I have further refined and sub-divided the plutons in Gilgit area into two distinct magma series: the sodic series (low-K) is present to the north of the Nomal - Barit volcanic septum and both deformed and undeformed potassic series (medium- to high-K) lie to the south of this septum (Fig. 2).

The deformation of Rakaposhi volcanics and northern deformed plutons (Matum Das plutons) was accompanied by metamorphic recrystallization of igneous minerals from upper greenschist to amphibolite facies at 76 ± 6 to 82 Ma (Treloar et al., 1989). The southern deformed plutons (Barit pluton) were cooled through about 500 °C to 530 °C, the Ar-blocking temperature of hornblende at approximately 48 ± 1 Ma. Figure 2 indicates that from north to south there is a gradual cooling decrease in age of biotite Ar-Ar ages from 50 Ma to 20 Ma, which reflects more recent uplift and cooling through about 300 °C (the biotite Ar-blocking temperature). In contrast, the hornblende ages indicate a sudden break at the Nomal-Barit septum of the Rakaposhi volcanics which separates the deformed sodic series plutons from the deformed potassic series plutons. This septum suggests a fault between these two series, which more recently, has uplifted the southern block through the 500-530 °C isotherm at about 50-55 Ma, where hornblende Ar-blocking temperatures were achieved. Thus, the data suggests that uplift and unroofing was earlier north of the Nomal-Barit septum than to the south.

Tonalites and low-K granodiorites, the most common rock types in the sodic series, display a limited range in modal and chemical composition and have several unifying characteristics. They are feldspathic, containing 45-50 per cent unzoned andesine to oligoclase and 0-1 per cent alkali feldspar. Quartz contents are typically 15-25 percent. Biotite is the major mafic constituent with minor hornblende yielding colour indices of 8-12 for most. The southern portion (potassic series) of the Kohistan batholith is characterized by a diversity of lithologic types, with gabbro, monzodiorite, monzonite, quartz monzodiorite, and granodiorite joining minor tonalite as common rock types. Gabbro with only minor quartz is not transitional to the more felsic rocks, but forming apparently independent intrusive bodies. Plagioclase in the potassic series is zoned than that in the sodic, low-K rocks. The more distinctive petrographic feature of the potassic series is the presence of thick subhedral books of biotite with more hornblende, which contrast with the small anhedral books of biotite present in the sodic series. This suggests that the potassic suite magma had a higher water content, which has been shown to produce early hornblende and biotite crystallization in granite melting experiments (Naney and Swanson, 1980). In the southern ranges of Kohistan batholith, tonalite appears to drop somewhat in abundance, being supplanted by monzogranite.

Major and trace geochemical evidence indicates that the sodic and potassic series are compositionally distinct from one another. The most important geochemical variations are higher K₂O content and K₂O/Na₂O ratio at given SiO₂, and the higher concentration of the K-group elements (Ba and Rb) and of highly charged cations (Th and Zr) in the potassic series relative to those of the sodic series rocks. The sodic series contain little MgO relative to FeO (total Fe) ($\text{MgO}/(\text{MgO}+\text{FeO}) < 0.5$). The compositional gap between the two series is also visible with respect to Nb, Ce, Zr, and Nd (e.g., Petterson and Windley, 1991). These compositional variations cannot be explained in terms of simple fractionation/melt processes. The goals are to distinguish among different major petrogenetic processes and to limit the composition of the source region or parental melts as proposed four different sources for these plutons by Petterson and Windley (1991).

Sr concentrations in whole rocks show a well-defined increase southward across the Kohistan batholith, with a second-order dependence on rock type. Similarly Rb concentrations also show a well-defined increase from north to south but are dependent on rock type in the potassic series. Both Sr and Rb show a marked step at Nomal-Barit volcanic septum. A similar step has been noted for Sr isotopic compositions. Rb-Sr isotopic studies in the Gilgit area of the batholith have revealed systematic geographic variations in initial ⁸⁷Sr/⁸⁶Sr ratios of whole rocks which rises from 0.7039 in the north to more than 0.7049 in the south (Petterson and Windley, 1985).

REE Chemistry in Kohistan Batholith

Chondrite-normalized REE patterns of Rakaposhi volcanics, sodic and potassic series are presented graphically in Figure 3a,b. The Rakaposhi volcanics and sodic series have low total REE (8xchondritic abundances) leading to generally increase from La to Lu on a chondrite normalized diagram. In all these rock types REE patterns are flat with La/Yb ratios of 1.15 to 2. Only a few samples of volcanics show slightly higher La/Yb ratios 4 to 5. Rocks corresponding to potassic series have higher total REE contents (10x100xchondritic abundances) with higher La/Yb ratios (11 to 28). The slope of LREE is steep and linear and corresponds to the medium- to high-K orogenic andesites (Jakes and Gill, 1970; Gill, 1981). The REE patterns of the rocks fall naturally into two principal REE fractionation groups and this variation is transverse to the structural trends but generally parallel to petrologic and geochronologic properties of the batholith. The Barit-Nomal volcanic septum probably marks the discontinuous zone between the northern and southern regions and transition between them therefore appears to be abrupt.

One of the most surprising feature of the data within the northern region is that the Matum Das tonalite, which intruded into metabasites have the same overall REE pattern shape as the metabasites, but differ from them in having abundances in REE and no Eu anomalies. The flat REE distribution patterns are considered to be typical for mantle derived rocks from a MORB like source (Johnson et al., 1990) at relatively high degrees of melting without major crustal contamination. Garnet was not a residual phase because the heavy REE are not depleted. Such rocks typically occur in tholeiitic island arc basalts (e.g. Wilson, 1989). Southern regions plutons (potassic series) have nearly identical ranges in REE contents (Fig. 3b) with no Eu anomalies and cross-cutting each other near medium-REE. The single monzogabbro (sample KA-15) is somewhat more steeply fractionated across the heavier REE than the monzodiorites. Similar source rocks and similar conditions of melting in the source of the parent magmas should result in consistent ratios at least of some trace elements, as already shown for the REE. Compared to the nearly flat relatively heavy REE abundances of the northern region (sodic series) rocks, the fractionated REE patterns of the southern regions rocks (potassic series) require the involvement of a phase or phases that would preferentially fractionate as well as retain in abundance the HREE. The REE geochemistry of the southern regions of the Kohistan batholith differs from that of oceanic island arcs in the presence of strongly HREE depleted and fractionated magmas. The sharp break in lithological diversity between the sodic and potassic series is suggestive of a major modification or readjustment to phase equilibria controls on magma compositions.

The regional variation in REE from north to south in Kohistan batholith is marked by depletion in LREE in the sodic series; fractionation in middle to heavy REE in the potassic series; no Eu anomalies and an increase in Sr contents. A single condition which can appear to satisfy the above observations is a phase transition in the residual mineralogy of compositionally similar source materials; from a plagioclase-bearing gabbroic assemblage for the sodic series to garnet-bearing, plagioclase poor (garnet-amphibolite) assemblages for the potassic series (e.g., Gromet and Silver, 1987).

Platinum group elements occur in mafic-ultramafic complexes, in some cases in exploitable quantities. These noble elements have also been the subject of preliminary studies in the Chilas and Jijal mafic-ultramafic complexes of the Kohistan island arc. This is a detailed study of the mineralogy, chemistry, and petrology of the platinum group elements in the Kohistan rocks. They are associated with both silicate rocks and chromitites. For more information, see Kausar et al. (2001).

K/39. Kausar, A.B., 1999. Hydrothermal alteration and sulphur isotopic study of sulphide deposits, Gilgit area, Kohistan arc, Pakistan. *Geologica* 4, 1-32.

Sulphide mineralization in the Gilgit area is hosted in the Kohistan arc terrane, which is a tectonic block lying between the Asian plate to the north and Indo-Pakistan plate to the south. These ore deposit include volcanogenic massive sulphide at Jutial and possibly Garesh and porphyry copper at Nomal and Barit. At Garesh, two pyrite-rich (pyrite 3-5%) lenses occur within the volcanic stratigraphy. The alteration is marked by sericite-chlorite (plagioclase-destructive alteration) in the center and is surrounded by albite-hornblende-epidote-biotite (propylitic) within submarine mafic and silicic lavas and tuffs. Pyrite is both disseminated and in quartz veins, and is associated with slightly anomalous values of Cu, Zn, Pb, and Au (average values 47, 21, 18, and <1 ppm, respectively). The Garesh zone is interpreted as a hydrothermal feeder zone of a submarine volcanogenic massive sulphide. At Jutial one or two well-defined layers of massive pyrite (>80 vol. %) approximately 1-3 meter thick are strataform in the Jutial quartzo-feldspathic paragneiss derived from a greywacke sequence. Hydrothermal alteration intensity ranges from weak along the flank (up to 50 m), to intense in the massive sulphide zone, where the entire host rock has been altered to sericite-chlorite-quartz-pyrite. This inner zone is surrounded by semi-massive sulphide consisting of pyrite (20-40 vol. %). The outermost alteration zone is garnet-biotite-muscovite-pyrite. The Jutial prospect is hypothesized to be a Besshi-type volcanogenic massive sulphide with 11 ppm Cu, 15 ppm Zn, 8 ppm Pb and 31 ppm Co.

At Nomal, sulphide mineralization and hydrothermal alteration in the sodic Matum Das composite pluton is centered in the Nomal quartz porphyry. The hydrothermal alteration consists of a central mixed assemblage of sericite+chlorite+biotite+pyrite (potassic-sericitic) zone (300 m wide and 1800 m long), which passed outward into a garnet subzone and then into the propylitic alteration (albite-epidote-actinolite-chlorite-calcite). Pyrite is both disseminated and associated with quartz veins in the potassic-sericitic zone, which averages 85 ppm Cu, 45 ppm Zn, 15 ppm Mo and Au <0.2 ppm. The Barit copper porphyry occurs within the Barit pluton of the deformed potassic suite, and is associated with skarn in adjacent carbonate wallrocks at Markoi. Hydrothermal alteration is characterized by pervasive and widespread biotite-epidote-calcite-K-feldspar (potassic) and younger-fractured controlled sericite-chlorite-clay (sericitic) assemblages. Up to 0.2 wt. % copper occurs in quartz-chalcopyrite veins and stockwork fracturing and is associated with potassic alteration. Sulphur isotopic compositions of sulphide from all the prospects range from -1.01 to +3.6 per mil and are interpreted to indicate sulphur is primarily of magmatic origin.

K/42. Kausar, A.B., Picard, C. & Guillot, S., 1998. Evidence for high-temperature-pressure crystallization during early magmatism of the Kohistan arc, Northern Pakistan. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 91-93.

In the southern Kohistan arc, the Jijal ultramafic complex is commonly interpreted as an assemblage of alpine-type ultramafic rocks intruding garnet granulites (Jan & Howie, 1981) or as the remains of a magma chamber (Coward et al., 1987; Miller, 1991) that formed at the base of an immature intra-oceanic island arc in response to northward-directed subduction of neo-Tethys ocean lithosphere during Late Jurassic and Cretaceous. Located just north of the MMT, it was tectonically emplaced over the gneissic basement of the Indian plate at 50 to 45 Ma.

Jijal complex contains two distinct sections. The basal section is composed of ultramafic rocks consisting basically of layered dunites and pyroxenites. Pyroxenites display large variations in mineralogy and are subdivided into four mappable macro-rhythmic units: olivine clinopyroxenite, websterite which evolves to garnet websterite and garnet clinopyroxenite to the top. The upper section is mainly composed of banded garnet gabbro with small amounts of garnet hornblendites.

All the ultramafic rocks present cumulative textures. The LREE depleted chondrite normalized patterns of pyroxenites ($0.07 < (La/Yb)_n < 1.09$) are consistent with pyroxene accumulation. In the garnet gabbros chondrite-normalized patterns are more REE enriched and are slightly depleted to flat ($0.64 < (La/Yb)_n < 1.26$). Crystallization of olivine and pyroxene minerals in ultramafic section can account at least partially for the LREE enrichment in garnet gabbro as these rocks are resulting from crystallization of residual liquids ($Mg\# = 0.79$ to 0.71). MORB normalized trace element pattern for garnet gabbro shows negative Ta and Nb anomaly, similar to modern arc related basaltic to andesitic rocks. This consistent REE behaviour supports the operation of magmatic crystallization processes and lends confidence to the application of mineral/melt fractionations to the interpretation of the course of plutonic crystallization differentiation.

The mineral chemistry also indicates that the Jijal complex represents a magmatic sequence formed by successive fractional crystallization. The ferromagnesian minerals show large chemical variations in accordance with the lithological change in the series from dunite - olivine clinopyroxenite-websterite-garnet websterite - garnet clinopyroxenite to garnet gabbro. Mg content of olivine regularly decreases from Fo94 to Fo78. Clinopyroxene is also characterized by continuous compositional variation from $Ca_{48}Mg_{49}Fe_3$ in dunite to $Ca_{49}Mg_{33}Fe_{18}$ in garnet gabbro. Al and Ti contents of clinopyroxene increase with decrease of Mg numbers ($Mg/(Mg+Fe)$). Orthopyroxene probably crystallized late with Mg number 85 in the earlier stage to 76 in the later. The slight variation in garnet composition is characterized by $Al_{37}PY_{30}Gr_{29}SP_2Ad_2$ in garnet websterite to $Al_{43}PY_{33}Gr_{21}Sp_1Ad_2$ in garnet gabbro.

The presence of abundant olivine clinopyroxenite and websterite, mineral chemistry of these ultramafic-mafic cumulates, as well as the petrological and field data are not consistent with crystal-liquid fractionation of a primitive basaltic magma at low pressures. It is proposed on the basis of mineral chemistry, crystallization sequences, garnet-clinopyroxene thermometry that the basal sequence of the Jijal complex was crystallized from a melt at pressures >10 kb and equilibrated at temperatures of 1050 to 1100°C which is consistent with data of Irvine (1974) indicating conditions around 14 kb and 1180°C.

Garnet websterite indicates excellent evidence for the exsolution of garnet and orthopyroxene from original aluminous clinopyroxene. This formation of garnet is consistent with the relatively low HREE contents of the garnet pyroxenites. The appearance of clinopyroxene and orthopyroxene having very high Mg number (92 to 85) and the absence of plagioclase as early fractionating phases coprecipitating with forsteritic olivine (Fo94-85) point to a crystallization history at high-pressure.

Al-poor phases such as olivine and pyroxene at moderately high temperatures and pressures, has increased the Al contents in the residual basaltic magma. The onset of the crystallization of plagioclase as a separate cumulate phase is reflected in increased Al_2O_3 and CaO and concomitant fall in MgO in garnet gabbro. This represents the product of evolved magma at relatively shallow level. Such processes are common mechanism for island arc magma evolution at depth (e.g., Aleutian arc, Alaska).

K/43. Kausar, A.B., Picard, C., Takahashi, Y. & Mikoshiba, M.U., 2001. Petrology and platinum group elements group distribution in the Chilas igneous complex, Kohistan island arc, northern Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 4-7.

The Chilas igneous complex, a large plutonic body extending more than 300 km between Nanga Parbat and western Dir, is composed of several isolated outcrops of ultramafic-mafic-anorthosite associations (UMA), which are intruded by rocks of "Main Facies Zone" (formerly known as gabbro-norite association). The ultramafic-mafic rocks represent plutonic core of the Chilas igneous complex. The largest mass of UMA is Chilas ultramafic-mafic-anorthosite association, located east of Chilas and described in detail by Khan et al. (1989).

In this study, we will refer the Chilas ultramafic-mafic-anorthosite association of Khan et al (1989) as Thak Gab ultramafic-mafic-association (TGUM). The rock assemblages of the TGUM and as a whole Main Facies Zone (MFZ) do not show the effects of intense regional metamorphism but at few places ductile shear zones are exhibited. These shear zones in the MFZ are typically narrow, ranging from centimetres to tens of metres, and are heterogeneously distributed. These are often anastomosing, separating great masses of relatively undeformed gabbro-norite and pyroxene diorite and are more frequently seen in the southern part of the Chilas complex. Most of these shear zones are trending northeast-southwest, with steep northerly dip. East-west trending antiforms and synforms are observed, indicating a folded structure in the Chilas igneous complex.

The TGUM is composed mainly of cyclic units of ultramafic and mafic rocks and crops out in an area as large as 5 km². The ultramafic cumulate consists of olivine cumulate (dunite), associated with minor amount of olivine-clinopyroxene cumulate (wehrlite) and orthopyroxene-clinopyroxene cumulate (websterite). It occurs as 10 to 100 metres thick layers, alternating with thin layers of plagioclase-dominant cumulate. Plagioclase-dominant cumulate (two pyroxene gabbro) occurs as layered, several metres thick and develops on the olivine cumulate. Phase layering, resulting from the appearance or disappearance of a cumulus phase is a dominant feature of the TGUM. The heterogeneous mafic unit comprises of troctolite, anorthosite, olivine gabbro, gabbro and gabbro-norite. This unit has a number of ultramafic xenoblocks. At many places, gabbroic dykes and pockets are also seen in the ultramafic cumulates, whereas in some outcrops ultramafic dykes are seen in the gabbro. All the units from TGUM are enveloped by massive, uniform gabbro-norite.

The rock assemblages from the MFZ form at least 85% of the Chilas igneous complex and has a wide range of rock types, ranging from gabbro-norite, gabbro, diorite, opx-diorite, qtz-diorite, granodiorite to trondhjemite, with the main lithologies typically being gabbro-norite, gabbro and diorite. All these rock units are so complexly mixed that the contact relationship among them is difficult to decipher. Several lines of evidence from the MFZ support a transitional character from tholeiitic to calc-alkaline arc affinity. Major and trace element geochemistry, and MORB-and chondrite-normalized patterns from the Swat- and Indus-Valleys do not differ significantly. The samples are characterized by enrichment of LILE and negative Ta and Nb anomalies, which are similar to modern arc related basaltic to andesitic rocks. Differences between the samples, from the two valleys, occur mainly in the overall REE abundances and not in the shape of the patterns.

Low values in Mg#, Cr and Ni contents, together with rapid decrease in Ni and Cr with decreasing Mg# and increasing Zr abundance, implies that much of the chemical variation in these rocks may be attributed to the crystallization processes. Positive to negative Eu anomalies in the REE profiles for the basic to more evolved rocks indicate that fractionation has taken place during magma evolution.

Another aim of this study is to investigate the platinum-group elements (PGE) and Au distribution in the rocks of the Chilas igneous complex (TGUM & MFZ). The samples have been analysed at the Institut Dolomieu, Grenoble University, France by ICP-MS, after extraction by hydrolysis/reduction using SnCl₂ and collection onto Se-Te (Amosse et al., 1986). PGE concentrations are generally associated with chromitite and sulphide occurrences in ultramafic and mafic rocks within large layered intrusions (Stillwater, Bushveld), or in greenstone belts of komatiitic affinity (Naldrett & Duke, 1980). A silicate type environment is also defined, in which no sulphide or oxide is visible to the naked eye. This type of deposit raises new questions on the origin of PGE concentrations and broadens the exploration field in areas insufficiently explored to date. No sulphide phase and no chromite assemblages of large concentrations are known in the ultramafic and mafic rocks of TGUM and MFZ. However, chrome-spinel occurs disseminated throughout the pyroxenite, and in the dunite, where it is an intercumulus phase forming <1 vol. % in dunite of Thak Gab complex. Small concentrations of chromite occur in the form of thin layers (<5 mm thick layer) or streaks in the dunite and may disappear laterally within a few metres, but very rare in the pyroxenites.

In the Chilas complex, dunite from the TGUM, has total PGE concentrations between 14 ppb and 334 ppb, except for some Cr-enriched dunite which has 1002 ppb abundances. Pyroxenite has total PGE concentrations from 13 ppb

to 19 ppb and total concentrations of PGE in gabbro range between 6 ppb and 20 ppb. In Main Facies Zone, gabbro-norite shows total PGE concentrations between 8 ppb to 17 ppb. This complex has low PGE concentration that correlate with indicators of magma evolution (Mg/Mg+Fe). So the Chilas igneous complex is not likely prospect for stratiform-sulphide mineralization owing to the failure of these melts to reach saturation and these rocks hold little economic prospects.

To allow comparison between samples, analytical data have been normalized against mantle concentrations. Metal patterns from the TGUM reveal that dunite display slightly positively sloping (Pd/Ir=4 to 7), which exhibits relative enrichment in Ni and IPGE. In contrast, samples from the pyroxenite display more pronounced positively sloping metal patterns from Ir to Pt, which indicates their relative enrichment in PPGE (Pd/Ir=4 to 30). These metal patterns indicate that the PPGE and Cu were preferentially incorporated into more evolved rocks and imply relatively incompatible behaviour for these elements. Such incompatible behaviour of Pt, Pd and Au in these rocks is attested by their increasing abundances in more evolved rocks. An exception to this general trend involves the Pt-enrichment for the dunite sample from the TGUM. The observed enrichment particularly in Pt in dunite rock may be related to the precipitation of isoferroplatinum alloy. The factors responsible for the anomalous high Pt abundances in this sample are however poorly understood. The profiles of mantle-normalized Ni-PGE-Au-Cu values of mafic rocks of MFZ shows that all the curves follow a positive slope from Ni to Cu, disturbed only by a strong negative Pd anomaly in some gabbro and gabbro-norite samples. The overall depletion in IPGE and enrichment in PPGE is a pattern typical of fractionation.

The IPGE and Ni were strongly partitioned into the most primitive rock (dunite), which reflects the compatible behaviour of these elements. The good positive correlation between IPGE, Ni and Cr clearly indicates that olivine fractionation in combination with early chromite removal can explain the decrease in Ir and Ni values between primitive and more evolved rocks from the Thak Gab complex. It also accounts for the substantial negative IPGE anomalies on the mantle-normalized diagrams of the complex.

Clear similarities in PGE signature exist between the different lithological units of the Chilas igneous complex and this offers support to hypotheses that similar geochemical processes may have operated on or around these lithologies.

K/45. Kazmer, C., 1986. The Main Mantle Thrust zone at Jawan Pass area, Swat, Pakistan. M.Sc. Thesis, University, Cincinnati, 79p.

The Main Mantle Thrust (or the Indus suture) zone is a *mélange* bounded to the north by Kohistan arc and to the south by the Indian plate rocks. This work delineates and describes the lithologies in the fault-bounded *mélange*. The *mélange* contains components of the Indian plate, Kohistan, and mafic-ultramafic ophiolitic rocks.

Key words: MMT, Jawan pass, Swat.

K/46. Kazmer, C., Hussain, S.S. & Lawrence, R.D., 1983. The Kohistan-Indian plate suture zone at Jawan Pass, Swat, Pakistan. *Geological Society of America, Abstracts with Program* 15, p.609.

The suture between the Kohistan Arc (KA) and the Indian Plate (IP) passes near Mingora in Lower Swat. This suture was identified previously as a single thrust fault, the Main Mantle Thrust, where arc-related amphibolites were brought over IP garnet-grade metasediments. In fact, the suture is a complex zone of thrust slices and *mélanges* bounded by two low-angle thrusts.

The most complete section is exposed SW of Mingora at the Jawan Pass. There, KA amphibolites are thrust over the suture zone. The suture zone consists of two parts: an upper part of imbricate greenstones and meta-volcanics, and a thin band of pelitic mélange comprising rounded to phacoidal serpentinite, metavolcanic, and exotic carbonate clasts in a sheared pelitic matrix; and a lower part of ultramafic (UM) mélange comprising greenstone, schist, serpentinite, and soapstone clasts in a talc-carbonate matrix. The UM mélange is thrust over the IP metasediments. Retrogressive metamorphism and carbonatization has affected the suture zone rocks and the upper section of the metasediments. The UM mélange is emerald bearing at Swat Emerald Mine in Mingora.

Four phases of folding are recorded in the IP metasediments. The UM mélange is found in F2 troughs. Thrusting of the KA amphibolites and greenstones-metavolcanics, formation of the pelitic mélange, and emplacement of some clasts into the UM mélange post-date F3.

The suture zone at Jawan Pass results from obduction of the KA amphibolites over the IP metasediments. The lower ultramafic part was emplaced as a serpentinite mélange prior to F2. The upper greenstone-metavolcanic part was emplaced concurrently with KA amphibolite emplacement but prior to F4.

Study of aerial photographs, Landsat imageries and seismological data has revealed a large number of lineaments which appear to be active faults. Recent fault activity is discernible through offsets of the topography, deformation of Late Quaternary deposits, offsets of cultural features, seismicity, and historic records. Fifty three such active

faults and features have been mapped and described briefly. These faults comprise four main types: (a) transform faults that mark the western plate boundary of the Indo-Pakistan subcontinent; (b) strike-slip faults which occur mainly along the inner or eastern margin of the axial fold belt and which are mainly responsible for the formation of syntaxial bends; (c) thrust reverse faults which are commonly arcuate faults and traverse the zone between each set of sterile slip faults, and (d) traces of basement geofractures which appear as lineament of various dimensions.

This study demonstrates the use of Landsat imagery, supplemented by aerial photographs, regional geological maps and seismological data in the delineating active fault systems which would remain otherwise untouched.

K/55. Kazmi, A.H., 1984. Pleistocene ice age cycle in the Himalayas. *Kashmir Journal of Geology* 2, 79-82.

Extensive and repeated glaciation of the northwestern part of the Himalayas occurred during the Pleistocene. Godwin (1859) was probably the first to record evidence of Pleistocene glaciation in the Himalayas. Further studies have revealed well preserved outcrops of terminal moraines, ground moraines and associated fluvio-glacial cut wash and boulder and gravel deposits in the Jhelum Valley in Kashmir, in the Pir Panjal Range and in Poonch area which indicate that these localities have witnessed a series of four glacial and three interglacial epochs during the Pleistocene. Whereas the glacial moraines and related boulder gravels provide evidence for repeated glaciation, the interglacial periods were characterized by deep erosion and valley down-cutting as indicated by benches and rock terraces in the valley profiles.

K/58. Kazmi, A.H., 1997a. Precious and semi-precious stones of Pakistan. *Abstracts, National Symposium on Economic Geology of Pakistan*, Islamabad, 1 p.

Gemstones have been intimately linked with the ancient history of Pakistan and since the early civilizations of Mohenjodaro, Harappa, Gandhara and Taxila, they have been used as objects of adornment symbols of power and glory and as exchange in trade. Cutting and polishing of gemstones by traditional methods is an old craft in this subcontinent as evidenced from archaeological remains of these cultures.

During the early years of Pakistan, the gemstone resources in the country remained unexplored. However since 1958 several gemstone discoveries have been made in Pakistan and presently the known occurrences include actinolite, agate, Aquamarine, azurite, emerald, feldspar (moonstone), garnet, onyx marble, pargasite, pink topaz, quartz, rodingite, Peridot, ruby, rutile, serpentinite, spinel, topaz, tourmaline and vesuvianite. Out of these the more significant deposits comprise the Swat emeralds pink topaz of Katlang rubies in Hunza and Azad Kashmir. Hunza spinel peridot from upper Kaghan and mineral specimens from the gem pegmatites of the Karakoram and the High Himalayas. These deposits are briefly described in the paper.

K/60. Kazmi, A.H., 2001. Active faults and related high-seismicity zones in Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 33-34.

Active faults are earthquake generating faults that discernible through offsets of topography, deformation of Late Quaternary deposits, offset of cultural features, seismicity and historic records. Several active faults have been identified in Pakistan. They comprise four main types: (1) transform faults that mark the western boundary of the Indo-Pakistan Shield, (2) strike-slip faults along structural arcs, oroclines and syntaxes, (3) thrust and reverse faults between sets of strike-slip faults, and (4) basement fractures. As may be expected, the active faults overlap high seismicity zones and have caused moderate to severe earthquakes. In this study the major seismotectonic zones have been identified and may be summarised as follows:

Tirich Mir Seismic Zone. It covers a large part of the Hindukush in Pakistan and Afghanistan and is probably linked with the Akbaytal Fault in Afghanistan. Numerous 5-7 magnitude earthquakes with 100-200 km focal depth have occurred in this zone. Yasin Seismic Zone, Located on the M1KT near Yasin town, it has generated several 3-5 magnitude events with focal depths less than 50 kms, Hamran Seismic Zone. In Ghizar Range the Hamran Valley has experienced frequent earthquakes of 3-5 magnitude and <50-100 km deep hypocentres. No active fault has yet been located, though focal mechanism of some events indicates thrusting on NW trending nodal planes.

Indus Kohistan Seismic Zone (IKSZ). It is a NW-SE trending zone between MMT and Hazara- Kashmir Syntaxis. It occurs along a detachment zone and it generated the 1974 Pattan earthquake. Tarbela-Hazara Seismic Zone. Located 60 kms SE of IKSZ, it is characterised by an upper seismic zone (the Tarbela zone) comprising steeply dipping strike faults, and a deeper seismic zone (the Hazara zone), where the hypocentres cluster along a steep basement fault. Cherat-Margalla Seismic Zone. It covers the lesser Himalayan ranges and the southern part of the Peshawar plain. Several 3-5 and a few 6 magnitude events have occurred in this region. The MBT and a number of other active faults are located in this zone.

Sargodha- Shahkot buried ridge. Two portions of this ridge, one SW of Khushab and the other in Lyallpur-Jaranwala area are seismically active and fault-plane solutions indicate extensional faulting. Sulaiman Range Seismic Zone. It is characterised by left lateral active faults along eastern and western margins of the Sulaiman Range. Fault plane solutions suggest strike-slip faulting. Sulaiman Lobe Seismic Zone. Though the entire Sulaiman lobe is seismically active, two regions particularly exhibit high seismicity, contain active faults and have suffered devastating earthquakes. One of these is the Loralai- Mekhtar region where several 3-6 magnitude, shallow (<50 km) events are attributed to the active Mekhtar Fault. The other is the 25 to 50 kms wide and 250 kms long Harnai-Kingri arc, which has experienced 3-7 magnitude events related to Khalifat, Kohlu, Tatra and Kingri faults. Focal mechanism solutions indicate strike slip faulting. North Kirthar Seismic Zone. It covers the northern part of the Kirthar fold belt. It has been devastated by a few shallow (30-40 km) earthquakes centered on the Mach, Johan and Kirthar faults.

Quetta-Kalat Seismic Zone. This is a narrow, 150 kms long, high seismicity zone traversed by the active Bhalla Dor, Ghazaband and Chiltan-Takhata faults. Several shallow (5-15 km) events of 5-6 magnitude have occurred in this zone including the devastating 1935 Quetta earthquake. Chaman Fault Seismic Zone. It follows the N-S, 850 kms long, left-lateral, active Chaman Fault and extends from Kharan to Kabul. It produced the destructive earthquakes of 1892, 1975 & 1978.

Makran Coast Seismic Zone. It is a shallow, active subduction zone with high seismicity. Most of the events are offshore, where an earthquake of magnitude 8 occurred in 1945. It uplifted the ocean floor forming small islands and revealed an E-W trending active fault. Inland many 3-6 magnitude events have occurred in the Hoshab- Mashkai Valley, along the Hoshab Fault. Rann of Cutch Seismic Zone. In this zone the frequency of earthquakes is apparently not so high, despite the fact that it has experienced some of the most destructive earthquakes like the one in 1819, which revealed the Allah bund Fault, or the recent Bhuj earthquake. In the remaining areas of Pakistan, the seismicity is relatively low; diffused, and apparently not aligned with 'any particular tectonic feature. In parts of the Indus Plain, particularly in the fore-deep region several lineaments have been traced and shallow, low-magnitude teleseismic activity has been recorded. These may be related to the bending of the lithosphere or due to active basement faults.

K/65. Kazmi, A.H., Lawrence, R.D., Anwar, J., Snee, L.W. & Hussain, S.S., 1986. Mingora emerald deposits (Pakistan): suture associated gem mineralization. *Economic Geology* 81, 2022-2028.

Emeralds occur disseminated and in veins along fractures and faults in an ophiolitic mélange of the Indus suture zone. Quartz, calcite and limonite are post-emerald fillings; the principal host-rock is talc-chlorite-dolomite schist, the matrix of the mélange. The occurrence is unique; the source of Be is sought in beryl-bearing granite gneiss of the adjacent Indian plate.

K/66. Kazmi, A. H., Lawrence, R.D., Dawood, H., Snee, L.W. & Hussain, S.S., 1984. Geology of the Indus Suture Zone in the Mingora-Shangla area of Swat, N Pakistan. Geological Bulletin, University of Peshawar 17, 127-144.

In the Mingora area the Indus suture zone is largely composed of metamorphosed ophiolites and mélanges which have been wedged in between the Indo-Pakistan crustal plate and the Kohistan andesitic arc block. The Indo-Pakistan subcontinental sequence is made up of the twice metamorphosed Manglaur crystalline schists, the intrusive Swat granite gneiss, and the unconformably overlying once metamorphosed Alpurai and Saidu schists. The recognition of this unconformity requires major revision of the stratigraphic correlation of these units which were previously all considered to the Precambrian. Those above the unconformity are probably Phanerozoic, and the Saidu schist may be the local metamorphosed equivalent of the Indus flysch of Ladakh. The ophiolitic and related rocks of the Indus suture mélange group are subdivided into three separate units. The Shangla blueschist mélange is locally present in the north and represents a subduction complex developed adjacent to the Kohistan arc. The Charbagh greenschist mélange crops out in the center of the group and could be of either mid-oceanic island or island arc origin. The Mingora ophiolitic mélange is obduction complex. It is characterized by metamorphism to talc-dolomite schist and emerald mineralization.

K/67. Kazmi, A.H. & O'Donoghue, M., 1990. Gemstones of Pakistan. Gemstone Corporation of Pakistan, 146p.

Pakistan is emerging as an important country for occurrence of wide range of gemstones. This nicely produced volume provides a wealth of information supported by 72 coloured photographs, 24 figures, 19 tables and many references. Following introduction the book describes the composition properties and distribution of gemstones.

The gemstones deposits of Pakistan have been divided into those associated with the Indus Suture, the Karakoram Suture, pegmatite-related, hydrothermal veins related and others. Occurrence, physical and chemical data (where available) and other information has been provided for many of the gems.

Key words: Gems, precious stones.

K/69. Kazmi, A.H. & Qureshi, I.H., 1997. A brief review of depositional and deformational history of northern Pakistan during the Neogene. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, p.34.

Consequent to the India-Eurasia collision, the deformation, magmatism and metamorphism along the Indian Plate margin has occurred intermittently over a period of about 50Ma. The deformation and uplift of the Himalayan region has been most vigorous during the Neogene. The Neogene sedimentary sequence of Northern Pakistan contains clues to several episodes of spasmodic uplift and deformation. Recent sedimentological paleomagnetic and paleontological researches by several workers have provided a wealth of information indicating abrupt changes in lithology and paleocurrents, facies and provenance changes reflected in the mineral and rock fragment assemblages of sedimentary sequences, facies migration, changes in fluvial sedimentation rates, syndepositional unconformities, angular unconformities, tectonic rotation, folding and faulting of relatively young strata and major mammalian fauna turn over events. These are not isolated events. They have occurred in response to the uplift and deformation of the Himalayan region. Based on this data a tentative chronology of the uplift and deformation of the NW Himalayan region since the Early Miocene has been prepared and discussed in this paper.

Key words: Deformation, neogene, Northern areas.

K/76. Kazmi, A.H., Snee, L.W. & Laurs, M.B., 1998. Himalayan Emeralds: Geology and Genesis. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 93-94.

The known Himalayan emerald-deposits and showing are confined to the NW Himalayas and occur within a narrow, 450 km long belt that largely comprises the Indus suture rock-sequence. Emeralds occur at Gandao, Nawe Kili, Bucha, Pranghar and Kot (Mohmand Agency); Maimola and Mor Darra (Bajaur Agency); Shamoza, Mingora, Char bagh, Makhad and Gujar Kili (Swat District); Allai Kohistan (?); and Khaltaro (Gilgit District). Some of these deposits have been studied by a number of authors, mainly by Jan 1968, Jan et al., 1981, Kazmi et al., 1986, Kazmi and Snee 1989, and Laurs et al., 1996.

The emeralds occur in a region characterized by three major tectonostratigraphic subdivisions. North to South these are (1) the Kohistan magmatic arc sequence which has been faulted against (2) the Indus suture melange group and the latter had been abducted previously onto (3) the Indo-Pakistan plate sequence. The Kohistan rocks have no bearing on the genesis of emeralds. The Indus suture melange and the Indo-Pakistan hand, directly involved in the formation of the emerald deposits.

The Indus suture melange group comprises tectonic blocks of ophiolites, blueschists, greenschists, metavolcanics and metasediments in a matrix of sheared and variously metamorphosed fine-grained sediments and/or serpentinite. These rocks occupy the MMT zone between the Kohistan andesitic arc and the northern margin of the Indo-Pakistan plate. The latter contains Paleozoic and Mesozoic shelf sediments, unconformably underlain by Precambrian crystalline schists and Paleozoic granitic intrusions. This sequence is intruded by Tertiary granites. The emeralds occur in two distinct geological environments. Except the Khaltaro deposit, all others are suture associated and occur as disseminations or pockets in talc-carbonate-schists. The mineralisation is confined to faults or shear zones. Emeralds formed late in the history of the suture associated rocks after major deformation had been completed as they are nowhere crushed, stretched or otherwise deformed. Emerald mineralisation apparently relates to the final stages of the metasomatic alteration of the ophiolite melange to talc-dolomite melange. The absence of granitic or pegmatitic veins in the melange, presence of beryl pegmatites and tourmaline in the granitic rock near Kot and Pacha Fort and the occurrence of young (tertiary) leucogranites near Karora, Iram and Saidu (close to the suture zone) suggest that the mineralising fluids came from these youngest granitic rocks. Emeralds developed only in the Mingora melange which provided the chromium.

The Swat emeralds are among the most Cr-rich known (up to 2 wt% Cr₂O₃). They have higher Mg and transition metals and lower Al per ¹⁸O atoms than the pegmatite Khaltaro emeralds. They contain inclusions of actinolite, chromite, dolomite, enstatite, feldspar, gersdorffite, magnesite, mica and pyrrhotite. Fluid inclusions are generally two-phase (brine+CO₂- vapour). Homogenisation temperature ranges from 305 to 349°C and salinity ranges from nil to 20 eq.wt% NaCl. The host rocks (talc-carbonate schists) have ultramafic geochemical signatures (930-2520 ppm Cr; 980-2540 ppm Ni). Altered rocks near emerald deposits are locally enriched in Al, Si, Be, and REE reflecting the hydrothermal addition of a continental crust-derived component. Collision of the Indian and Asian plates along the Indus suture zone was an important factor in the genesis of the deposits because it juxtaposed sources of Cr (ophiolitic melange) with sources of Be (continental crust).

South of the Indus suture zone, the Indo-Pakistan plate sequence in the Haramosh Range, comprising Proterozoic schists and layered gneisses, hosts the Khaltaro emeralds. Emeralds occur in thin (0.1-1.0m) hydrothermal veins and granitic pegmatites occurring as sill-like body within garnet-mica schist. The pegmatites give ⁴⁰Ar/³⁹Ar muscovite date of 9.13±0.04 Ma. Emeralds are found mainly within thin (< 30cm) veins of quartz and tourmaline-albite and more rarely in pegmatites, near the contacts with altered amphibolite. The pegmatites are zoned, having an inner zone of biotite, tourmaline and fluorite with local albite, muscovite, quartz, and rare beryl, an intermediate zone containing biotite and fluorite with local plagioclase and quartz and an outer zone of amphibolite containing sparse biotite and local quartz. According to Laurs et al. (1996), the inner and intermediate zones experienced gains of K, H, F, B, Li, Rb, Cs, Be, Ta, Nb, As, Y and Sr, and losses of Si, Mg, Ca, Fe, Cr, V and Se. The outer alteration zone has gained F, Li, Rb, Cs, and As. Oxygen isotope analyses of igneous and hydrothermal minerals indicate that a single fluid of magmatic origin produced the pegmatite-vein system and hydrothermal alteration at temperatures between 550° and 400°C. The emeralds formed due to introduction of HF-rich magmatic-hydrothermal fluids into the amphibolite, which caused hydrogen ion metasomatism and released Cr and Fe into the pegmatite-vein system.

K/80. Keller, H.M., 1977. Magnetic polarity stratigraphy of the upper Siwalik deposits, Pabbi Hills, Pakistan. Earth and Planetary Science Letters 36, 187-201.

Over 1000 m of fluvial molasse, exhibiting a stable detrital remanent magnetization, is exposed in a mammal-bearing sequence in the Upper Siwalik Group of the Pabbi Hills, Pakistan. The magnetic polarity chronology reveals that the sequence records a time period of 2.6 m.y., extending from the early Gauss Normal Epoch into the Brunhes Normal Epoch. During this period, sedimentation rates increased upward in time from 0.25 m/1000 yr to 0.45 m/1000 yr. The sudden disappearance of red beds and a change in the lithoclastic composition of basal channel sands suggests that about 800,000 years ago the primary source area began shifting from the metamorphic terrane of the Himalayan Orogen to a more local sedimentary terrane on the folded margins of the Himalayan foredeep. About 500,000 years ago the anticlinal Pabbi Hills attained surface expression. Uplift continued at a minimum rate of 1 m/1000 yr.

A local Pliocene/Pleistocene boundary based on the Olduvai Normal Event is clearly recognized. Local fossil finds reveal that *Equus*, diagnostic element of the Pinjor faunal zone, appeared locally about 1.8 m.y. ago and that *Hipparion*, a faunal element of the Tatrot and earlier faunal zones, persisted locally until at least 3.0 m.y. ago.

K/81. Kelley, J., 1997. The significance of fossil hominoid discoveries from the upper Nagri Formation, Potwar Plateau, Pakistan. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, p.68.

Almost all of the fossil hominoid specimens known from the Siwalik Nagri Formation have come from a single locality, Y3 11. Y3 11 lies in the uppermost part of the formation and is dated approximately 10 m.y. based on magnetic polarity stratigraphy. It is the richest hominoid locality in the Siwalik Sequence of the Potwar Plateau; approximately 25% of all fossil hominoid specimens collected from the Potwar Plateau since Dehm's first expedition in 1939 have come from this locality. This total includes fully half of all the hominoid postcranial specimens recovered. All of the hominoid material from Y3 11 has been assigned to a single very large species of *Sivapithecus*, *S. parvada*, which is not definitely known from any other Siwalik locality. The *S. parvada* material has contributed significantly to questions concerning hominoid phylogeny and paleobiology. Postcranial remains reveal that large individuals of *S. parvada* were as large as female gorillas or male orangutans, and that body size sexual dimorphism was probably substantial. They also indicate that *S. parvada* was primarily a quadrupedal rather than a suspensory ape. This has raised questions about the relationship of *Sivapithecus* to the extinct orangutan, *Pongo*, established on the basis of craniofacial morphology. Juvenile specimens of *S. parvada* have permitted an estimation

of the overall rate of maturation in the species, based on the ability to calculate absolute ages at death using growth lines preserved on tooth germs. Maturation rate is one of the most fundamental biological attributes of a species and sharply distinguishes, for example, living monkeys and apes. *S. parvada* appears to have matured at approximately the same rate as living apes. The paleobiology of *S. parvada* is now more completely characterized than that of almost any other fossil hominoid.

K/82. Kemp, A.J. & Leake, B.E., 1975. Two hydrous-rich aluminous hornblendes. *Mineralogical Magazine* 40, 308-311.

Previous studies of aluminous hornblendes rich in aluminosilicates, $\text{Ca}_2\text{Mg}_3\text{Al}^{\text{vi}}_2\text{Si}_6\text{Al}^{\text{iv}}_2\text{O}_{22}(\text{OH})_2$, have shown that no natural amphiboles are known that closely approach this composition (Leake, 1971). From a careful scrutiny of about 1500 analysed amphiboles with at least Ca 1.00 in the half unit cell and from reanalysis of a number of perceptibly selected Al-rich samples, it was shown that the maximum possible Al^{vi} in natural amphiboles increased as Al^{iv} increased and it was suggested that the maximum possible Al^{vi} value in natural hornblendes when the half unit cell contained $\text{Si}_6\text{Al}^{\text{iv}}$ was not above 1.40 although the highest reliably determined Al^{vi} value known was only 1.35 (Leake, 1971). Subsequently Bunch and Okrusch (1973) have described a quite extraordinary iron-poor aluminous amphibole (with 22.6 Al_2O_3), which has $\text{K}_{0.16} \text{Na}_{0.54} \text{Ca}_{1.99} \text{Mg}_{3.35} \text{Fe}_{0.01} \text{Ti}_{0.16} \text{Al}^{\text{vi}}_{1.47} \text{Si}_{5.47} \text{Al}^{\text{iv}}_{2.26} \text{O}_{22.13}(\text{OH}, \text{F}, \text{Cl})_{1.87}$. One of the highly aluminous amphiboles described in this paper is from corundum-bearing amphibolite of timargara, Dir (see Jan et al., 1971).

A suite of Tertiary alkaline porphyritic microgranites and hybrid and peralkaline granite from northwest Pakistan is described, with six rock analyses (five of them new). The microgranites, an earlier group of which some contain garnet, have undergone metamorphism, lacking in the granites. The microgranites are shown to be precisely similar to those from the Shewa-Shahbazgarhi area, for which four analyses (two of them new) are presented, and related to a third group from Tarbela. The mineralogy of the rocks is discussed, with seven new analyses of aegirine, riebeckite, ferrohastingsite and astrophyllite, and X-ray determinations of the feldspar compositions. The granites are considered to be related to the undersaturated syenites and associated rocks of Koga, and a petrogenetic scheme for the alkaline province is presented, with a K/Ar age determination, tentatively deriving the source magma (quartz trachytic) from a Himalayan tholeiite.

K/86. Kempe, D.R.C., 1978. Acicular hornblende schists and associated metabasic rocks from North-West Pakistan. *Mineralogical Magazine* 42, 405-406.

A suite of unusual acicular hornblende schists is found at Warsak (34° 10' N. 71° 23' E.), some 30 km WNW of Peshawar, North-West Pakistan. The schists occur in association with sill-like masses of amphibolite facies meta-

igneous rocks, possibly a metamorphosed gabbroic and doleritic, dioritic, and granitic calc-alkaline series, and intrusions of alkaline granite and microgranite. These rocks lie within Palaeozoic metasediments and all are folded synclinally. The area was first described by Ahmad et al. (1969).

The rocks of the acicular hornblende schist suite (fig. 1) consist essentially of large, idioblastic hornblende crystals—comprising some 30–60 % of the rock—in a fine-grained granoblastic matrix of oligoclase feldspar with minor quartz, iron oxide, biotite, and rutile. The boat-shaped, blue-green hornblendes, twinned on {100}, reach 5 mm in length and are often grouped in sprays or clusters; they are sieved with quartz, ilmenite, and patchy calcite. The groundmass also contains patches and veins of calcite, associated with ragged patchy areas of reddish brown, amorphous iron oxide or hydroxide, perhaps introduced hydrothermally. The schists coarsen in grain size outwards through the sill-form, the hornblendes reaching 4 cm, become rich in chlorite and biotite, and grade into the apparently metagabbroic amphibolitic rocks.

The acicular hornblende schists have a generally basaltic composition, while the hornblendes are tschermakitic. An analysed amphibole has 16.5% Al_2O_3 , is slightly zoned with alumina increasing from core to rim, and has the formula: $\text{K}_{0.06}\text{Na}_{0.50}\text{Ca}_{1.90}\text{Mg}_{2.13}\text{Fe}_{1.49}^{2+}\text{Mn}_{0.02}\text{Fe}_{0.14}^{3+}\text{Ti}_{0.04}\text{Al}_{1.16}^{\text{vi}}\text{Si}_{6.31}\text{Al}_{1.69}^{\text{iv}}\text{O}_{21.97}(\text{OH},\text{F})_{2.03}$

Three hypotheses of the origin of the rocks were considered; metamorphism of a suite of basic tufts is the most favoured. Origins involving metamorphism of a lamprophyre-appinite suite or of a gabbroic marginal facies are therefore rejected. Texturally the rocks strongly resemble metatuffs (fig. 2) that occur associated with metagreywackes in the Otago schists of New Zealand (Turner, 1933); like many similar Alpine schists they also contain tschermakitic hornblendes. The Warsak tufts could have formed originally, together with the meta-igneous rocks, possibly as lavas, in an inter-plate tectonic environment; the high Al content of the hornblende, which is typical of many amphiboles from the surrounding alpine environment in North-West Pakistan, and other mineralogical evidence in the region support a high pressure environment for the metamorphism of the rocks to just within the amphibolite facies, at moderate temperatures of approximately 465 °C.

K/88. Kempe, D.R.C., 1983. Alkaline granites, syenites, and associated rocks of the Peshawar plain alkaline igneous province, NW Pakistan. In: Shams, F.A. (ed.) *Granites of Himalaya, Karakorum, and Hindu Kush*. Institute of Geology, Punjab University, Lahore, Pakistan, 143-169.

Alkaline rock complexes are distributed in a semicircle around northern half of the Peshawar plain, NW Pakistan. Stretching west to east for over 200 km, they occur in eastern Afghanistan, Mohmand Agency, Khyber Agency, Warsak, Malakand, Shewa-Shahbazgarhi, Koga-Ambela unit, Tarbela and possibly Mansehra. The rocks, which are described, include alkaline granites and microgranite, albitites, syenites, carbonatites, and silicocarbonitites, intruded generally along fault zones into mainly Early Paleozoic metasediments. They are thought to be associated with rifting, caused partly by relief tension or compression release perhaps during very Late Cretaceous or Early tertiary times, following contact between the Indo-Pak plate and the island arc(s) or southern continental margin of the Eurasian plate.

Key words: Alkaline granites, syenites, carbonatites, Peshawar plain alkaline province, NWFP.

K/89. Kempe, D.R.C., 1986a. A note on the ages of the alkaline of the Peshawar plain alkaline igneous province, NW Pakistan. *Geological Bulletin, University of Peshawar* 19, 113-119.

The available ages published for the alkaline rocks and carbonatites of the Peshawar Plain alkaline igneous province are reviewed, with no new data, and briefly discussed. Repeated magmatism has apparently occurred, over the period ca 315 to 31 m.y. ago, due to rifting and the development of thrust planes.

K/95. Kerrick, D.M. & Caldeira, K., 1995. Himalaya-Karakoram metamorphic CO₂ degassing and Cenozoic paleoclimate: Revisited. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

Kerrick and Caldeira (1993, 1994) proposed that CO₂ generated by metamorphic decarbonation during post-collisional metamorphism in the Himalayan orogenic belt may have contributed to the Eocene greenhouse global warming. The validity of their hypothesis depends upon the timing and duration of prograde metamorphism, the amount of metamorphic CO₂ generated at depth from CO₂ source rocks (i.e., carbonate-bearing protoliths), and the flux of CO₂ to the Earth's surface. Their hypothesis requires that prograde metamorphism was contemporaneous with the late Paleocene-early Eocene warming (ca. 55-45 m.y.).

Recent geochronologic evidence for the timing of prograde metamorphism suggests that early Cenozoic metamorphism was confined to the Himalaya and Karakoram in northern Pakistan (i.e., west of the Nanga Parbat syntaxis). Here, carbonate rocks that enjoyed early Cenozoic metamorphism are abundant in the Swat region, Kaghan Valley and southern Karakoram. Following the methodology outlined by Kerrick and Caldeira (1993, 1994), the amount of metamorphic CO₂ produced from these rocks was estimated from bulk-rock compositions and computed decarbonation reaction progress from modal estimates of calc-silicates. Locally there are tremolite-bearing metacarbonate rocks that produced as much as 20 wt % CO₂. However, in the abundant siliceous carbonate rocks of the Kaghan Valley and southern Karakoram, the limited average modal amounts of calc-silicates (<5 vol. %) implies that less than 5 wt. % CO₂ was produced from the bulk of the metacarbonate rocks. At the present level of exposure, metacarbonate rocks occupy less than 10 vol. % of the Karakoram range and Pakistan Himalaya. Coupling this volumetric estimate with average reaction progress, and estimates of the duration of prograde metamorphism based on the timing of collision and geochronologic data, the amount of metamorphic CO₂ generated during the Paleocene-Eocene metamorphism was <1018 moles/m.y. Even with a large crustal permeability, this amount of CO₂ would be insufficient to substantially contribute to the atmospheric CO₂ content and thus to Eocene global warming.

Geochronology data suggests that prograde metamorphism in the central and eastern Himalaya (i.e., Zaskar and eastward) coincides with mid-Miocene global warming. The small proportion of metacarbonate rocks in this region (< 5 % of the Higher Himalayan Crystalline Sequence) suggests insignificant metamorphic CO₂ production from such lithologies. However, in light of the volumetric proportion of metapelitic rocks in this region, coupled with average carbonate and organic carbon contents of pelitic protoliths, the computed amount of CO₂ generated from metamorphism of pelites (>1018 moles) could have contributed to the Miocene paleoclimate. Widespread Miocene metamorphism in the other parts of the Tethyan orogen could have also generated significant metamorphic CO₂.

In Himalayan-Karakoram-Tibet region there were large "pulses" of extrusive and intrusive magmatic activity correlative with the Eocene and Miocene global warming. However, estimates of the volumetric extent of the intrusive and extrusive rocks, coupled with data on the CO₂ contents of magmas, implies that the amount of magmatic CO₂ produced from this region would not have significantly contributed to the atmospheric CO₂ contents during these time periods.

Of all metamorphic belts worldwide, the Cordilleran belt in western North America is the best (and probably only) candidate for climatically significant metamorphic CO₂ degassing during the early Cenozoic. Based on convective hydrothermal circulation modeling, Nesbitt, Mendoza and Kerrick (1995) concluded that Cordilleran metamorphic CO₂ production in the early Cenozoic may have been 1018 -1019 moles/m.y. and thus sufficient to have significantly contributed to paleoatmospheric CO₂ contents at that time.

Based on our preliminary compilation of the volumes of magmatic rocks through time, coupled with estimates of the CO₂ contents of magmas, we conclude that magmatic CO₂ degassing has been a significant factor in the global carbon cycle and a major contributor to paleoatmospheric CO₂. The global cooling in the last 100 m.y. is compatible with diminished volumes of igneous rocks through this time period.

Key words: Metamorphism, CO₂ degassing, paleoclimate, Cenozoic, Himalaya, Karakoram.

K/96. Kerrick, D.M., Caldeira, K. & Kump, L.R., 1993. Paleoatmospheric consequences of CO₂ released during Tertiary regional metamorphism in the Himalayan orogen. Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 37-38.

Fluxes of metamorphic CO₂ to the atmosphere have been suggested to be climatically important (Fyfe, 1986; Varekamp et al., 1992; Touret, 1992). Using an overly simplified model of decarbonation of a 1 km-thick carbonate layer, Fyfe (1986) concluded that atmospheric CO₂ content could have been significantly affected by the Tertiary Himalayan orogenesis. However, the validity of the suggestion that metamorphic CO₂ has significantly affected the atmosphere critically depends upon a number of factors; i.e., duration of prograde metamorphism, abundance and composition of CO₂ source rocks, and escape of CO₂ to the Earth's surface. The Himalayan orogenic belt affords an excellent case study for analysis of these variables in determining the quantities and fluxes of CO₂ released by metamorphic decarbonation and graphitization.

The Eocene was the warmest epoch of the Cenozoic, with published estimates of Eocene atmospheric CO₂ content ranging from two to six times the current value. The Early Eocene (50-55 Ma) global warming may have been produced by the greenhouse effect arising from elevated CO₂ contents. Our calculations of CO₂ consumption by silicate weathering show that metamorphic CO₂ releases of Ca. 1018/Ma could readily account for inferred Eocene atmospheric CO₂ contents and, consequently, Eocene warming.

Because of the lack of evidence for Eocene metamorphism in the central and eastern portions of the orogen, we focused on Eocene metamorphism in the western portion of the orogen (i.e., Zaskar and westward). Duration of prograde metamorphism was constrained by the timing of the India-Tibet collision (50-65 Ma) and the peak of prograde regional metamorphism (ca. 40 Ma). Due to lack of published estimates of the proportions and bulk compositions of metacarbonate and graphitic lithologies in the western Himalayan orogen, we coerced selected colleagues (J.A. DiPietro, M.S. Hubbard, K.P. Hodges, and M.P. Searle) into providing "guesstimates" of the proportions of such lithologies. In our computations we assumed marl as the model metacarbonate source rock and that 5wt % of CO₂ was released during prograde metamorphism (Ferry, 1982). With a conservative assumption that carbonate rocks constitute ca. 10% (by volume) of the western Himalayan orogen (J.A. DiPietro, M.P. Searle), and that CO₂ was generated at a constant rate during the prograde event, we estimate that ca. 1019 moles/Ma of metamorphic CO₂ were produced at depth. Assuming 0.5% (by volume) of carbonaceous lithologies, CO₂ released from the graphitization of carbonaceous material is estimated to be Ca. 1018 moles/Ma. These calculations assumed that CO₂ was linearly released during prograde metamorphism; however, because extensive devolatilization of marls and carbonaceous lithologies occurs during progradation through the lower greenschist facies (Ferry, 1982; Labotka et al., 1988), CO₂ production may have been two to four times more rapid than these estimates.

The possibility of escape of metamorphic CO₂ to the atmosphere is indicated by the global correlation between the distribution of major zones of seismicity and carbon dioxide discharged from hot springs (Barnes et al., 1978). Release of metamorphic CO₂ to the atmosphere would have been impeded by retrograde carbonation and carbonate vein formation in the shallower (lower grade) portions of the orogens. However, in light of large fluid/rock ratios, significant expulsion of CO₂ to the atmosphere may have occurred by focused fluid flow along the Main Central Thrust (MCT) in the Himalayan orogen. Transient expulsion of large amounts of metamorphic volatiles is expected to have accompanied seismic activity along the MCT.

Geochronologic analyses reveal a remarkable similarity in peak metamorphic ages (40-50 Ma) for many areas within the Tethys and Circum-Pacific orogens, thus supporting the concept of a major, world-wide Eocene regional metamorphism. This metamorphic culmination was contemporaneous with increased Eocene atmospheric CO₂ and associated global warming. World-wide Eocene regional metamorphism could well have generated ≥ 1020 moles CO₂ /Ma at depth. Even if only 1% of the total metamorphic CO₂ produced escaped to the Earth's surface, there would have been significant paleoclimatic consequences.

K/97. Khadim, I.M., 1995. Magnetic minerals in red beds of Murree Formation, Barsala area, Azad Kashmir: A preliminary study. In: Khadim, I.M. & Yoshida, M. (eds.), *Rock Magnetism and Paleomagnetism. Recent Progress in Pakistan*, Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad, 13, 43-57.

Ferromagnetic minerals contained in red beds of Murree Formation are examined by optical microscopy, thermomagnetic analysis, dual frequency susceptibility measurement, hysteresis loop analysis, and IRM acquisition experiment. The major carrier mineral for ferromagnetic properties of the rock is hematite but a trace amount of goethite is also identified. The red bed is rather inhomogeneous in population of magnetic minerals; some specimens contain iron sulfides, such as pyrite and troilite. Laboratory heating often formed secondary minerals, magnetite (Ti-poor titanomagnetite) and hematite, which are probably decomposed products of the multistage and/or Fe-bearing

minerals by laboratory heating. Goethite is probably a product of weathering. The presence of hematite may prove Murree red bed to possibly maintain the primary remanence component which can be used for paleomagnetic study.

K/98. Khadim, I.M., Ahmad, M.N., Yoshida, M. & Hussain, I., 1996. Magnetic susceptibility variation of granitoid in the Kohistan-Ladakh island arcs, northern Pakistan. Extended Abstracts, International Seminar on Paleomagnetic Studies in Himalaya-Karakoram Collision Belt and Surrounding Continents, November 20-21, 1996, Islamabad. Geosciences Lab, Geological Survey of Pakistan, Islamabad, 109-111.

Magnetic susceptibility data of rocks is extremely useable for the interpretation of geomagnetic data, assessing mineral potential and classification of rock type based on magnetic mineralogy. With particular reference to granitic rocks, a classification depending upon constituents magnetic mineral has been suggested by Ishihara (1977) as magnetite-series and ilmenite-series which provide sufficient information on assessment of mineral potential of the host rocks. The present study accomplishes susceptibility data along main traverse of Karakoram Highway in Kohistan island arc and along Gilgit-Skardu road, Satpara-Deosai track, Shigar, Kharmang, and Khaplu valleys in Baltistan area in the Ladakh island arc. The observation points along KKH were located about three kilometers apart but different exposures of geological units were also measured (Ahmad et al., 1995) while in Ladakh arc mainly granitic rocks and other associated rocks were measured.

The northern Pakistan is divided into three major terrains, Indo-Pak subcontinent (Indian Plate), Kohistan (on western side) and Ladakh (on eastern side) island arcs and Karakoram block (a part of Eurasian continent). There are two major collision zones in this area: the northern Main Karakoram Thrust (MKT) zone and southern Main Mantle Thrust (MMT) zone.

Kohistan island arc between MKT and MMT is a fragment of Mesozoic intra-oceanic island arc sandwiched between the Eurasian and Indian Plates (Tahirikheli et al., 1980) while the Ladakh terrain is bounded by the Shyok suture zone (MKT) to the north and the Indus suture zone (MMT) to the south. The Ladakh terrain is dominantly composed of granitic rocks of the Ladakh batholith and is variously known as Kohistan batholith in Pakistan (Searle, 1991).

Kohistan arc is divided into four major units from north to south, which has been considered to represent a complete sequence of island arc crust. The northern upper most part of the sequence is comprising metasediments and metavolcanics. Phylitic slates and metavolcanics of this upper most part has very low susceptibilities, $0.1 - 1 \times 10^{-3}$ SI. The first horizon in the north is Kohistan batholith, which comprises granites, granodiorite and diorite and susceptibilities of the granitic bodies in the lower part of the batholith show values $< 1 \times 10^{-3}$ SI except the upper part of the batholith. The next Chilas Complex is consisting of ultramafic to mafic igneous rocks: dunite and gabbro and show high values ($2-5 \times 10^2$ SI), while gabbro and diorite show low values ($< 1 \times 10^{-5}$ SI). The third is Kamila Amphibolite which mainly comprises of metamorphosed amphibolites situated between Chilas and Jijal Complexes. This expresses quite low susceptibility (8×10^{-4} SI).

The lower most unit, the Jijal complex consisting of garnet granulite, pyroxene granulite and serpentine facies. The granulites reveal low susceptibilities but serpentine yields highest value ($> 8 \times 10^{-2}$ SI). The above results clearly show two values of susceptibilities over the granitoids along Kohistan arc (KKH). This study led to measure the susceptibilities over granitic rocks in Ladakh island arc. Here main six sections were measured. On Satpara-Deosai traverse, metasediments and Kohistan-Ladakh batholith exhibit variable character towards susceptibility. Ladakh batholith, comprising of undifferentiated granites, granodiorite and quartz diorite relatively shows higher susceptibilities ($3.5 \sim 10 \sim$ SI) while metasediments show 1.2×10^2 SI. Metasedimentary rocks include greenschist, slates and phylites. In Shigar valley, rocks of Ladakh batholith and Shyok suture zone show high values to moderate (1.8×10^{-1} SI and $4.0 \sim 10^{-1}$ SI). Shyok suture zone rocks include highly deformed, folded and thrust sequence of greenschist facies volcanic rocks, limestones, shales, conglomerates and quartzite. Recent alluvium exhibits very low susceptibilities.

The Ladakh batholith on Kharmang valley traverse repeats high values (2.3×10^{-2} SI) while Chalt Volcanic group rocks indicate low values ($< 3.0 \times 10^{-4}$ SI). The Chalt Volcanic group comprises subaerial and submarine volcanic arc lavas, tuffs and volcaniclastic sediments, metamorphosed to greenschist facies.

The Gol-Saling and Khaplu road profiles were along the Shyok River: the first on the right bank while latter on the left bank. The rocks are almost identical across the river. Ladakh batholith, on the Gol-Saling profile, reflects

generally high values reaching to 2.7×10^{-2} SI while on Khaplu road profile, it reaches to a maximum 4.7×10^{-2} SI whereas the most of the values range in $4-10 \times 10^{-3}$ SI.

Most of the part of the Skardu-Gilgit Road is covered with low susceptibility rocks such as Iskere gneiss, composed of layered quartz-feldspar-biotite-muscovite gneiss, probably orthogneiss with rare meta-sedimentary layers, showing very low values ($<1.0 \times 10^{-3}$ SI). Similar attitude is observed by Nanga Parbat-Haramosh gneisses. They are Precambrian basement gneisses and Paleozoic sedimentaries intruded by Cambrian granites. There are two high values observed across Ladakh batholith ($0.9-3.0 \times 10^{-2}$ SI) and gabbro (-2.4×10^{-3} SI) Metasediments again show very low values ($<1.0 \times 10^{-3}$ SI).

These results clearly show two major types of granitic rocks in the Ladakh arc. one that carrying high susceptibilities (magnetite-series, values $>3.0 \times 10^{-3}$ SI) and the other possessing low susceptibilities (ilmenite-series, values $<3.0 \times 10^{-3}$ SI). There are two regimes of granitoids in northern Pakistan. Kohistan island arc is abundant in ilmenite-series granites while magnetite-series granites are more common in Ladakh arc. The magnetite-series granites might be produced because of relatively reducing environments related to the subduction along the collision belt. The present study recommends further mineral potential oriented research studies should be taken in these island arc areas.

K/100. Khadim, I.M., Yoshida, M., Ahmad, M.N. & Shirahase, T., 1997. Magnetic susceptibility variation of granitoids in the Ladakh arc, Baltistan, northern Pakistan, and surrounding terrains: Its implications for mineralization assessment. In: Khadim, I.M., Zaman, H. & Yoshida, M. (eds.), *Paleomagnetism of Collision Belts*. Geoscience Laboratory, Geological Survey of Pakistan, Islamabad, 73-83.

Low-field magnetic susceptibility was observed for the granitoids and associated rocks in the eastern Ladakh arc, Baltistan area, northern Pakistan. These results were compared with previously reported magnetic susceptibility data of granitoids obtained from the Karakoram block of Asian plate, Kohistan arc, and Indo-Pakistan subcontinent. The granitoids in Karakoram block and Indo-Pakistan subcontinent generally show low susceptibility values, thus relating to the ilmenite-series. Similarly the granitoids in Kohistan arc mostly give low susceptibility values of ilmenite-series except the northern part of Kohistan batholith which shows high susceptibility values indicating, the effect of magnetite-series. On contrary, the majority of granitoids in Ladakh arc marks considerably high susceptibility values which are related to the magnetite-series. This discrepancy between two terranes is probably related to different type of magmatism for each island arc in the Cretaceous-Tertiary time.

Key words: Granitoid, magnetic susceptibility, Kohistan, Ladakh, island arc.

K/101. Khalid, A., 1981-83. *Geology of Northern Hunza*. M.Sc. Thesis, Punjab University, Lahore, 94p.

This report describes the results of the geological studies in Passu area Upper Hunza Valley, Gilgit Agency.

A geological map on scale of 1:250,000 is prepared with main outcrops of granodiorite, limestone, dolomite and slates. The micro-paleontological description of the area is brief, as there is no findings of any fossil by us in given area. The petrographic analysis of these rock units is reported in detail. The petrogenesis (Texture, Mineralogy General description) of these rock units have also been discussed.

Along with the petrographic description the tectonic evolution of Karakoram, stratigraphy and structure of the Karakoram, paleogeography is also discussed. Regional (Lower grade) metamorphic has produced slates from shales and fine-grained dolomite as well as limestone. It is assumed that fossils have been crystallized due to metamorphism. Intense tectonic disturbance is evident from the frequent occurrence of strained and crushing effects on the minerals. The area shows the evidence of extensive mountain glaciation in the Quaternary and glacial deposits are common features due to the presence of huge glaciers.

This paper presents a geological map, petrography and structure of about 160 sq. km of Deshai-Diwangar area, Swat Kohistan. The area consists of metasedimentary rocks (? Paleozoic to Mesozoic), intruded by Tertiary Plutonic igneous rocks. The plutonic rocks consist of gneissose-quartz diorites, orbicular diorites, and quartz diorites of Early to Middle Tertiary period. The Early Tertiary gneissose quartz diorites are intruded by Diwangar Granite (? Middle Tertiary). Locally, small granitic intrusions and veins of a later age than Diwangar Granite are irregularly distributed in the area. Pegmatites and aplites are associated with all types of rocks.

Structurally the area is not very complex. A main fault runs along the Ushu Valley and is older than the Diwangar granite.

K/108. Khaliq, A., 1997. Orientation studies for gold and precious metals in Chitral area, Hindu Kush Ranges, Northern Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

To find out the best methods for geochemical exploration of gold and precious metals in Karakoram. Himalaya and Hindu Kush. an orientation study based on different sampling techniques. was conducted around the known gold prospect at Shagor in Chitral, N. Pakistan. This study demonstrates that panned-concentrates give superior anomaly/background contrast compared to wet-sieved and dry-sieved stream sediments. In the case of gold, panned-concentrates are not very successful in the present situation because of the presence of fine-grained gold. which

cannot be recovered in panning. However, for other metallic minerals it is very effective. Wet-sieved stream sediments samples give more useful results.

The effectiveness of panned-concentrates in detecting the mineralization is due to the dominance of clastic dispersion and insolubility of many metallic minerals in the cold alkaline river waters. Wet and dry sieved sediments suffer from excessive dilution by silicates. Therefore, panned-concentrates should be used for regional surveys in the mentioned and similar terranes. Nevertheless, panned sampling should be accompanied by wet-sieving if fine-grained gold search is involved.

K/109. Khaliq, A. & Ahmad, J., 1997. Hydrogeochemical prospecting for uranium in Peshawar Basin. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

A reconnaissance hydrogeochemical survey for uranium search was carried out in the intramountain Peshawar basin. Stratigraphy of sediments filling this basin is not known due to the Pleistocene alluvial cover. Nevertheless, marginal stratigraphy indicates that the alluvial cover is underlain by sediments equivalent to the sediments of Siwalik group since Siwalik group contains sandstone type uranium deposit, a hydrogeochemical survey was undertaken in the basin for comparable mineralization.

A total of 683 groundwater samples were collected from tube-wells from the entire basin at an average of one sample per 4 sq.km. Analytical results of these samples reveal that besides containing high uranium anomalies at Charsadda, Mardan and Swabi the groundwater of Peshawar basin has generally a high uranium (9pph) background value. Moreover, from the close association of uranium with Cu and V, the signature of sandstone type uranium deposits was recognized which probably registers the presence of Siwalik group and/or equivalent sediments beneath the alluvial cover of Peshawar basin.

K/113. Khaliq, A., Moon, C.J. & Ahmad, J., 2001. Pyrite-gold-uraninite association in Indus Basin, Gilgit Kohistan, northern Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 17-18.

The association of pyrite, gold and uraninite is found in Indus basin and most of the major rivers and their tributaries in Gilgit area of Kohistan, including the Hunza valley north of the Indus suture zone. This association is similar to

the mineralization in the Witwatersrand Basin of South Africa, which has been extensively studied and is the best example of paleo-placer gold uraninite deposits (Khaliq, 1991). However, in the Kohistan area of northern Pakistan and in the Indus basin this system has not yet been studied systematically. In this work an attempt has been made to study and examine the factors controlling the dissolution of uraninite and assess its stability as a detrital mineral in recent alluvial sands of the Indus basin. Moreover, the probable sources of pyrite-gold-uraninite assemblage have been discussed.

The distribution of radioactivity, percentage of pyrite and number of gold flakes in different rivers and streams in the region were studied chemically using SEM on panned concentrate samples.

The concentration of pyrite varies in different valleys and some valleys such as Bagrot, Pisan, Shamshal and Hasis valleys (Ishkuman) contain > 45 % pyrite in panned concentrate samples. Pyrite is mostly fresh and occur as euhedral cubes but there are also some grains showing rounded margins, corrosion and alteration. The microprobe study, of pyrite grains from Bagrot valley, shows some high values (several hundred ppm) for gold (Khaliq, 1991).

Gold flakes have different shapes (rounded, tabular, ellipsoidal and irregular) and sizes (<1 mm to >6mm) which probably show different distances they traveled from their sources. Investigations indicate that the radioactive material consists mainly of thorium-uraninite with lesser uraninite, and monazite grains (Khaliq, 1991 and Khaliq & Moon, 2000). Grains of the radioactive minerals are very fresh and show well-defined crystal faces, some have cubic forms with little evidence of corrosion. However, there are few grains which show rounded margins and corrosion. As far as the size is concerned, they are in the very fine-to fine range of the sand size.

K/115. Khaliq, A., Moon, C.J. & Khattak, M.U.K., 1997b. Regional geochemical prospecting for minerals in Chitral, northern Pakistan. Geological Bulletin, University of Peshawar 30, 191-207.

A comprehensive regional geochemical survey was carried out in Upper Chitral area. This survey was based on panned concentrates sampling techniques, during which a total of 68 samples were collected from most of major rivers and their tributaries covering an area of more than 1000 km².

The aim of this geochemical investigation was to determine metals dispersion, their relation to mineralization, and regional distribution in the drainage system of the area. Our research reveals that Chitral area has a high potential for mineralization. Some valleys contain polymetallic anomalies while others have either precious or base metals.

Strong anomalies of precious and base metals, together with As and Sb were detected in the northernmost part (Tirich Gol valley) of the surveyed area in which the respective ranges of Au, Ag, As, Sb, Cu, Pb, and Zn are 20-2500 ppb, 2-22 ppm, 2-1500 ppm, 1-18 ppm, 50-400 ppm, 100-1200 ppm, and 50-550 ppm. The significant mineral occurrences are found north of Reshun Formation. The central part (Barum, Pasti and Shoghor) of the survey area shows polymetallic signature with significant enrichment of precious metals Au=10-200 ppb, Ag=1-12 ppm, As=10-200 ppm and Sb=1-10 ppm). The southern part, mainly Kafiristan valley, is high in Pb (100-1800 ppm) with some anomalies of Au (1-100 ppb) and Ag (2-17 ppm).

New targets for mineral prospecting were located at several localities of Chitral valley. Important regional structures, such as faults and their significance regarding mineralization were also defined during this investigation.

Key words: Geochemical prospecting, metal dispersion, stream sediments, Chitral.

K/116. Khaliq, A., Moon, C. J. & Khattak, M.U.K., 1998. Gold potential of Northern Pakistan, An Assessment Based on the Results of Geochemical Exploration Survey for Gold in Northern Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 95.

Northern Pakistan, comprised of three geological units; the Asian Plate, the Kohistan arc and the Indian Plate which are separated by major suture zones, offers a high potential for a variety of mineral deposits occurring in similar geological environments elsewhere in the world. Due to its geotectonic history and associated igneous and metamorphic processes the area seems to be very promising for mineral prospecting. The region is a challenging ground for the mineral prospector because of its complex geological environments and geomorphic features.

Orientation studies based on regional panned-concentrates and geochemical exploration surveys were conducted for gold and precious metals in two geologically different terranes of Northern Pakistan. The Chitral area forms part of the Asian Plate and the Gilgit region is part of Kohistan arc sequence. These two are separated from each other by Northern Suture and from Indian Plate by Main Mantle Thrust (MMT).

Our regional survey in Chitral reveals that the area has a high potential for gold mineralization associated with Ag, As and Sb. Gold anomalies of moderate to high nature were detected in various valleys of the area. The mentioned anomalies contain gold ranging from (10-5000) ppb with an average of 380 ppb. Ag, As, and Sb range between 1-21 ppm, 2-1500 ppm and 1-16 ppm respectively. As far as zonation of anomalies is concerned the area north of Shoghor limestone and the Reshun Formation is better prospects than that to the south of it. Strong anomalies were located in Tirich, Barum and Past valleys while moderate anomalies were found in Kafiristan valley.

The regional panned-concentrates survey of Gilgit area (Kohistan arc) demonstrates that many of the valleys contain anomalies of precious metals along with Ag and As. In these anomalies gold ranges from 10-7800 ppb with an average of 700 ppb and the concentrations of Ag and As are in the range of 10-25000 ppb and 2-1400 ppm respectively. In Bagrot valley, however, the concentration of gold ranges from 2-14 ppm which is associated with very high concentration (up to 6000 ppm) of As. Highly anomalous valleys, for precious metals along with silver, arsenic and antimony, are Bagrot, Dainyor, Pisan and Minapin in the area of Gilgit town.

The project area lies in some parts of Kohistan and Mansehra districts, covering about 150 sq. kms area, including south easterly sides of Jijal and Patan complexes, starting from Karakoram highway spreading up to Pashto village. The work has evolved geological mapping of the area on a scale of 1:50,000. This thesis deals with the geological, petrographical and petrogenetical studies of the Jijal and Patan complexes and their relation with Kayal complex. The project area lies in the frontal part of the Kohistan island arc which covers about 36,000 sq Km area, structurally bounded by sutures named as Main Mantle thrust (MMT) and Main Karakorum thrust (MKT) on its southern and northern sides respectively. The Kohistan arc is intruded by a large number of basic complexes starting from a very primitive Dasu complex up to Jijal complex along with a Kohistan batholith which was intruded at last. Previously, the metamorphosed mafic complexes have been lumped together as an undifferentiated mass called Kamila amphibolite. Now we under the guidance of our supervisors have divided the Kamila amphibolite into three complexes starting from very older Dasu complex down to Kayal complex and last emplaced Patan complex. Dasu complex is the oldest pluton which is highly metamorphosed, intruded in the island arc. Dasu complex is underplated by another pluton the Kayal complex which is metamorphosed.

Key words: Petrography, Jijal, Patan, Kohistan.

K/119. Khan, A., 1992. Origin of abnormal pressure in the Potwar area of northern Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, 21-22.

The occurrence of highly pressured formations in the earth's crust has been well documented in recent years. This geological phenomenon has caused severe problems in most Petroleum areas of the world with Adhi Field in

Northern Pakistan supposedly the most difficult area to accomplish successful drilling. Statistically nearly one half of all land wells have experienced trouble of one type or another by drilling through abnormally pressured formations. In Northern Pakistan the structures where high pressure sands had resulted in premature abandonments of wells are Adhi, Chak Beli Khan and Bains (Bhangali). Abnormal pressure can be formed by any one of a number of developments. These include among others rapid sedimentation rates, tectonic activities, and salt diapirism. The origin of abnormal pressures in the Potwar area of Northern Pakistan on evidence of data collected from Adhi wells shows no indication typical of undercompacted sediments (rapid sedimentation); thus the abnormal pressure appears of tectonic origin which includes faults communication. The origin of abnormal pressures has been summarised, following a brief account of the area's stratigraphy and general geology anomalies of copper, gold, silver and platinum be studied on regional scale.

K/120. Khan, A., 1998. Mineralogy, petrology and geochemistry of manganese mineralization and associated rocks in Saidgi area, north Waziristan. M.Phil. Thesis, University of Peshawar, 119p.

North Waziristan is dominantly composed of rocks of the Waziristan ophiolitic complex, Indian plate and the quaternary deposits. The ophiolite complex is composed of ultramafics, gabbros, sheeted dikes, pillow lavas, pelagic sediments and plagiographites which are overlain by massive sedimentary sequences. The rocks of the Indian plate are mainly limestone, shale and sandstone of Jurassic to Cretaceous age. The quaternary deposits occur as heterogeneous material of variable size. The Saidgi and Shuidar Mn-deposits are a part of the Waziristan Ophiolitic complex. These deposits are banded and massive in nature and hosted by metachert. In Shuidar area the Mn-ore bodies are generally banded by having Mn-rich layers alternating with the metachert. The Saidgi ore bodies are generally massive in character and are in the form of lenses. The metacherts are finely crystalline, thin to medium bedded hard rocks. These are generally overlying the metavolcanics (pillow basalts) in the study area. Both Saidgi and Shuidar are bodies are having braunite as the Mn-bearing mineral. Braunite and 'cryptocrystalline quartz are the main constituents, however, the Shuidar are bodies have hematite as an additional phase. The chemistry of braunite has similarity with the natural braunite and a/so with that of the Mn-deposits found in ophiolites- else where in the world. The metacherts of both Saidgi and Shuidar areas have similar field and mineralogical characteristics. These are exceedingly microcrystalline aggregates of microcrystalline quartz, chalcedony, and lesser hematite. Chemically the Saidgi Mn-deposits have higher MnO, but lesser SiO₂ and Fe₂O₃ as compared to that of Shuidar Mn-deposits. The Shuidar Mn-deposits, however, have higher amount of trace elements (Cu, Pb, Zn, Ni, Cr, Co) relative to that of Saidgi Mn-deposits. Both these deposits are, characterized by low Fe/Mn ratio. Majority of the major and trace element data fall within the fields defined for hydrothermal Mn-deposits in various discrimination diagrams and, therefore, have no relation with hydrogenous deposits. Metacherts of Saidgi and Shuidar areas are similar in chemical composition. These have Fe/Mn ratio typical of hydrothermal origin. Both Saidgi and Shuidar Mn-deposits are spatially separated from each other but are cogenetic. These were formed by the submarine hydrothermal solution in an ocean floor spreading environment within the Neo-Tethys Ocean. These deposits are, therefore, originated along sea floor spreading centers (Mid-ocean ridges) and are later on abducted on land alongwith the other ophiolitic rocks of the area. This study also suggest that the Saidgi Mn-deposits (~34000 metric tons) are of greater economic importance as compare to the Shuidar Mn deposits.

K/130. Khan, A. & Salam, M., 1990. Discovery of a normal Paleozoic rock sequence in the Khyber Agency, NWFP, Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, p. 36.

The Khyber Agency, erstwhile considered a very complicated area tectonically, presents a rather simple and undisturbed geological picture in the light of the present study.

A normally folded, Paleozoic rock sequence has been identified for the first time in the area. The sequence is more than 28,000 metres thick. The succession has been established on the basis of the study of contact relationship and the structure of the area.

The prevalent concept of pre-folded thrusts and allochthonous blocks has rather poor and insufficient field evidences. Most of the thrust contacts of the previous workers are clearly normal transitional contacts. The argillites of the area are not a single unit but rather represent different geological horizons. The sequence can be presented as a type Section for the Paleozoic Rocks of the NWFP as observed of late.

The area of investigation lying in the eastern part of the Khyber Pass, between Jamrud and Waran Ghundai, is covered by the formations of the Lower and Upper Palaeozoic ages. They are represented by the Landikotal Slate (? Ordovician-Lower Silurian), the Shagai Limestone (? Middle to Upper Silurian) and Ali Masjid Formation (Upper Silurian to? Lower Carboniferous).

All of these are marine, and clastic sedimentary rocks account for more than two-third of the total thickness of the strata exposed in the area. The Landikotal Slate constitutes as much as ± 6000 feet of clastic sedimentary rocks.

Of all the formations the Ali Masjid Formation is the only fossiliferous formation. It is reefoid, and extensive reef deposits occur in it. *Thamnopora*, *Cladopora*, and *Favosites* are the important tabulate corals. Other fossils present are stromatoporoids, orthoconic cephalopods, byrozoans, brachiopods, and abundant crinoidal stems and columnals. The fossil assemblage indicates an age between Upper Silurian and Lower Devonian. Large-scale metamorphism and dolomitization has occurred, which has resulted in the obliteration of the details of fossils. This has rendered difficult to identify many fossils even at generic level. The effect of metamorphism increases towards north and the reef limestones are converted to marble.

Late Cretaceous and Early Tertiary igneous activity is indicated by the dolerite, gabbro, and (?) microgranite intrusive bodies. Most of these are sills. Dolerite and gabbro sills have mineralized the calcareous phyllites and reef limestones. Extensive and large deposits of soapstone occur within calcareous phyllites and reef limestones (converted to marble). The area is traversed by NS and NW-SE striking thrust faults. In the northeastern part of the area the rocks are folded into a NE plunging syncline. Recent movements have occurred in the area as indicated by elevated terraces and alluvial valleys.

K/137. Khan, A.H., 1992. Phosphate rock exploration in Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.22.

Alive to the significance of phosphates in Pakistan's agronomy, Geological Survey of Pakistan in collaboration with United States Geological Survey, launched a program of exploration in 1956. But in 1966 eminent Phosphate geologists concluded that suitable environment for the deposition of marine phosphate rock had not become available in Pakistan. GSP have not taken serious interest in phosphate exploration since then. Team members of Geological and Mining Consultants were not discouraged and Mr. Ikramuddin Ali discovered high grade commercially workable Cambrian phosphate deposits (1970-71) in Hazara which are being currently exploited. This discovery has by no means exhausted the possibility of finding more deposits in Hazara and elsewhere.

In 1989-90 GMC carried out preliminary phosphate rock exploration for Directorate of Mineral Development, Balochistan and identified extensive phosphatization in basal and top horizons of Cretaceous. Scope of work permitted reconnaissance of only 30% of prospective area. Although huge tonnages of phosphate rock exist the grade averages 4 to 5% with some 28% P₂O₅ showings. While searching for condensed successions, GMC discovered large deposits of bauxite suitable as feedstock in conventional plants. Although Rs 4 billion worth of phosphates are being imported, little interest is being taken in exploration of indigenous resources.

The Swargali - Bakote - Muzaffarabad road project covers part of Punjab, NWFP and Azad Kashmir areas and lies in the outer Himalayas occupying the western limb of Hazara - Kashmir Syntaxis. The 98 KM long new alignment traverses on highly rugged mountains terrain, linking about 25 villages and crossing two major rivers; Jhelum and Kunhar. It also shows a relief of about 6000 feet between starting and end point. The geological formation of the project area, ranges in age from Cambrian to Recent and includes sedimentary rocks. The major rock units include Hazara Slates (Cambrian) and Murree Formation (Miocene) that composed of shales, clay and sandstone. The two have been juxtaposed against each other by a major thrust known as Murree Fault. While fixing the alignment the highly unstable Murree Formation and Murree fault have been avoided. Geological comparison between the existing road on left bank of river Jhelum and the proposed alignment on the right bank of river Jhelum shows that the latter is more stable and economically viable.

Keeping in view the nature of terrain and geology, the road has been carefully designed in order to meet the required specifications of geometrics, traffic load and construction economics. One of the most modern software system of highway design, known as MOSS has been utilized to attain optimum accuracy and economy. The rock cut slopes and drainage have also been designed in such a way to provide sustainable stability to the road and to control geological hazards including landslide, mudflow and rockfall.

The gem resources of Pakistan are mostly found in the Himalaya-Karakorum-Hindukush region. The paper describes emerald, ruby, topaz, aquamarine, tourmaline, zircon, garnet, moonstone, chalcedony, and apatite. These occur in a variety of tectonic setup and have been attributed to complex processes.

Slope stability problems in Sub-Himalayan regions have been investigated for foundation engineering, road construction, abutments, for housing and retaining walls. A survey has been undertaken to investigate slope stability problems during 1985-1995. The stable and unstable slopes were separated on right and left bank of river Neelum and river Jhelum. Mahor landslides in unstable slopes have been marked in Murree Formation of Miocene age from crown to toe due to nearness of active fault (MBT), pore water pressure, sink holes at crown, undercutting for road widening, shale undercutting by differential weathering and undercutting by river currents. A method for remediation has been suggested for foundations in slopes, load-bearing capacity of rocks and soils based on in situ and laboratory investigations. The bearing capacity of foundations on level ground is higher as compared to the slopping surface depending upon the slope angle, composition of the soil, flooding in the river, moisture content of the soil and earthquake intensity which agitate the rocks and soils underlying the foundations. The foundations in such regions depend simply on local conditions, footing size, proximity to the slope, depth of footing and design geometry.

K/150. Khan, A.M. & Mariano, A.N., 1992. Mineralogical characteristics of Katlang pink topaz: Cathodoluminescence analysis. Abstracts, First South Asia Geological Congress, Islamabad, p.24.

The autoclastic limestone of probably Silurian- Devonian age in Katlang district Mardan, NWFP, hosts highly prized, exclusive variety of natural pink topaz. Under Cathodoluminescence (CU) it shows blue and violet red color and sectoral zoning. The colors are attributed to the presence of crystal defect in tetrahedral position and Cr^{3+} as ion impurity activator that has probably substituted Al^{3+} in the octahedral site. Mass spectrographic analyses, electron microprobe analyses and CL omission spectrum show that Cr^{3+} is directly related to the violet red CL and pink coloration. Proton induced X-ray excitation (PIXI) analyses indicate that combination of Cr^{3+} , V and Ge are diagnostic for Katlang pink topaz. The sectoral zoning is due to F and OH ordering. Variation in color of crystal and co-occurrence of brecciated and idiomorphic crystals in the same rock indicate several episodes of topaz crystallization.

Flotation studies were carried out to update galena in the lead ore of Besham to make it saleable. The important flotation parameters examined were type and dosage of collector, dosage of the depressant, dispersant and frother, conditioning time for collector and depressant and impeller speed. During step-wise optimization of flotation parameters, lead was upgraded from 3.1% to 16% in the first cycle, and from 16% to 26% in the second cycle of flotation.

K/156. Khan, B. & Ahmad, N., 1991. General geology of the Kakul phosphate Deposits, Hazara, Pakistan. Proceedings, First SEGMITE Symposium, Peshawar, 51-60.

Phosphorite in the Kakul area occurs in a folded, thrust and faulted succession of Cambrian to Jurassic sediments. The succession forms part of the Garhi Habibullah syncline on the western flank of the Hazara-Kashmir syntaxis, a major structural element of the southern part of Himalaya orogenic belt. The geology of the Kakul area has been complicated by thrusts which are approximately parallel to the strike and has divided the succession into a number of discrete thrust sheets, one phosphorite of Kakul mines and the other Kakul west phosphorite. Mineralization extends along a discontinuous belt for some 2.5 miles to the North West as far as Iambidogi. The depositional environment of the phosphorite at Kakul mine is notably different from that at Kakul west, indicating that large horizontal movements took place along the thrust planes which brought into juxtaposition rocks of widely different facies of phosphorite deposition.

K/158. Khan, B., Husain, V., Bilqees, R. & Sultan, S., 1992. Correlation of palaeogeography with phosphorites of Pakistan and India. Abstracts, First South Asia Geological Congress, Islamabad, p.21.

The marine phosphorites of Early Cambrian age presently being exploited in Pakistan occur in an area of about 155 km² at the foot of Himalaya in Abbottabad, Hazara. The proved reserves for these deposits (Kakul, Lagarban and Tarnawai) are 8 million tonnes with up to 20 million tonnes of resources known in the area. These phosphorites are associated with dolomite, chert, siltstone and black shales occurring in upper part of the Abbottabad Formation.

The presence of Early Cambrian age is characteristic of these phosphate beds. Hazara phosphorites resemble Birmanian phosphorites, western Rajasthan and Tal phosphorites, Mussoorie, India, in their composition and origin.

due to their close palaeogeographic relationship. All these phosphorites contain carbonate fluorapatite, quartz, dolomite, calcite, clays, pyrite, orthoclase and muscovite. In thin sections, phosphates occur as a variety of nodular clasts, mostly oval, coarse to fine grained, made up of microcrystalline apatite embedded in chertquartz- calcite matrix. All these deposits are of marine origin, occurring in a few inches to several feet thick beds, containing 10-35% P₂O₅.

The palaeontological, geological and geochemical data support the view that Birmania phosphorites and-Hazara phosphate bearing areas were part of an extensive Palaeozoic (Cambrian-Ordovician) sea with undefined boundaries which came into existence through the subsidence of the old prePalaeozoic land surface. Phosphorites in the areas appear from the stratigraphic and petrologic evidence to have formed authigenically at the sediment - water interface, a common mode of formation in ancient deposits.

K/159. Khan, F., Latif, M., Fayaz, A. & Khan, M.S.Z., 1987. Geology and mineral investigations of Hunza-Nagar area, Northern Areas. Geological Survey of Pakistan, Information Release 291, 32p.

Geological mapping and minerals investigation of Hunza and Nagir areas was carried out in May to June 1985. The mapped area is underlain by metasedimentary rocks of Baltit Group, Chalt ophiolitic mélange zone, and igneous rocks of Karakoram Granodiorite along with veins and dykes of both basic and acidic nature, pegmatites and quaternary deposits.

The area is well known for its ruby deposits in the limesilicate marble of Baltit Group. The Baltit Group mostly consists of gneisses, schists quartzite and marble, The Chalt ophiolitic mélange zone consists of schists, phyllites, marble, dolomitic limestone, slates and Cherty conglomerate. The grade of metamorphism increases from west to east with low grade schists, to limesilicate marble of cata zone. The regional metamorphism is caused by intrusion of Karakoram batholith. The two thrust the main Karakoram thrust and Hispar Hunza thrust are the prominent structural features in the mapped area which both runs in the east-west direction.

The Hispar Hunza thrust is intraformational and separates the high grade rocks from the low grade within the Baltit Group. The area does not possess any other, deposits of economic interest except small pegmatites and an alteration zone near Yal area. A total of 7 samples were analyzed from alteration zone which contains 21-1490 PPM Cu, 32 to 310 PPM Mn, 91-301 PPM Zn and only three samples having Ni values from 177-271 PPM. The higher Cu values are due to malachite veins which are present in the zone. The overall values are not so encouraging to suggest further detail work of the area for Cu mineralization.

K/160. Khan, F., Latif, M. & Khan, R., 1991. Geology and mineral investigation of the Yasin quadrangle, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 494, 19p.

Geological mapping and mineral investigations of Yasin valley were carried out from September to October 1987. The investigated area falls in the Survey of Pakistan topo sheet No. 42 H/7.

The project area is covered by metasedimentary rocks of Darkot group; meta-volcano sedimentary rocks of Yasin group and meta-volcanic rocks of Greenstone complex which were later intruded in multi phases by the Ladakh - Kohistan granitoids. Owing to the presence of the collision boundary zone between the Asiatic Mass and island arc, the rocks of the investigated area are severely disturbed thus resulting in a number of folds and faults.

K/161. Khan, G., 1983-85. Geotechnical studies for slope stability analysis along Muzaffarabad-Kohala Road. M.Sc. Thesis, Punjab University, Lahore, 90p.

The Muzaffarabad-Kohala road is the main way of transportation between Pakistan and Azad Kashmir. A number of landslides occur along this road which damaged and blocked it for hours and sometimes for days. Due to the vital importance of the road this frequent sliding is unbearable. So this field report is prepared with the aim to study the area in detail and to explore the reasons of sliding.

For the present study the area was mapped, and lithological and structural discontinuities are marked. The major structure is the Jhelum Fault, which extends full length of the project area. Attempts have been made to give an idea about the stability conditions prevailing in different zones. On the basis of existing condition in the field, the area along the road is divided into three types of zones i.e., Stable zone, Potentially unstable zones, Unstable zones.

Samples from potentially unstable and unstable zone were collected for laboratory tests. The purpose of this test was to evaluate the strength parameters which are responsible for driving and resisting moments. This report also includes the study of the factors responsible to activate the sliding process and their economical and practical remedies. Conclusion and recommendations are given in the end.

The epigenetic vein type barite deposits occur at several localities near Havelian in limestone and shale sequence belonging to Eocene age. Barite veins varying in thickness from a few inches to several feet occur in gray colored argillaceous limestone and shale. Thin bands of barite and galena are also seen in some samples. Important minerals occurring along with barite are calcite, quartz and magnesite. In polished sections, galena, pyrite and goethite were also identified. Petrographically, barite occurs in several textural types: massive, crystalline, lath or platy shaped ranging from fine to coarse in size. The BaSO_4 content in Havelian barite samples ranges from 20 to 92%. Major impurities are SiO_2 , CaO , MgO , Fe_2O_3 and Al_2O_3 . Barite deposits in Havelian are structurally controlled vein and cavity filling type deposits. These barite deposits have not been developed and mined systematically. Barite deposits of this district are good in quality and need detailed investigations for determining mineable reserves. The physical and chemical characteristics of Havelian barite show their suitability for paint, paper, rubber, petroleum drilling and chemical industries with or without processing.

K/164. Khan, I., 1990-91. The structure, stratigraphy & petrography of the western limb of Hazara-Kashmir Syntaxis, Mansehra-Dalola area, Hazara, Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 74p.

The Mansehra-Dalola area lies on the western limb of Hazara-Kashmir syntaxis (HKS) in Attock Hazara foreland fold-and-thrust belt. The Hazara-Kashmir syntaxis is a regional antiformal structure of vital significance in the geological and tectonic framework of the Western Himalayas. A sequence from Late Proterozoic to Mesozoic has been deformed during the pre-Himalayan and Himalayan orogenies. The western limb of the HKS shows a complex juxtaposition of three tectonostratigraphic zones. These are the Garhi Habibullah-Abbottabad zone, the Panjal zone and the Mansehra zone.

Several diverse lines of evidence including the presence of metamorphic clasts in unmetamorphosed Cambrian conglomerates, angular relation of Cambrian rocks to the older cleavages and hornfelsic overprint in contact aureoles of Cambrian granites on older cleavages establish a distinctively pre-Himalayan orogenic event of late Proterozoic age. The D2 deformation event is related to the first phase of the Himalayan orogeny. It produced large scale south verging recumbent folds. A strong S2 foliation is axial planar to these F2 folds.

The D3 deformation event forms F3 folds. The F3 folds in the area are Garhi Habibullah syncline, Tarkot anticline, Doga syncline and Gali Mohri anticline. These are southeast verging open to tight folds. D3 thrusts are the Panjal fault, Garhi Habibullah fault, Naroka thrust, Lagarban fault and Sattu fault. Near surface backsteepening due to oblique thrusting and more resistant strata is also documented as a later phase of the D3 deformation. During D4 deformation earlier thrusts and axial planes of F3 folds are refolded into broad map-scale northwest plunging F4

folds. The F4 folds are synchronous to the development of NNW plunging antiformal structure of the Hazara-Kashmir syntaxis. The major counter-clockwise movement along the western limb of the syntaxis also produced Rheidberg faults in addition to sinistral-slip along major thrusts.

K/170. Khan, I.A., 1992. River systems recorded within the Miocene Siwalik Group, eastern Potwar Plateau, Northern Pakistan. Abstracts, Annual Meeting, Geological Society of America, Cincinnati, USA, p.A352.

Sedimentologic characteristics of paleochannel and overbank deposits are documented in a kilometer-scale coarsening upward succession of the entire Siwalik Group. (Chinji- Nagri- Dhok Pathan and Soan Formations) exposed in Mahesian and Rohtas areas, eastern Potwar plateau, northern Pakistan.

The major channel sandstone bodies are composed of several storeys, stacked both vertically and laterally and represent either single or superimposed channel-belt deposits. The arrangement and internal characteristics of the storeys indicate deposition as bars and channels hills within low sinosity braided channels. Paleochannel reconstruction from channel-belt deposits, within the Chinji Formation indicate widths of 167-500m, depths of 3.5 to 16 m. bend wavelengths of 1.4-4 km and discharge of 600 – 1300 m³/s. larger channels form the Nagri Formation show widths of 200-1300 m, depths of 3-21 m, bend wavelength of 0.7 – 6.2 km and discharge of 300 – 6000 m³/s. relatively smaller channel segments from the Dhok Pathan Formation indicate widths of 114 – 156 m, depths of 3.5 – 6/7 m, bend wavelengths of 0.9 to 1.6 km and discharge of 300 – 1000 m³/s.

Key words: River systems, Miocene, siwaliks, Potwar.

K/171. Khan, I.A., 1993. Evolution of Miocene-Pliocene fluvial paleo-environments in eastern Potwar Plateau, northern Pakistan. Doctoral Dissertation, State University of New York Binghamton, USA. 188p.

The fluvial Miocene-Pliocene Siwalik Group (Nagri, Dhok Pathan and Soan Formations) in the Mahesian and Rohtas areas, eastern Potwar plateau, northern Pakistan, was studied in order to reconstruct the evolution of depositional environments and the controls on this evolution.

The major sandstone bodies are composed of storeys, stacked both vertically and laterally and represent either single or superimposed channel-belt deposits. Internal characteristics of the storeys indicate deposition as bars and channel fills within low sinuosity (1.1-1.2) braided channels which had a braiding index of at least 2 or 3. Individual channel segments in the Lower Nagri Formation had widths of 167-500m, maximum bankfull depths of 7-17m, bend wavelengths of 1.4-4 km and bankfull discharges of 300-1300 m³/s. The discharges of the channel belts in the Nagri Formation were on the order of 1000 m³/s.

Relatively smaller channel segments from the Dhok Pathan Formation had widths of 114-156m, maximum bankfull depths of 6.7m, bend wavelengths of 0.9 to 1.6km and bankfull discharges of 300-1000m³/s. Overbank sandstone bodies have lenticular, wedge, sheet and channel filling geometries and are interpreted as the deposits of crevasse-splays, levees or floodplain drainage channels. Mudstone sequences consist predominantly of finely laminated to disrupted/bioturbated siltstones which show well developed pedogenic features. Mudstones were deposited from episodic, suspended load deposition from slow moving flood flows on broad, low relief floodplains. Comparison of the Siwalik river systems with modern Himalayan river systems suggests their deposition on large sediment fans and interfan areas.

The following vertical variations are observed within the Siwalik Group: 1) major sandstone bodies coarsen from fine to medium sandstone through the Nagri Formation, there is abrupt fining at the base and top of the Dhok Pathan Formation, followed in the Soan Formation by increasing grainsizes of all facies; 2) the proportion of major sandstone bodies generally increases upwards in the Nagri Formation; however, variation in grainsizes and proportion of major sandstone bodies are not correlated in the Dhok Pathan and Soan Formation; 3) thicknesses of major sandstone bodies increase upwards in the Upper Nagri Formation, due to both thicker storeys and more vertically stacked storeys, and decrease at the base and top of the Dhok Pathan Formation; 4) mean paleocurrent orientations are generally towards the southeast; however, they change to southwest in the Upper Nagri Formation and shift towards the south in the Lower Dhok Pathan and Soan Formations; 5) a decrease in sedimentation rate from 0.34 to 0.25 to 0.21 mm/yr in the Nagri, Dhok Pathan and Soan Formations, respectively, corresponds to a decrease in proportion of major sandstone bodies and increase in proportion of mature paleosols. The association of decrease in sedimentation rates with easterly paleocurrents and increase in sedimentation rates with southerly paleocurrents might be related to periodic regional progradation of wedges or lobes of sediment from the Himalayas. Basin-wide increase in sediment accumulation rate, grainsize and proportion of major sandstone bodies, and changes in their composition in the Nagri Formation are associated with tectonic uplift of the Himalayas, progradation of wedges or lobes of sediment to the south and southeast and increasing depositional slope. Variation in eustatic sea-level had no effect on sedimentation of the Siwaliks. The lack of clear variation in paleochannel geometry through the marked climatic-vegetation change around 7.5-6.5 m.yr suggests river discharges were not affected by climatic change.

Key words: Paleo-environments, Miocene, siwaliks, Potwar.

K/172. Khan, I.A., 1994. Alluvial architecture and sandstone petrology of the stratotype Chinji Formation, Siwalik group, northern Pakistan. *Himalayan Geology* 15, 123-141.

The stratotype Chinji Formation (14.0-10.8 ma) is composed of alternating sheet sandstones (active channel deposits) and mudstones (lower energy overbank flow deposits). The stratigraphic details of the Chinji Formation are based upon measurement of three complete vertical logs in the stratotype area and lateral tracing of lithofacies for kilometers. On the basis of sandbody geometry, the sandstones are classified as "sheet", "ribbon", and "shoestring" types. The mudstones are micaceous and sandy and in the lower part of the formation fine upward into claystones. Thirty-eight sandstone samples in the medium sand range, from the base and top of each sandstone, are analysed by point counting for their modal composition. Quartz (14-36%) is subdivided as monocrystalline non-undulatory (47.12%), monocrystalline undulatory (8.19%), polycrystalline with 2-3 crystals per grain (25.57%) and polycrystalline with > 3 crystals per grain (18.35%). The feldspar (4-16%) consists of plagioclase, orthoclase, microcline and perthite. The lithics are composed of sedimentary (3-29%), metamorphic (7-29%) and volcanic (1-

4%) rock fragments. Calcite (7-36%) occurs as allochems (1-9%), intraclasts (1-7%) and cement (2-26%). The relative percentages of quartz types, plotted on a diamond diagram (Basu et al., 1975), indicate that the sandstones are derived from middle and upper rank metamorphic rocks. The QFL (quartz-feldspars-lithics) triangle after Folk (1968) shows that the sandstones are litharenites to feldspathic litharenites. The LsLmLv triangle after Folk (1968) shows that the sandstone are phyllarenites. The volcanic lithics are mostly pyroclastics. The relative abundance of allochem and intraclast calcite suggests that the rivers drained older limestones during this time. A major uplift of the Kohistan arc began about 15 ma ago and its focus has been Nanga Parbat and Hunza region (Zeitler et al., 1982). Kohistan island arc could be a possible source for metamorphic minerals since the time of deposition of the Chinji Formation.

K/174. Khan, I.A., 1995b. Controls on evolution of Neogene fluvial environments in the northwestern Himalayan Foreland Basin. In: Abstract volume (Dissanayake, C. B., Almond, D. C., and Cooray, P. G., eds.), Second South Asia Geol. Cong., Colombo, Sri Lanka, p.240.

The Neogene Siwalik Group (Chinji, Nagri, Dhok Pathan and Soan Formations) in the northwestern Himalayan foreland consists of two major 100m-scale coarsening upward sequences. The lower sequence (Chinji and Nagri Formations) records coarsening upward from fine to medium sandstone, followed by basin-wide abrupt fining at the Nagri/Dhok Pathan Formations boundary. Upward coarsening is associated with increases in grain size, clast, thickness, lateral extent and proportion of channel-sandstone bodies. The highest proportion of major channel-sandstone bodies (e.g., upper Nagri Formation) is associated with relatively thick, laterally extensive and interconnected channel-sandstone bodies, which have relatively thicker and vertically superimposed sandstone storeys. These are generally interpreted as superimposed channel-belt deposits. The upward increase in mean grain size (e.g., upper Nagri Formation) is probably associated with a regional increase in alluvial slope, possibly due to progradation of a large alluvial cone. A high proportion of sandstone bodies in the Nagri Formation might be related to increasing numbers of channels in the area, either simultaneously or due to frequent channel avulsions (diversions). Increasing avulsion frequency into an area might be related to preferred tectonic subsidence, intrabasinal faulting (subsurface controls) and/or increased channel-belt deposition rates, possibly related to basin-scale progradation of large active wedges or lobes of sediment to the south and southeast due to orogenic pulses in the orogenic belts. Although the trends in sandstone body proportion over hundreds of meters of strata can be correlated regionally, the local correlation of the 100m cycles suggests a more local cause such as intrabasinal tectonism or fan progradation.

The abrupt fining at the base of the upper 100 m-scale sequence (Dhok Pathan and Soan Formations) is followed by increasing grain sizes of all facies. Basin-wide decrease in sediment accumulation rates from 0.34 to 0.25 to 0.21m/yr through the Nagri, Dhok Pathan, and Soan Formations, respectively, corresponds to a decrease in proportion of major sandstone bodies and an increase in proportion of mature paleosols. Abundance of overbank channels is generally associated with increase in proportion of major channel sandstone bodies and deposition rate, which might be due to a greater tendency towards river diversions.

The basin-wide trends in increase in sediment accumulation rate, grain size and proportion of major sandstone bodies, and changes in their composition, are approximately coeval with a major eustatic lowering of the sea-level (Chinji-Nagri Formations boundary) and subsequent rise (Nagri-Dhok Pathan Formations boundary). There is no sedimentological evidence for climatic change through the Chinji to Dhok Pathan Formations.

Molassic, fluvial rocks of the Siwalik Group record changing depositional environments in the Himalayan foreland basin. In the Potwar plateau, Chinji, Nagri, Dhok Pathan and Soan formations of this Group comprise relatively thick (tens of meters) sandstone bodies and mudstones that contain thinner sandstone bodies (meters thick) and palaeosols. Thick sandstone bodies extend for kilometers normal to paleoflow, and are composed of sandstone storeys stacked laterally and vertically adjacent to each other. Sandstone bodies represent single or superimposed braided-channel belts, and storeys represent channel bars and fills. Channel belts had widths of km, bankfull discharges on the order of 103 cumecs and braiding parameter up to about 3. Individual channel segments had bankfull widths, maximum depths, and slopes on the order of 102 m, 101 m and 10-4 respectively, and sinuosities around 1.1. These rivers are comparable to many of those flowing over the magafans of the modern Indo-Gangetic basin, and a similar depositional setting is likely. Thin sandstone bodies within mudstones extend laterally for on the order of 102 m and have lobe, wedge, sheet and channel-form geometries. They represent crevasse splays, levees and floodplain channels. Mudstones are relatively bioturbated/disrupted and represent mainly floodbasin and lacustrine deposition. Mudstones and sandstones are extremely disrupted at places, showing evidence of prolonged pedogenesis. These 'mature' palaeosols are meter-scale thick and extend laterally for kilometers. Lateral and vertical variations in the nature of their horizons apparently depend mainly on deposition rate.

The kilometer scale thick Siwalik Group is comprised of two major 100 m scale coarsening upward megasequences. The lower sequence (Chinji and Nagri Formations, Ca 14-9 Ma) records coarsening upwards from fine to medium sandstones, followed by basin-wide abrupt fining at the base of the upper sequence (Dhok Pathan and Soan Formations, Ca 9-2 Ma). The highest proportion of major channel sandstone bodies (upper Nagri Formation) is associated with laterally extensive and interconnected channel-sandstone bodies, which have relatively thicker and vertically superimposed sandstone storeys. Compacted deposition rates decrease with sandstone proportion (0.53 mm/year for Nagri, 0.24 mm/year for Dhok Pathan and 0.21 mm/year for Soan), and palaeosols are not as well developed where deposition rates are high. Within the Siwalik formations there are 100 m-scale variations (representing on the order of 105 years) in the proportion and thickness of thick sandstone bodies, and tens-of-m-scale alternations of thick sandstone bodies and mudstone-sandstone strata that represent on the order of 104 years. Formation-scale stratal variations extend across the Potwar plateau for at least 100 km, although they may be diachronous: however, 100m and smaller scale variations can only be traced laterally for up to tens of milometers.

Alluvial architecture models indicate that increases in the proportion and thickness of thick sandstone bodies can be explained by increasing channel-belt sizes (mainly), average deposition rate and avulsion frequency on a megafan comparable in size to modern examples. 100-m-scale variations in thick sandstone-body proportion and thickness could result from regional shifts in the position of major channels, possibly associated with fan-lobes on a single megafan or with separate megafans. However, such variations could also be related to local changes in subsidence rate or changes in sediment supply to the megafan system.

Formation-scale and 100-m-scale stratal variations are probably associated with interrelated changes in tectonic uplift, sediment supply and basin subsidence. Increased rates of hinterland uplift, sediment supply and basin subsidence, recorded by the Nagri Formation, may have resulted in diversion of a relatively large river to the area. Alternatively, changing river sizes and sediment supply rates may be related to climate changes affecting the hinterland (possibly related to tectonic uplift). Climate during deposition of the Siwalik Group was monsoonal. Although the Siwalik sequence contains no direct evidence for climate change, independent evidence indicates global cooling throughout the Miocene, and the possibility of glacial periods (e.g. 10.8 Ma, corresponding to the base of the Nagri Formation). If the Himalayas were periodically glaciated, a mechanism would exist for varying sediment supply to megafans on time scales of 10⁴–10⁵ years. Although eustatic sea-level variations are related to global climatic changes, they are not directly related to Siwalik stratigraphic changes, because the shoreline was around 1000 kilometers away during Miocene.

Key words: Sedimentation, fluvial facies.

K/181. Khan, I.A., 2000b. Fluvial facies complexities in Himalayan foreland basin. Abstracts, Third South Asia Geological Congress, Lahore, 33–35.

Detailed sedimentological variations documented through the Siwalik Group (Chinji, Nagri, Dhok Pathan and Soan formations) in northwestern Himalayan Foreland Basin reveal that kilometer-scale thick depositional succession is comprised of two 100 m-scale coarsening upwards megasequences. The lower megasequence (Chinji and Nagri formations, Ca 14–9 Ma) records coarsening upwards from fine to medium grained sandstones, followed by basin-wide abrupt fining at the base of the upper megasequence Dhok Pathan and Soan formations Ca 9–2 Ma). Upward coarsening is associated with increases in clast, thickness, lateral extent and proportion of channel sandstone bodies. The highest proportion of major channel-sandstone bodies (upper Nagri Formation) is associated with relatively thick, laterally extensive and intercohesed channel-sandstone bodies, which have relatively thicker and vertically superimposed sandstone storeys. Sandstone bodies represent single or superimposed braided-channel belts, and storeys represent channel bars and fills. Channel belts had widths of km, bankful discharges on the order of 10³ cusecs and braiding parameters up to about 3. Individual channel segments had bankful widths, maximum depths and slopes on the order of 10² m, 10 m and 10⁴ respectively, and sinuities around 1.1. Overbank sandstone bodies have lenticular, sheet and channel filling geometries and are interpreted as deposits of floodplain drainage channels. Mudstone sequences consist predominantly of finely laminated to disrupted/bioturbated siltstones which show evidence of prolonged pedogenesis. These "mature" paleosols are meter-scale thick and extend laterally for kilometres. Lateral and vertical variations in the nature of their horizons depend upon sedimentation rate.

Compacted deposition rates decrease with sandstone proportion (0.53 m/year for Nagri, 0.24 m/year for Dhok Pathan and 0.21 m/year for Soan), and paleosols are not as well developed where deposition rates are high. Within the Siwalik formations, there are 100 m-scale variations (representing on the order of 10⁵ years) in the proportion and thickness of thick sandstone bodies and mudstone-sandstone strata that represent on the order of 10⁴ years. Formation-scale stratal variations extend across the Potwar plateau for at least 100 km, although they may be diachronous; however, 100 m and smaller scale variations can only be traced laterally for up to tens of kilometres.

Quantitative and qualitative interpretations of the Siwalik depositional environments modeled through: 1) comparison of the sedimentological characteristics of the strata with computer simulated paleochannels and floodplains; 2) sedimentological correlations between time-equivalent rocks; 3) 3-D alluvial stratigraphy models; reveal that upward coarsening (upper Nagri Formation) is associated with a regional increase in alluvial slope, possibly due to progradation of large alluvial fan. A high proportion of sandstone bodies in the Nagri Formation

might be related to increasing number of channels in the area, either simultaneously or due to frequent channel avulsions (diversions). Increasing avulsion frequency into an area might be related to preferred tectonic subsidence, intrabasinal faulting (subsurface controls) and/or increased channel-belt deposition rates, possibly, related to preferred basin-scale progradation of alluvial fans to the South and southeast due to orogenic episodes in the orogenic belts. Formation-scale and 100 m-scale stratal variations are probably associated with interrelated changes in tectonic uplift, sediment supply and basin subsidence. Climate during deposition of the Siwalik Group was monsoonal. Although the Siwalik sequence contains no direct evidence for climate change, independent evidence indicates global cooling throughout the Miocene, and the possibility of glacial periods. If the Himalayas were periodically glaciated, a mechanism would exist for varying sediment supply to megafans on time scales of 10^4 to 10^5 years. Although eustatic sea-level variations are related to global climatic changes, they are not directly related to Siwalik stratigraphic changes, because the shoreline was around 1000 kilometres away during Miocene; however, basin-wide trends in increase in sedimentation rate, grain size, proportion of sandstone bodies and changes in composition of sandstones are coeval with a major eustatic fall of the sea-level (Chinji-Nagri formations boundary) and subsequent rise (Nagri-Dhok Pathan formations boundary).

The Miocene-Pliocene Siwalik Group records changing fluvial environments in the Himalayan foreland basin. The Nagri and Dhok Pathan Formations of this Group in the eastern Potwar Plateau, northern Pakistan, comprise relatively thick (tens of metres) sandstone bodies and mudstones that contain thinner sandstone bodies (metres thick) and palaeosols. Thick sandstone bodies extend for kilometres normal to palaeoflow, and are composed of large-scale stratsets (storeys) stacked laterally and vertically adjacent to each other. Sandstone bodies represent single or superimposed braided-channel belts, and large-scale stratsets represent channel bars and fills. Channel belts had widths of km, bankfull discharges on the order of 10^3 cumecs and braiding parameter up to about 3. Individual channel segments had bankfull widths, maximum depths, and slopes on the order of 102 m, 101 m and 10–4 respectively, and sinuities around 1-1. These rivers are comparable to many of those flowing over the megafans of the modern Indo-Gangetic basin, and a similar depositional setting is likely. Thin sandstone bodies within mudstone sequences extend laterally for on the order of 102 m and have lobe, wedge, sheet and channel-form geometries: they represent crevasse splays, levees and floodplain channels. Mudstones are relatively bioturbated/disrupted and represent mainly floodbasin and lacustrine deposition. Mudstones and sandstones are extremely disrupted in places, showing evidence of prolonged pedogenesis. These ‘mature’ palaeosols are m thick and extend laterally for km. Lateral and vertical variations in the nature of their horizons apparently depend mainly on deposition rate.

The 500 m-thick Nagri Formation has a greater proportion and thicker sandstone bodies than the overlying 700 m-thick Dhok Pathan Formation. The thick sandstone bodies and their large-scale stratsets thicken and coarsen through the Nagri Formation, then thin and fine at the base of the Dhok Pathan Formation. Compacted deposition rates increase with sandstone proportion (0-53 mm/year for Nagri, 0-24 mm/year for Dhok Pathan), and palaeosols are not as well developed where deposition rates are high. Within both formations there are 100 m-scale variations (representing on the order of 105 years) in the proportion and thickness of thick sandstone bodies, and tens-of-m-scale alternations of thick sandstone bodies and mudstone-sandstone strata that represent on the order of 104 years. Formation-scale stratal variations extend across the Potwar Plateau for at least 100 km, although they may be diachronous: however, 100-m and smaller scale variations can only be traced laterally for up to tens of km.

Alluvial architecture models indicate that increases in the proportion and thickness of thick sandstone bodies can be explained by increasing channel-belt sizes (mainly), average deposition rate and avulsion frequency on a megafan comparable in size to modern examples. 100-m-scale variations in thick sandstone-body proportion and thickness could result from ‘regional’ shifts in the position of major channels, possibly associated with ‘fan lobes’ on a single megafan or with separate megafans. However, such variations could also be related to local changes in subsidence rate or changes in sediment supply to the megafan system.

Formation-scale and 100-m-scale stratal variations are probably associated with interrelated changes in tectonic uplift, sediment supply and basin subsidence. Increased rates of hinterland uplift, sediment supply and basin subsidence, recorded by the Nagri Formation, may have resulted in diversion of a relatively large river to the area. Alternatively, changing river sizes and sediment supply rates may be related to climate changes affecting the hinterland (possibly linked to tectonic uplift). Climate during deposition of the Siwalik Group was monsoonal. Although the deposits contain no *direct* evidence for climate change, independent evidence indicates global cooling

throughout the Miocene, and the possibility of glacial periods (e.g. around 10-8 Ma, corresponding to base of Nagri Formation). If the higher Himalayas were periodically glaciated, a mechanism would exist for varying sediment supply to megafans on time scales of 10⁴-10⁵ years. Although eustatic sea-level changes are related to global climatic change, they are not directly related to Siwalik stratigraphic changes, because the shoreline was many 100 km away during the Miocene.

The Miocene-Pliocene Siwalik Group records changing fluvial environments in the Himalayan foreland basin. The Nagri and Dhok Pathan Formations of this Group in the eastern Potwar Plateau, northern Pakistan, comprise relatively thick (tens of m) sandstone bodies and mudstones that contain thinner sandstone bodies (m thick) and paleosols. Thick sandstone bodies extend for km normal to paleoflow, and are composed of large-scale stratsets (storeys) stacked laterally and vertically adjacent to each other. Sandstone bodies represent single or superimposed braided-channel belts, and large-scale stratsets represent channel bars and fills. Channel belts had width of km, bankfull discharges on the order of 10³ cumecs and braiding parameter up to about 3. Individual channel segments had bankfull widths, maximum depths and slopes on the order of 10² m, 10¹ m and 10⁴ respectively, and sinuosity around 1.1. These rivers are comparable to many of those flowing over the megafans of the modern Indo-Gangetic basin, and a similar depositional setting is likely. Thin sandstone bodies within mudstone sequences extend laterally for on the order of 10² m and have lobe, wedge, sheet and channel-form geometries: they represent crevasse splays, levees and floodplain channels. Mudstones are more-or-less bioturbated/disrupted and represent mainly floodbasin and lacustrine deposition. Mudstones and sandstones are extremely disrupted in places, showing evidence of prolonged pedogenesis. These 'mature' paleosols are meters thick and extend laterally for km. Lateral and vertical variations in the nature of their horizons apparently depend mainly on deposition rate.

The 500 m-thick Nagri Formation has a greater proportion and thicker sandstone bodies than the overlying 700 m-thick Dhok Pathan Formation. The thick sandstone bodies and their large-scale stratsets thicken and coarsen through the Nagri Formation, then thin and fine at the base of the Dhok Pathan Formation. Compacted deposition rates increase with sandstone proportion (0.53 mm/yr for Nagri, 0.24 mm/yr for Dhok Pathan), and paleosols are not as well developed where deposition rates are high. Within both formations there are 100 m-scale variations (representing on the order of 10⁵ years) in the proportion and thickness of thick sandstone bodies, and tens-of-m-scale alternations of thick sandstone bodies and mudstone-sandstone strata that represent on the order of 10⁴ years. Formation-scale stratal variations extend across the Potwar Plateau for at least 100 km, although they may be diachronous: however, 100-m and smaller scale variations can only be traced laterally for up to tens of km.

Alluvial architecture models indicate that increases in the proportion and thickness of thick sandstone bodies can be explained by increasing channel-belt sizes (mainly), average deposition rate and avulsion frequency on a megafan

comparable in size to modern examples. 100-m-scale variations in thick sandstone-body proportion and thickness could result from 'regional' shifts in the position of major channels, possibly associated with 'fan lobes' on a single mega fan or with separate mega fans. However, such variations could also be related to local changes in subsidence rate or changes in sediment supply to the megafan system.

Formation-scale and 100-m-scale stratal variations are probably associated with interrelated changes in tectonic uplift, sediment supply and basin subsidence. Increased rates of hinterland uplift, sediment supply and basin subsidence, recorded by the Nagri Formation, may have resulted in diversion of a relatively large river to the area. Alternatively, changing river sizes and sediment supply rates may be related to climate changes affecting the hinterland (possibly linked to tectonic uplift). The study for platinum-group minerals (PGM) was carried out as a part of training for the exploration of these in Jijal and Dargai areas which included the geochemical sampling by stream sediment panning and rock chip media in the areas already proved anomalous in the previous surveys. The ore microscopy and microprobe analyses were conducted for the identification of PGM. The EPMA work included extensive high-speed qualitative analysis of the panned concentrates and the polished rock samples. The sample JO-2 revealed a strange PGM composition in qualitative analysis with Pt, Pd, Te, Fe, S. & Ni elements in it. The PGM was mapped by H-111 system for four elements (Pd, Te, Fe and S) for homogeneity check and the center of the mineral was analyzed by quantitative method.

The PG mineral discovered after this analytical work is the merenskyite-(Pt, Pd)Te, which is first time discovered with the host rock other than Sudbury deposit i.e. primary-type, massive sulfide vein in ultramafics of the Jijal complex. The significance of this discovery is towards the further work for the exploration of PGE deposits in Jijal area. The discovery and association of merenskyite (PGM) is described through this report.

The recovery process of talc and emeralds, contained in the emerald bearing altered talcose schists of Gujar Killi were found to be feasible at the bench and pilot plant scale. The various units required for the washing and screening plant were tested. A detailed investigation of size analysis of the head and ground samples, liberation and association of emerald/gangue particles, pulp density, product size analysis and optimization of grinding were undertaken. A tentative block diagram was developed as a result of laboratory tests. The study conducted for the Gem Stone Corporation of Pakistan is encouraging and can be applied to the mechanical recovery of talc and emerald in the Gujar Killi emerald mine.

K/194. Khan, I.H. & Yoshida, M., 2000. Mineral magnetic and EPMA analyses of oolitic ironstone, Hazara area, North Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, 35-36.

The oolitic ironstone, known as the Langrial ore (Khan and Ahmed, 1966) Laterite bed (Latif, 1969) underlying the Paleocene Lockhart Limestone as an unconformity, is distributed widely in Hazara, Kalachita and other areas. This ironstone is investigated by mineral magnetic analyses, mineralogy by XRD and mineral chemistry by EPMA (Electron Probe Micro-Analyzer). Yoshida carried out field sampling in Southern Hazara and mineral magnetic studies. The selected sample collected near Bagnotar village was investigated in detail for mineralogy and chemistry. Two mineral magnetic analysis techniques: TM (thermomagnetic) and IRM (isothermal remnant magnetization) were used to identify the magnetic minerals. The Curie temperatures by TM indicated the presence of goethite, Ti-poor titanomagnetite or magnetite and hematite. Two IRM has shown the presence of high coercive ferromagnetic minerals, hematite/goethite with trace amounts of maghemite or magnetite.

The XRD analyses showed the presence of chamosite, hematite, quartz, goethite and siderite for untreated specimen whereas in heated specimen hematite quartz and little smectite were identified. The exact distribution of these minerals was checked by 6-elements (Ca, Al, Fe, Si, Ti and Mg) for corresponding Ka X-rays mapping using EPMA. On the basis of relative intensity of these, the oolites are classified into three types i) A-type mainly goethite - hematite - titanomagnetite and siderite ooides with very low chamosite, ii) B-type-considered chamosite- hematite-goethite ooides and iii) C-type with high Si-content and negligible other elements; the matrix of this oolite is

composed of chamosite, siderite, calcite and quartz. The first two are considered primary and later as secondary type- These studies revealed that formation of these oolite has passed from wide range of conditions (oxic to anoxic, non-sulphidic methane type) as drowning to starvation conditions existed during deposition in the southern hemisphere close to 10' South. The matrix minerals are mainly of secondary origin.

The project area is located in district Haripur (N.W.F.P). It covers about 60 sq. km. It is the part of topographic sheet No.43 G/1 published by Survey of Pakistan at the scale of 1: 50000.

Geological map at the scale 1:12500 of Jabri, Akhora, Faqir Muhammad, Lassan and Dunna Nauri area is presented along with complete record of Pre-Cambrian to Eocene rock units especially, Hazara Formation, Samana Suk Formation, Chichali formation, Lumshiwal Sandstone, Kawagarh Limestone, Margala Hill Limestone, Chorgali Formation, exposed in the area.

On the basis of field observations and petrographic studies the depositional environments of rock units have been interpreted. The formations exhibit varying fauna and lithology and microfacies from bottom to top.

Basal unit i.e. Hazara Formation which is predominantly slates and Samana Suk Formation which is mainly oolitic Limestone and shows shallow marine environment. The Chichali Formation which is dominantly Black slates with Iron Pyrite nodules, is the result of anaerobic conditions (lagoon environments) Glauconitic and ferrogenous Sandstone of Lumshiwal Formation shows open marine shelf environment. Kawagarh Formation possesses mainly, fine grained micritic Limestone, which show deep sea environment. Hangu Formation having laterite Bauxite, limonite, quartzite, red clays, Oolitic Haematitic sandstone and Carbonaceous shales which represent facies change and shows that the area was eroded during that time of deposition and marks unconformity between Cretaceous to lower Paleocene which is the result of regression of the sea for long period.

Lockhart Limestone is mainly nodular, Limestone, medium to fine grained with bituminous smell having shales and marl at various places which shows shallow marine environment. Patala Formation having Khaki shales with fossiliferous Limestone and marl which shows that the environment is shallow marine (Circa littoral sub zone).

Over 520 sq. km of the Baraul Valley has been investigated geologically and mapped on 1:63, 360 scale. Quartzites are the oldest rocks, exposed in the eastern part of the valley, and overlain by the mixed series of Paleocene-Eocene age which covers the central part of the area. The series includes interbedded volcanics (andesite, dacite, rhyolite, tuff and agglomerates) and metasedimentary/sedimentary rocks (pelitic, calcareous and arenaceous) intruded by small post-Eocene dioritic rocks. A large part of the valley, in the north as well as the south, occupied by (?) Cretaceous

Eocene diorites, quartz diorites, granodiorites and leucodiorites. The northern contact between the diorites and the mixed series is probably faulted.

Key words: Paleocene-Eocene, volcanics, metasedimentary rocks, Baraul, Dir.

Different mineral acids were used for the leaching of the Pb-Zn ores. Bench-scale parameters, i.e., effect of acid concentration, temperature and leaching time are set up. The results obtained were encouraging and about 90% separation as well as recovery of lead-zinc was obtained.

Key words: Acid leaching, Pb-Zn deposits, Kohistan.

K/205. Khan, K.S.A., 1980. Pattan Earthquake of December 28, 1974 and reconstruction programme in the effected areas of Swat, Hazara and Kohistan Districts. Geological Survey of Pakistan, Record 47, 35p.

Geological studies were carried out during the field seasons of 1974-76 in Pattan and other areas of Swat and Hazara Kohistan region, Northwest Frontier Province which have been seriously affected by an earthquake of moderate intensity on 28th December 1974. The earthquake completely destroyed the towns of Pattan, Jijal and Dubair and caused large scale destruction in the area. The investigations were aimed at selection of safe and suitable sites for the

construction of model colonies in the region, study of various road alignments to connect the interior regions with the main Karakoram Highway and to examine the suitability of various bridge sites along these roads.

The rock types exposed in the area are Palaeozoic schists, marbles and quartzites, late Cretaceous amphibolites, gabbros, diorites, and early to middle Tertiary granitic rocks and serpentinites. The age of garnet gneiss exposed at Pattan is unknown. From engineering geology point of view, the rocks are heterogeneous in texture and composition, and behave differently under different atmospheric and ground conditions. The sites for the construction of townships at Pattan and Besham were selected after a study of the topography, accessibility, availability of space, earthquake intensity and rock and soil conditions of the area.

Road alignment was studied keeping in view landslide problems and slope stability. Rock and soil conditions guided designing of slope. However, as a general rule the ratio of cuts for slopes at 1 horizontal : 3 vertical to 1 horizontal : 4 vertical were recommended in medium hard to hard rocks and 1 horizontal : 5 vertical in very hard rocks. Gentler slopes were recommended in unconsolidated deposits and weak strata. Benches may be provided at each 8 metre interval. The study of bridge sites over the river Indus at Pattan and Besham require detailed surface and sub-surface investigations.

Key words: Earthquake, Pattan, Swat, Kohistan.

K/207. Khan, K.S.A., Babar, M.Z., Khan, I.H. & Shakoor, T., 1986. Landslide investigation at the site of Cereal Diseases Research Institute, Pakistan Agriculture Research Centre, Murree. Geological Survey of Pakistan, Information Release 271.

The C.D.R.I. building is faced with the problem of subsidence and development of cracks in the building compound. The cracks have enlarged in magnitude with the passage of time giving rise to small slip circles on the north and northeast slopes. The Murree Formation, consisting of shale and sandstone, is exposed in the area. It is underlain by thick overburden material forming steep slopes.

The initiation and enlargement of the slide is attributed to the excessive infiltration of rain and snow-melt-water, the lithological characteristics of the sediments and the environmental changes in the natural slopes of the area. Based on the site conditions restraining structures such as retaining and crib walls, spur and catch-water drains are recommended to effectively control the problem of slumping and subsidence.

Key words: Landslides, Murree.

K/208. Khan, K.S.A. & Fayaz, A., 1987. Geological appraisal of Malam Jabba Ski-Lift and tourists resort site Swat, Pakistan. Geological Survey of Pakistan, Information Release 281, 14p.

A geological reconnaissance of the Malam Jabba Tourists Resort site in Swat was carried out in August, 1985 to evaluate the stability of slopes and foundation conditions at various tower positions of the skilift.

The area is underlain by mica and graphitic schists with thick accumulation of overburden material consisting of soil and humus. The bedrock at most of the tower positions is deep and beyond the foundation depth of the towers. The rocks are fractured and highly weathered. The foundations of the towers are designed at a bearing capacity of 1.0 Kg/C m². However, the foundation conditions may be improved by filling of fractures by grouting. The stability of slopes may also be improved by construction of retaining walls and catch-water drains.

Key words: Reconnaissance, mica, graphite schists, Malam Jabba, Swat.

K/211. Khan, K.S.A., Fayaz, A. & Latif, M., 1988a. Road alignment studies along Rakhiot-Astor road, District Diamir, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 378, 37p.

On the request of Frontier Works Organization (FWO), road alignment studies were carried out by the Geological Survey of Pakistan along the Rakhiot-Astor Road in 1974 which was followed by detailed geological investigations in 1989. The investigations comprised identification of landslide prone areas and measures for their control and correction, application of slope stabilization techniques and foundation studies for bridge sites. The road passes over a variety of rock and soil material, comprising igneous and metamorphic rocks, loose glacio-fluvial deposits and scree all along its length.

These rock and scree deposits are lying at their critical angle of repose and prone to sliding. Depending upon their angle of repose, stable cutslopes have been proposed. The road crosses three major landslide areas namely Lichar, Shah Pul and Mushkin which need special treatment. Methods for their control and stabilization have been proposed. The road also passes over a number of nullahs which have steep banks and deep channels and need construction of permanent bridges. The foundation conditions for the proposed bridge sites have been studied in detail and recommendations made according to the geological conditions prevailing at each site.

Key words: Road engineering, Raikot, Astor, Nanga Parbat, Diamir.

K/212. Khan, K.S.A., Fayaz, A., Latif, M. & Khan, M.S.Z., 1987. Study of landslide problem along the Rawalpindi–Murree–Kohala Road, (Kashmir Highway). Geological Survey of Pakistan, Information Release 279, 36p.

Landslide Investigations were carried out along the Rawalpindi-Murree-Kohala Road (Kashmir Highway) during the field season of 1984-85 on the request of Highways and Forest Departments, Government of the Punjab. Kashmir Highway is an all-weather road and links the Punjab with Azad Kashmir. Landslide activity often blocks the road and hinders the flow of traffic, particularly in the rainy season. The geotechnical problems of the area were thoroughly investigated and classified according to their mode of origin such as landslides, mudflows and bridge abutment problem.

In all, 14 slides have been studied and discussed in this report, Study of slides includes type of rock/material involved in the affected area, reasons of its occurrence and remedial measures to check them. The Kohala landslide has been studied in detail owing to its critical nature as well as its repeated occurrences involving large amount of falling material and road block. Proper execution and proposed implementation of the recommendations may help a great deal in prompting the stability of the Kashmir Highway.

Key words: Road engineering, landslides, Kashmir highway.

K/213. Khan, K.S.A., Fayaz, A., Latif, M. & Khan, M.S.Z., 1988. Development of cracks in village Danser, Kharmang sub-division, Baltistan. Geological Survey Pakistan. Information Release 276, 14p.

The village of Danser, Kharmang Sub-Division, district Baltistan was badly affected by sliding and slumping during the winter of 1985. The sliding caused heavy damage to the land and property of the people and is still in the process of further enlargement in its area of effectiveness.

Diorite rocks constitute the northern side of the Danser village whereas thick alluvial silt, gravel, and talus compose the southern terrane.

The large scale sliding could be due to the underground caving of terraces as a result of sub-surface flow and channelization of the stream from the Shaheen nullah on the eastern side of the village terraces. The effect of caving accentuates because of the infiltration of surface water from the irrigation “Kouhle” constructed at the contact of loose and porous overburden material and the diorite rock basement.

In view of the active nature of the slide and possibility of its further enlargement, the local people should be evacuated and rehabilitated in safe areas. However, the sliding may partially be controlled by constructing a dyke at the nullah bed level and diverting the flow of Shaheen nullah at its point of entrance under the village terrace. The infiltration from the irrigation “Kouhl” can easily be checked by cementing and lining of the drain.

Key words: Landslides, hazards, cracks, Baltistan.

K/214. Khan, K.S.A., Fayaz, A., Latif, M. & Khan, N.A., 1998. Engineering geological suggestions for improvements of road links in and around Chilas district Diamir, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 673, 36p.

Geological investigations were carried out along various side-valley roads in the Diamir district in 1996. These investigations were aimed at improving the present road conditions in relation to their gradient, slope stabilization, bridge locations and excavation problems to be encountered during widening of these roads.

The following road sections were studied in detail:

1. Chilas-Babusar Pass Road.
2. Nihat Gah Valley Road.
3. Chilas-Buto Gah Road
4. Kiner Gah Valley Road
5. KKH-Gini Gah Road.

The rocks and soils exposed along these roads comprise igneous and metamorphic rocks of various types, glacio-fluvial deposits, and unconsolidated materials consisting of boulders, gravels and scree. These deposits lie at their critical angle of repose and are prone to sliding frequently. The slopes are unstable, road gradients are usually steep and curvatures are difficult to negotiate. All these problems were studied in detail and remedial measures have been suggested for their improvement and stabilization as the case may be.

Key words: Engineering geology, Chilas.

K/215. Khan, K.S.A., Fayaz, A., Latif, M. & Wazir, A.K., 1986. Rock and debris slides between Khunjerab pass and Gilgit along the Karakoram Highway. Geological Survey of Pakistan, Information Release 272, 56p.

Rock, debris and scree slides from Gilgit to Khunjerab pass along the Karakoram Highway (KKH) are discussed in this report. Study of slides include type of rock/material involved in the affected area, reason of their occurrences and remedial measures to check the mass movement phenomenon. Kafir Pahar slide zone, Notorious killing zone and Shita Pari slide are studied in detail due to their critical position on the KKH; and the magnitude and repeated occurrences involving large amount of material fall. Specific recommendations for the stabilization of slopes have been proposed for each of the affected areas.

Continuous maintenance of the KKH requires considerable efforts in terms of time and money. Proper execution and implementation of the recommendations proposed in this report may help a great deal in reducing the manpower and maintenance cost of the KKH.

Key words: Debris slide, Karakoram Highway, Khunjerab Pass, Gilgit, Hunza.

Geological investigations for river bed erosion control were carried out during 1989 in Hunza, Ishkuman and Yasin River valleys in the Gilgit and Ghizar districts, Northern Areas Pakistan. The rocks exposed in these valleys comprise mostly metamorphic with small intrusions of igneous rocks and some outcrops of sedimentary rocks especially in the Yasin and Ishkuman valleys. The Hunza valley is characterized by two major Cretaceous-Tertiary granitic belts alternated by metasedimentary rocks and a metavolcanic complex which are known as the Ladakh-Kohistan granitic belt and Karakoram granitic belt. Geomorphologically, these valleys are drained by the Hunza, Ishkuman and Yasin Rivers which are perennial streams and fed by glacial melt waters. These rivers have a general north-south flow direction and are in their youthful stage of development. A much greater length of these rivers are confined by high alluvial/colluvial terraces and valley fill, presumably created by tectonically induced incision during the late Quaternary age. Geomorphologically the main river channels of the area are divided into Straight/Gorge River Channel, Meander River Channel and Braided River channel.

Based on the river capture system and mechanism of meandering 28 plantation sites in the flood plain areas have been identified in Hunza, Ishkuman and Yasin River valleys for channelising stream flow and reducing the large scale river bed erosion. These plantations may help in stabilising the river beds against erosion and add to the fuel, fodder and timber resources of the area in the future.

Key words: Riverbed erosion, Hunza, Ishkuman, Yasin, Gilgit.

This is a 1:250,000 scale geological map of the highway stretching for 875-km from Islamabad to Pak-China Boarder at Khunjerab. There are 25 plates (photographs), including three on the covers, showing various aspects of geology and geomorphology. Further data on geography, regional geology, mineral showings, and seismic risk is contained in seven inset maps and two tables.

Key words: Geomorphology, geology, KKH, Islamabad, Khunjerab.

K/221. Khan, K.S.A., Latif, M., Hussain, H. & Fayaz, A., 1999. Geomorphological mapping and engineering geological appraisal of the road links of Skardu-Shigar area, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 693.

Engineering geology investigations for road alignment and geomorphological classification of land forms in the Skardu-Shigar quadrangle was carried out on 1:50,000 scale in 1993.

The Shigar Valley is one of the most picturesque areas in Baltistan and serves as a land route to the K-2, Concordia, Broad Peaks and other famous peaks in the region. The valley is traversed by two roads which run on each side of the Shigar River. These roads are jeepable tracks and pass through a variety of land forms which need slope

correction, improvement of gradients and tackling of engineering geological problems during construction and have been described in detail in the section-wise description of each road.

The rock types ranging in age from Cretaceous to Eocene are exposed in the investigated area and comprise Katzarah formation, Greenstone complex, Deosai Volcanics, and the Yasin Group rocks. The metasediment found in the area are slate, phyllite, schists, gneisses, marble and quartzite. The volcanic rocks are composed of basalt and andesite intersected by felsic and mafic dykes. The main Karakoram Thrust (MKT) is encountered in the vicinity of Tassar village in the upper reaches of Shigar Lungma. Geomorphologically, various types of erosional and depositional land forms are identified and these have been classified into fluvial, aeolian denudational and structural units. This classification may help a great deal in tackling the envisaged problems during construction of the road.

K/223. Khan, M., 1995. Engineering properties of some building stones from Peshawar plain, NWFP., Pakistan. M.Phil. Thesis, University of Peshawar, 64p.

Rock types including limestone, marbles, quartzite, granites and basic rocks already in use as building and decorative stones are exposed in the surrounding of Peshawar basin. To ensure their safest use in building and other structure, some important geotechnical properties such as compressive strength, tensile strength, compressive strength/tensile strength, durability, water absorption and specific gravity of the se rocks were carried out. Highest compressive strength values are shown by Misri Banda quartzite and are in the range of 12188 to 18179 PSI, whereas Malakand granite show lowest compressive strength values 4559 to 6422 PSI values. Tensile values are highest in Misri Banda quartzite and Tor Warsak marble. Whereas Tor Warsak marble, Bagh and Malakand granite have lowest tensile strength. Tarako marble and Shewa Shahbaz Garhi granite show highest compressive strength/tensile strength ratio. All the geotechnical properties of these rocks are found to be within or very close to the recommended values of American Standards of Testing Materials (ASTM).

Key words: Geotechnical, limestone, marble, granite, Malakand, Misri banda, Peshawar basin.

K/225. Khan, M., Riaz, M. & Khan, K., 1996. Extraction of alumina from Nepheline Syenite by sintering with limestone. Pakistan Journal Scientific and Industrial Research, 39, (1–4), 25–31.

Nepheline Syenite of Koga (Lower Swat Area) Pakistan was sintered at 125⁰C with suitable quantity of limestone followed by water leaching for the formation of alkali aluminates which are further processed for the extraction of alumina. Parameters such as particle size variation, ratio of nepheline syenite and limestone, time temperature of sintering and sodium hydroxide concentration were optimized to obtained maximum recovery of alumina. The extraction of alumina on the basis of alumina in Nepheline syenite has been found to be about 70%. Such a process may be of vital importance to countries without ready access to supplies of alumina in the form of bauxite.

Key words: Alumina extraction, nepheline syenite, Lower Swat.

K/226. Khan, M.A., 1968. The stratigraphic section on the southern slop of Handyside Fort, Kohat, West Pakistan. Geological Bulletin, University of Peshawar 3, 15-18.

The area of investigation, which lies on the southern slope of the Handyside Fort, is formed of formations of Upper Mesozoic and Cenozoic ages.

The formation of Upper Mesozoic ages are represented by Oolitic Limestone-Late Jurassic, Green Shale-lower Cretaceous, Sandy-shale and silt-stone Middle Cretaceous, and Limestone- Middle Cretaceous. The formations of Cenozoic age are represented by Nodular limestone-Palaeocene and Gritstone-Conglomerate-shale-Paleocene. Of all the formations, the Gritstone, Conglomerate, and Shale represent deposition under fluvial, fluvio-lacustrine, and lacustrine conditions. The carbonate rocks (mainly limestone) account for more than three-fourth of the total thickness of the strata exposed in the area of investigation. The area is very much disturbed. Intense folding and faulting – which occurred during the Tertiary Era has complicated the stratigraphy and structure of the area.

Key words: Stratigraphy, lithology, Kohat Pass.

K/227. Khan, M.A., 1969. Siluro-Devonian reef complex of Ghundai Sar and vicinity, Jamrud, Khyber Agency. Geological Bulletin, University of Peshawar 4, 79-82.

A Siluro-Devonian 'reef complex', striking east-west, and dipping in a northward direction, is exposed to the north of Jamrud Fort along the Warsak Canal. The 'reef complex' forms the entire Ghundai Sar hills comprises four distinct units.

Gray and yellowish-gray dolomitized quartzite; Reef Breccia and talus; Reef Core; Phyllites and crinoidal limestone. Unit 2 and 3 represent the characteristics structural layers of reef.

Key words: Sedimentology, reef complex, Jamrud, Khyber Agency.

K/228. Khan, M.A., 1970. The Ali Masjid Group, Jamrud, Khyber Agency. Geological Bulletin, University of Peshawar 5, 90-95.

Of all the formations exposed in the north of Jamrud, the Ali Masjid Formation is the most diverse lithologically. A detailed work revealed that the so-called Ali-Masjid Formation contains many well-defined and stratigraphically valid formations. As such the Ali Masjid Formation is considered here as a group. Evidence for this conclusion consists of: The snowy white and grayish-white quartzites, which form the base of the group, are traceable over most of the Khyber Agency, Mulla Gori, and in Hazara. The Kandar Phyllite, a formation of considerable distribution, ranges in thickness from 600 to 900 feet. Both lithologically and paleontologically, it is distinguishable from the underlying and the overlying rocks. The Ghundai Sar Reef, already recognized as the Nowshera Formation (Siluro-Devonian), forms a part of the Ali Masjid Group.

The Quartzite conformably overlying the Nowshera and other reef carbonates and measuring about 600 feet in thickness is recognized as the Misri Banda Quartzite. The Warran Ghundai Formation, about 1200 feet thick, is both lithologically and palaeontologically different from other formations exposed in the area. It represents varieties of environment of deposition.

Key words: Stratigraphy, lithology, Khyber Agency.

K/229. Khan, M.A., 1979a. Petrography and sedimentology of the Ghundai Sar reef complex, Jamrud Khyber Agency: Pakistan. Geological Bulletin, University of Peshawar 12, 32-40.

A belt of Siluro-Devonian Coralline limestone of pink, yellowish-pink, and grayish-white color is exposed in the hills of Gundai Sar, near Jamrud; Khyber Agency. The entire formation represents deposition on a stable shelf. The environments were conducive for the development of coral reef. The ortho-quartzites associated with dolomite and limestone supports this observation.

In this paper, petrography and sedimentology of the reef limestone is discussed in detail. 101 specimens were collected and 30 sections were cut to describe the petrography. The limestone and dolomite show variations in their mineralogical composition. All variations from arenaceous limestone to calcareous ortho-quartzite occur.

Key words: Petrography, sedimentology, reef complex, Jamrud, Khyber Agency.

K/231. Khan, M.A., 1985a. Geology of the Babusar-Thak valley, and its implications on the configuration of the Kohistan island arc sequence. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

Most of the stratigraphic and tectono-metamorphic zonation suggests for the Kohistan arc sequence is based on the geological information collected from the Indus- and Swat valleys, the two most accessible traverses across the Kohistan. The Babusar-Thak valley in the SE Kohistan presents an additional section through the southern half of the arc sequence. Unlike the central and western Kohistan, where the southern arc sequence is principally made of amphibolites (together with enclosed isolated zones of blueschist and bodies of ultramafics) and Chilas ultramafic-mafic complex, in the Babusar-Thak valley the sequence is much more varied. Here the sequence principally comprises a thick pile of low-grade metavolcanics and plutons of diorite, granodiorite composition, bounded on the either side (both in the north and south) by amphibolites. The southern of the amphibolite sequence encloses at least one ultramafic body, and amphibolite sequences encloses at least one ultramafic body, and rests tectonically on the Indian plate metasediments. In the northern amphibolites have a banded appearance similar to the ones in the central Kohistan. These amphibolites have a tectonic contact with the Chilas complex in the north, which is marked by 30m thick shear zone.

The stratigraphic succession of gabbroic to metabasaltic amphibolites, island arc type tholeiite-andesite volcanics and calc-alkaline diorite-granodiorite plutons together with the tectonic contacts with the Indian plate metasediments in the south, and with the Chilas Complex in the north, suggest that the southern Kohistan sequence holds a separate entity within the Kohistan sequence, and may represent yet another island arc.

Key words: Tectonics, metamorphism, Babusar, Kohistan arc.

K/235. Khan, M.A., 1988-90. Geology and structure of Kotli-Nikial Khuiratta Area. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 115p.

Geological and structural mapping of Kotli-Nikial-Khuiratta area of about 300 square km was carried on 1:50,000 scale of toposheet No's 43 K/2, 43 K/3, 43 G/11 and 43 G/15 of survey of Pakistan. The lithostratigraphic units described range in age from Pre-Cambrian to Pleistocene and consist mainly of sedimentary rocks. The Pre-Cambrian rock formation is Dogra Slate and Cambrian rock unit is Sirban Formation. In this area apart from Lower Cambrian, all the formations of Paleozoic and Mesozoic are missing. Either they were not deposited or were

weathered to form Bauxite/Fireclay representing an unconformity of a big gap. In the Tertiary period, Patala Formation, Margala Hill Limestone, Murree Formation and rocks of Siwalik Group were deposited. Section measurements were done to establish the stratigraphy. The rocks are folded and faulted comprising the major and minor structures of the area. The major folds of the area are khairatta-Kohali anticline (11pp/325pp), Devigarh-Palana anticline (04pp/313p), Tattapani-Karela anticline (6pp/116pp) and Khad-Bahni syncline (6pp/228pp). The major fault is the Himalayan Frontal Thrust with minor thrust like Gala Thrust and Khad Thrust. Deformational events and stereographic projection of the area have been interpreted. The tectonic setup has been also discussed. About eighty five rock samples were taken from the field and carried back to the laboratory for petrographic studies. In the field of economic geology, a number of deposits including Fireclay, Bauxite, Coal, Limestone, Chalk and Dolomite are of economic interest.

K/237. Khan, M.A., 1990-92. Sedimentary Petrology/sedimentology of Paleocene Hangu Formation and lithostructural mapping of Changla Gali Area in Galiat region, Hazara, Northern Pakistan. M.Sc. Thesis, Punjab University, Lahore, 97p.

A Comprehensive study of Geology and structure of Chhangla Gali area is, presented along with special constraints on the sedimentology of Hangu Formation. Large scale (1: 7000) Geological mapping of a small segment of the Lesser Himalaya in the Chhangla Gali area is presented. The lithostratigraphic unit range from Upper Jurassic to Upper Eocene, Samanasuk Formation being the oldest. Structurally the area comprises NE-SW trending double plunging folds constituting anticlinoria and synclinoria. The folds are tight to isoclinal with a general vergence to the southeast. The folded sequence is disrupted by a number of high angle dip slip strike faults especially within or on the margins of anticlinoria. A detailed petrographic study of a section of Hangu Formation that comprises 18 microfacies. The deposition of Hangu Formation took place in humid, arid, subtropical conditions.

K/244. Khan, M.A., 1997a. Bearing capacity of foundations in slopes of sub-Himalaya regions. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p. 34.

The foundations of important national buildings, bridges, common houses and roads are mainly on slopes. Most of the slopes are destabilized by road widening, active landslides and the presence of faults. All the civil engineering structures are designed without prior investigation of grave landslides, active faults and level of seismicity in the area. This paper describes a method of designing foundations on slopes of cohesionless material such as clays and normally consolidated sandy clays. The method is based on the results of physical centrifuge tests. In order to extend the centrifuge findings under the slope, the results of other model tests were incorporated into the design procedure which is outlined. The method presented, is based on mechanical tests. The bearing capacity of a footing on or near the slope is rated as percentage of the capacity that the same footing would have on the surface of level ground. The use of local experience can determine the safe bearing capacity of reference level ground footing. The designer needs correct data of the tests run on footing of reasonable scale. The method is simple to use and covers the design geometries that are most likely to be met in practice.

K/245. Khan, MA., 1997b. Slop stability analysis in Higher and Sub-Himalayan regions of Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

A biplaner shear lies at a depth of 10-25m below the surface affecting the bridge and highway abutment in northern Pakistan. The overlying rocks are highly cracked, sheared, fractured and jointed. Many landslides occur in thick mass on down dip exposures on shear planes in Himalayan regions. An extensive investigation was undertaken to delineate shear zones and other significant stress creating features such as folds and faults, for further probable slides which would endanger the highway and bridge structures in northern Pakistan. An analysis was made to determine the extent and nature of treatment that would be required to stabilize the rock mass.

Shear nets were used to determine failure modes faced with combinations of joint sets and shear zones. Two dimensional studies were conducted leading to 3d i.e. the wedge angle method. Alternative treatments were conducted on the same slope. A monitoring system was installed to document the initial slope movement and the results obtained from this investigation.

K/246. Khan, M.A., 1997c. Tectonic evolution of southeast Kohistan, Northwest Himalayan Pakistan. Ph.D. Thesis, University of Peshawar, 320p.

The Kohistan island arc terrane in the northwestern Himalayas of N. Pakistan is sandwiched between the Indian and Karakoram plates. Structures related to collision tectonics have exposed more or less a complete crust of the arc terrane from its very base at Moho to its subaerial volcano-sedimentary cover. Within southeastern Kohistan, recent geological mapping along a N-S transect across the lower to middle crustal part of arc terrane, provides new and

important information relating to the magmatic emplacement of the principal units. The base of the arc here, is occupied by a major stratiform ultramafic-gabbroic complex (the Sapat-Babusar complex), which overrides the crust of the Indian plate along the Indus suture (i.e., the Main Mantle Thrust; MMT). The complex was intruded into the base of a thick pile of metavolcanics (the Kamila belt) which comprise a tectonic collage of MORB-type tholeiitic basalts (Jal-Niat amphibolites), island-arc tholeiites (Babusar amphibolites) and calc-alkaline andesites (Sumal amphibolites). The Chilas complex comprising ultramafic and gabbro-norite rocks is also intrusive into the Kamila belt but unlike the Sapat-Babusar complex, it was emplaced onto the top, rather than the base, of the belt. The Kamila belt is intruded by a suite of [1]raniloid rocks (gabbro, gabbro-diorite/tonalite-granodiorite granite and trondhjemite). The first group is closely comparable with the host Jal Niat amphibolites, second group rocks are similar to the subduction-related plutonic rocks from Kohistan (e.g., Kohistan batholith), and the trondhjemites were formed from the partial melting of Jal-Niat amphibolites. The field relations suggest a two-stage history of crustal thickening in lower and middle part of the arc crust. From its initiation at ca. 125-120 Ma until ca. 90 Ma, the arc grew by magmatic emplacement, into its base, of stratiform ultramafic-gabbroic plutonic complexes one below the other. In stage two, the focus of crustal growth shifted upwards from the base of the arc with the emplacement of the Chilas complex on top of the Kamila belt. This stage of crustal thickening was accompanied by crustal shortening associated with 90-80 Ma aged Kohistan-Karakoram collision.

K/247. Khan, M.A., 2001. Tectonics of north Pakistan: Consensuses and controversies. Abstracts, 4th Pakistan Geological Congress, Islamabad, 35-37.

North Pakistan is a prime example of continent-island arc-continent collision zone resulting in world's most fascinating mountain ranges of Karakoram, Hindukush and Himalaya. Tectonic evolution of this orogenic belt has remained focus of several national and international research programmes in the past three decades. These studies have greatly enhanced our understanding of orogenic processes and mountain building activity, which in turn, have led to the refinement of metallogenic models. At times, however, detailed studies have revealed several complexities leading to controversies.

Karakoram-Hindukush Block

A consensus has developed regarding plate tectonic position of Karakoram-Hindukush block (KHB) as a microcontinental plate accreted to Eurasia in Late Jurassic. Between Late Jurassic and Middle Cretaceous (~90 Ma), KHB served as an active margin for the subduction of the northern Neotethys, before it was accreted by the Kohistan island arc at its southern margin. The presence of subduction related granitoids (145-90 Ma) of the Karakoram batholith and an absence of marine sedimentation younger than Middle Cretaceous testifies to this plate tectonic scenario. The pre-Middle Cretaceous history of the KHB is recorded in well-preserved and superbly exposed stratigraphy dating back to Ordovician. A pre-Ordovician basement has first time been recorded in KHB directly below the Ordovician and younger cover sequence. Faunal comparisons testify to Gondwanic affinity of the 11KB, its separation from Gondwana in the Permian together with other micro continents like Afghan block and Lahasa, and finally collision with Eurasia in Late Jurassic at the expense of Palaeotethys. Despite a Middle Cretaceous minimum age of collision at the margin of the 11KB, recent radiometric dating shows that much of metamorphism and deformation in KHB is Late Tertiary in age and thus related with Himalayan orogeny. Some of the world's largest batholiths of crustal-melt derived leucogranites of Late Tertiary age form an interesting element in the geology of Karakoram and Hindukush.

Kohistan Island-arc Block

The discovery of blueschists from Shangla, Swat (1970) and recognition of two sutures, Main Mantle Thrust in the south and the Main Karakoram Thrust (now commonly referred to as the Shyok Suture) in the north (1976) led to discovery of Kohistan island arc block between the Indian plate and the KHB. This interpretation has withstood the test of time spanning about three decades. There are, however, still some differences of opinion on details:

The high pressure-temperature Jijal complex crystallized in a deep-seated magma chamber as such, or in a shallow-seated magma chamber that was subsequently subducted to depths of ~50 km? or alternatively, Jijal complex represents a mantle-crust transition? The same applies to the Chilas complex, which is interpreted as cumulates crystallized in a magma chamber or alternatively, a solid state intrusion of the mantle slab?

Kohistan formed as an island arc just offshore of Karakoram just like current example of Japan offshore of China, or it formed within the Neotethys far away from both India and Karakoram? This, in turn, questions the size of ocean separating Kohistan from Karakoram; was it of the size of Sea of Japan or of that of Pacific? Subduction polarity is

another issue; most workers prefer a northward subduction polarity for the origin of Kohistan while Khan et al. propose a southward subduction to explain boninites in Chalt volcanics.

Indian plate

Detailed work in N. Pakistan in past two decades has greatly resolved mysteries of Himalayas. For instance we now know ages of peak metamorphism, phases of magmatism and events of deformation. There is a consensus however, that there is a considerable difference in the Himalayas of N. Pakistan compared to those of India and Nepal. Despite this, attempts to stretch some boundary faults into Pakistani Himalayas generate interest. Main Central Thrust (MCT) is one such debatable issue. Other interesting points still under debate include:

The discovery of eclogites from Kaghan and recent recognition of coesite from these rocks suggest a pressure of ~30 Kbars (~90 km depth). More importantly what tectonic processes brought these rocks back to the earth's surface (exhumation) from such depths in such a short span of 5-8 Ma? The age of rift-related magmatism? Dating by radiometric methods with high closure temperatures (Rb-Sr, U-Pb on Zircon) clearly manifested a Permo-Carboniferous age for rift-related magmatism in Peshawar Plain. Is there still a phase of alkaline magmatism as young as Late Tertiary as suggested by some recent data? Compressional tectonics vs transpressional tectonics? In the context of foreland of Pakistan 'Himalaya, some recent work has stressed role of transpressional tectonics in Kohat Plateau. If so how this tectonic style changes to mainly compressional tectonics in the Potwar Plateau, just across the river? This talk is aimed at highlighting some recent advances made in our understanding of the tectonics of N. Pakistan. In this context some unsolved issues are pinpointed to identify the future course of research in this unique orogenic belt.

K/248. Khan, M.A., Abbasi, I.A., Khan, S.R., Hadi, S. & Tariq, M., 2001a. Tectonic subdivision of India-Afghan collision zone, Waziristan-Kurram region, NW Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 37-38.

The India-Afghanistan collision zone exposed in Kurram-Waziristan area of NW Pakistan comprises a stack of thrust sheets derived from various parts of a continental shelf-ocean floor transition formerly located at the NW margin of the Indian plate (Beck et al., 1996). From SW to NE, these thrust sheets include; Waziristan ophiolite, Khaisora nappe of outer shelf sediments, Shahur Tangi-Kahi nappe of deep-marine olistostromal sequence and Isha nappe of inner continental shelf Late Palaeocene and younger shallow-marine and fluvial sediments unconformably overlying the thrust stack and are involved in deformation. Four stages of tectonic evolution are recognized in the Waziristan-Kurram collision zone:

Middle Cretaceous (~90 Ma): An early phase of intraoceanic ophiolite obduction at ~90 Ma gave rise to Shahur Tangi-Kahi group of sediments in a fore-deep setting. This event conforms to a regional Middle Cretaceous orogeny (Semail ophiolites; Kohistan-Karakoram collision; Kamila shear zone, Kohistan).

Early Palaeocene (~65 Ma): A major thrust displaced the extensive nappe of Shahur Tangi-Kahi group eastward onto the entire NW continental shelf of the Indian plate during the Early Palaeocene, contemporaneous with and directly above the syndepositional breccia of Lockhart Formation. A closely following break-back thrusting event involved internal imbrication of the Waziristan ophiolite, thrust emplacement of the Waziristan ophiolite stack eastward onto the outer shelf (Khaisora group) and that of the Khaisora nappe onto the Shahur Tangi-Kahi nappe. This Palaeocene thrust stacking was complete prior to the deposition of Late Palaeocene Patala Formation onto the Shahur Tangi-Kahi group (Thai area), that of the Datakhel Formation on the stacked Waziristan ophiolite, and that of the Ghazij Formation and the younger sediments on the contact between the Isha and Shahur Tangi-Kahi groups (Khajuri Post area).

Post Middle Eocene (~45 Ma): Late Palaeocene-Middle Eocene shallow-marine transgression onto the thrust stack was followed by a major hiatus that marked onset of fluvial sedimentation at the expense of marine sedimentation. Late Miocene Kamliyal Formation in the north (near Thai) and the Pliocene Litra Formation (near Bannu) mark the earliest molasse sediments in this region.

Quaternary (<2 Ma): Molasse sediments in Waziristan-Kurram foreland are uplifted, tilted and folded. An extensive sequence of conglomerates overlying the Litra Formations is tilted to high angles in the foreland region near Bannu, suggesting Holocene (<1 Ma) age for this deformation event. A Quaternary transpressional upright fault brings base of the Shahur Tangi-Kahi group in tectonic contact with Ghazij Formation near Shinki Post (Bannu-Miran Shah road section). In the hinterlands, the Quaternary deformation event may be responsible for large structures of Drasmand and Khadimak antiforms together with associated thrust faults.

Whereas the Middle Cretaceous intraoceanic ophiolite obduction event correlates well with documented tectonic events in Kohistan and Oman, the Early Palaeocene thrust stacking is probably related with a second phase of ophiolite obduction similar to that of Spongtag, Ladakh (Searle et al., 1986), rather than with the India-Eurasia collision (Beck et al., 1996). The tectonic event related with Late Eocene termination of marine sedimentation could be the manifestation of India-Afghan collision in this region that continues into Quaternary due to an oblique collision and associated transpressional deformation.

K/251. Khan, M.A., Ahmed, R., Raza, H.A. & Kemal, A., 1986. Geology of petroleum in Kohat-Potwar depression, Pakistan. *American Association of Petroleum Geologists Bulletin*. 70, 396-414

The 36,000-km² Kohat-Potwar depression in northern Pakistan has more than 5,000 m of marine deposition (Precambrian to Eocene, with a major break during Ordovician to Carboniferous). More than 10,000 m of Miocene to Pleistocene alluvial sediments overlies the marine sequence. The tectonic depression formed as a result of continent-to-continent collision at the northwestern margin of the Indian plate. Although the region has been under active petroleum exploration since the mid-nineteenth century, it has been tested by only 60 exploratory wells. Ten oil fields have been discovered; original recoverable reserves total 200 million bbl, of which 112 million bbl has been produced. The region has several attractive features for petroleum generation and accumulation including source-reservoir-trap assemblages and thermal maturity regimes. Total ultimately recoverable hydrocarbon resource of the area is estimated at 2.4 billion bbl of oil equivalent.

Many unexplored surface and subsurface prospects and stratigraphic leads are known. Parts of the region, particularly the Bannu depression and Kohat salt zone, can be regarded as frontier areas; based on the exposed geology and available seismic information, we believe these areas are promising. Recent discoveries of Dakhni field (1983) and Dhurnal field (1984), which were the first discoveries in the northern part of the platform zone of the Potwar plateau, and production from Paleozoic horizons have added new dimension to petroleum prospects of the area. The region needs careful reevaluation of available information, exploratory drilling on selected targets, and detailed exploration in its western part.

K/255. Khan, M.A. & Din, S.M., 1994. Landslide incidences in western limb of Hazara Kashmir syntaxis. Abstracts, Second SEGMENT International Conference on the Export Oriented Development of Mineral Resources and Mineral Based Industries, Karachi, p.25.

The northwestern limb of Hazara- Kashmir Syntaxis, is an area of high landslide incidences. The valley system is characterized by steep sided river valleys cut into bed rock and river deposits. The steep slopes, undercutting of the Psammatic and Pilitic slates (Hazara Slates), silty and clayey soils, and humid climate of the area. All this area contributes to landsliding in the region. The situation has been further aggravated by road widening, effects of Main Boundary Thrust (MBT), and seismic activities resulting in many major landslides. Slumping, rock-falls, creep and at places earth-flows or combination of these are most common modes of failure.

The dormant and active landslides were investigated in detail because of their large size and proximity to roadways and residential area. Geological and topographic maps were prepared for each site and soil samples were collected to investigate geotechnical properties involved in failure and to establish stratigraphy of the sites.

In addition to the site investigation, a landslide map of the area was prepared using field reconnaissance and aerial photographs. All slope failures were marked on the map according to their damage severity. A high concentration of slope failure occurs on the western limb of Hazara Kashmir Syntaxis and on the eastern side of Kunhar River. The results indicate that slope failure occurs due to high swelling potential of soils, active faults and shear failures.

Key words: Landslides, MBT, Hazara-Kashmir Syntaxis.

K/256. Khan, M.A. & Foster, C.T., 1998. Geothermobarometry in Landakai and Chakdara areas, Swat and Dir Districts NWF Province Pakistan. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, p.98.

The Landakai and Chakdara areas, occupy the northern part of the Indian Plate south of the Main Mantle Thrust. The oldest rock unit in the area is the metamorphosed Swat granite gneiss of Cambrian age. The schists, marble and amphibolite exposed in the region are believed to be continental shelf sediments of Silurian-Devonian age which have a tectonic contact with gneisses. The rocks of the MMT/Mingora ophiolitic melange were tectonically emplaced upon the metasediments of the Indian Plate during late Cretaceous to early Tertiary time.

Metamorphism in the area ranges from low to medium grade at relatively high pressure. The rocks exposed north of the Swat River belong to the greenschist facies, whereas rocks exposed south of the river fall in the Kyanite zone of the amphibolite facies. Retrograde metamorphism has affected the area throughout but is more intense north of the river.

Geothermobarometry was carried out in pelites and amphibolites south of the Swat River. Applications of the garnet-biotite geothermometer and garnet-aluminum silicate-plagioclase geobarometer in metapelites gave a T and P range from 535° C, 8.3 kb to 662°C, 11kb. In amphibolites, the garnet-hornblende geothermometer and garnet hornblende-plagioclase geobarometer gave a T and P range from 588°C, 10.8 kb to 705°C, 11.9kb.

K/258. Khan, M.A., Habib, M. & Jan, M.Q., 1985. Ultramafic and mafic rocks of Thurlly Gah and their relationship to the Chilas complex, N. Pakistan. Geological Bulletin, University of Peshawar 18, 83-102.

Detailed field and petrographic studies in Thurlly area substantiate the idea of a two-fold subdivision of the Chilas Complex. Much of the area is occupied by the association of "Main Norites" with subordinate pyroxenites and anorthosites displaying only local layering. Apparently intrusive into these is the association of ultramafic-mafic rocks occurring principally in a 2.5×1 km lensoid body. These possess well-developed sedimentary features, especially layering, and comprise dunite, peridotite, pyroxenites, troctolite, norite, anorthosite, and olivine/pyroxene pegmatites. There are distinct differences in the mineralogy of the two associations, especially in the composition of plagioclase and oxide minerals. It is suggested that the ultramafic-mafic association was derived from a picritic magma emplaced in the floor of a crystallizing (main) noritic magma. There is a strong concordance in the planar structures of the two associations and the crystallization of the ultramafic-mafic rocks apparently preceded all deformational events.

K/259. Khan, M.A., Hamidullah, S., Khattak, M.U.K., Sayab, M. & Jan, M.Q., 1999. Geology and structure of the south-eastern Nanga Parbat Syntaxis, NW Himalaya, Pakistan. Terra Nostra 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 83-85.

The Nanga Parbat Syntaxes in N. Pakistan marks a crustal-scale structural bend in Himalaya that is accompanied by an unusually fast exhumation and uplift rate and a phase of Pliocene-Pleistocene regional metamorphism and crustal anatexis that is unique in the tire Himalaya. Despite its significance for understanding collision-related crustal geodynamics, the region has remained poorly mapped, particularly in southern and south-eastern parts, mainly because of the inaccessibility but also due to the location in proximity to the border with Indian Kashmir. In this paper, we present results of our new mapping in south-eastern parts of the Nanga Parbat region. Our observations are based on traverses along the Astor valley and its eastern tributaries (i.e., Gurikot, Rupal and Maiche) and a 40-km traverse across the 4564 m high Shontargali Pass, between the villages of Rattu in the Astor valley and Kel in the Neelum valley.

The Astor Section: Mapping in the Astor valley shows a continuation of the Iskere and Shengus gneiss units (Madin et al., 1989) from the Indus valley. These gneisses occupy the core of the massif, with the Iskere unit in the west and the Shengus unit in the east. The contact between the two, in the Astor valley, passes to the west of the village Harchu and is faulted. Whereas, the Iskere gneiss unit is a grey orthogneiss (quartz, k-feldspar, biotite ± garnet), that is often weakly porphyroclastic and migmatitic, the Shengus unit in Astor is a characteristic pink paragneiss (a reflection of garnet and biotite abundance; kyanite and sillimanite locally present) which contains local calc-silicates and quartzite intercalations. The marginal parts of the syntaxis at both sides (east and west) are occupied by a sequence of metasedimentary rocks. The metasedimentary unit at the eastern margin comprises kyanite-sillimanite-garnet schists and paragneisses (derived from calc-pelites), marbles and calc-silicates and together with common amphibolites, is classified as the Rattu Unit (Tahirkheli, 1988). The metasedimentary succession at the western margin is highly attenuated and comprises siliceous schists, marbles and amphibolites. A thin slice of the Rattu unit is observed in the core of the syntaxis near Mushkin that is closely associated with a sequence of amphibolites, together forming part of a narrow (faulted) syncline. The Astor section contains at least two sets of mylonitic gneisses derived from granites. The Mongdoian mylonitic gneiss is characteristically grey with medium-grained feldspar porphyroclasts and occurs enclosed in the metasedimentary unit at the western margin of the massif, while the Harchu pink mylonitic gneiss occurs at the contact between the Iskere and Shengus gneisses. Additionally, a

granite gneiss with characteristic feldspar laths and a pink mylonitic matrix (the lath unit) intrudes the contact between the Shengus and Rattu units. Finally, there is a weakly porphyritic granite in the Astor section that is apparently undeformed and intrudes the grey Mongdoian mylonitic gneiss at the western margin. A partly undeformed granite of similar general characteristics but an extensive geographic distribution has been noticed at the SW margin of the syntaxis in Bunar area (the Jalhari granite of Edwards et al., 1997). Structurally, the Astor section comprises at least two major antiformal fold structures, with a narrow faulted syncline at Dichilli confluence. The strata near the two margins is overturned (dipping inward to the core of the syntaxis) at topographic higher parts, suggesting outward “ballooning” of the syntaxis through crustal-scale fold structures. At the eastern Nanga Parbat-Ladakh terrane contact in Astor section, we have noticed ultramafic lenses that confirm preservation of the Indus Suture melange.

Gurikot, Rupal and Maiche Sections: Traverses along these western tributaries of the Astor river show a continuation of the geology observed in the Astor section. The part of the Gurikot section we covered includes Indus-suture melange comprising ultramafic lenses set in a matrix of basic mylonites, Rattu Unit, a very attenuated ‘Lath unit’, Shengus unit (large kyanites in pink-paragneisses) and Harchu pink mylonite gneiss unit. The entire sequence in the Gurikot section dips steeply to the west and is overturned. The Rupal section that gives access to most central parts of the syntax is in the SE comprises, from margin inward, Indus Suture mylonite melange, Rattu unit and an attenuated Shengus unit. The core of the massif here is occupied by the Rupal augen gneiss, which is unique to the southern parts of the massif. The dominant fabric (SI) in the Rupal augen gneiss trends E-W (dips 60-80° N) in the core of the massif but changes to NNE-SSW in the east near Tarshing. Strong stretching lineation associated with this fabric plunges shallowly to the NNW. Edwards et al. (1996) interpret SI to be associated with a major shear zone which they term Rupal-Chhichi shear zone. A relatively weaker fabric (S2) is superimposed on SI with a constant attitude of NW-SE /~80° SW. The Rupal augen gneiss contains E-W trending screens (several tens of m wide) of low-grade siliceous schists and quartzites at the ridges flanking the Rupal valley to the north and south (Tahirkheli, 1988; this study). The stratigraphic position and contact field relations of these metasediments are not known.

Rattu-Shontargali-Kel Section: The Rattu unit, in the area to the south of Rupal is bifurcated into two, at the limbs of a north-plunging antiform. The eastern limb of this antiform runs along the Indus suture and the western, along the Chhichi valley. The antiform is cored by grey migmatitic gneisses that resemble the Iskere gneiss, followed by a mixture of pink and grey gneisses (the Shengus unit) and finally the Rattu unit at limbs. The traverse along the Mir Malik River crosses obliquely through this antiformal structure. At Rattu, the Indus Suture melange contains abundant lensoid bodies of ultramafic rocks set in greenschist mylonites. The Rattu unit is well exposed at the lower reaches of the Mir Malik valley that is followed by the pink paragneisses in the Shengus unit. Much of the upper reaches of the Mir Malik valley and the Shontargali Pass comprise grey migmatitic gneisses locally intercalated with coarse-grained marbles, calc-silicates and garnetiferous amphibolite sheets. We correlate these gneisses with the Iskere unit. A thick thrust slice comprising tremolite marbles, calc-silicates, calc-pelitic schists and amphibolites (resembling the Rattu unit) occurs enclosed in the Iskere gneisses in the upper reaches of the Mir Malik valley. The paragneisses resembling Shengus unit reappear on the SW side of the Shontargali Pass in the upper reaches of the Shontar valley. These together with a sequence of tremolite-marble, calcsilicates, calc-pelites and amphibolites (the Rattu unit, locally called Nangimahli Formation; Malik, 1995) dominate the Shontar valley. The NW-verging Shontar thrust (Tahirkheli, 1988) runs along the Shontar valley and thrusts Shengus unit on to the Rattu unit. A tight hangingwall anticline and relatively open syncline that are followed to the NW by another pair of NW-verging anticlines and synclines accompany the Shontar thrust. The Shengus unit is in contact with Rupal augen gneisses both to the NW, in the Sarawali glacier area, and to the SW near Kel.

Discussions: The south-central and southeastern Nanga Parbat syntaxis is divisible into three mappable units, Iskere, Shengus, Rattu, that occur in a “stratigraphic” order. Of these the Iskere unit of grey orthogneisses (often migmatitic) is clearly an Early Proterozoic basement gneiss (Zeitler et al., 1993) while the Rattu unit is metamorphosed cover either of Palaeozoic (equivalent Abbottabad Group; Latif, 1970) or Permo-Triassic (equivalent Panjal Group) age. The Shengus unit is interpreted here to be predominantly metasedimentary and may be equivalent of the Precambrian pelites widespread in Lesser Himalayas of N. Pakistan (e.g., Salkhala, Hazara, Attock slates). The Rupal augen gneiss, the Harchu pink mylonites, Mongdoian grey mylonites, the Lath unit and the Jalhari granite are newly recognised units that owe their origin to granite magmatism of discrete but unknown ages. Structurally the Astor section is dominated by two large, N-plunging antiforms intervened by a narrow faulted synform. This fault possibly joins the Rupal-Chhichi shear zone in the south (Edwards et al., 1996). The NW verging Shontar thrust and related fold structures are reworked by SE-verging Rupal-Chhichi shear zone at the high topographic levels marking the drainage-divide between Rupal and Neelam valleys (Figure 1), which we interpret as the southern limit of the affect of Pliocene-Pleistocene exhumation of Nanga Parbat.

K/260. Khan, M.A. & Jan, M.Q., 1990. Transition from island arc to intra-arc rift tectonics reflected in successive phases of magmatism in the Chilas Complex, Kohistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 24-25.

Two distinct phases of magmatic activity indicating differences in tectonic setting of magma generation have been recognized in the Chilas Complex. The first and main phase crystallized mainly into homogeneous or weakly layered non-cumulate ultramafic and anorthosite rocks. Detailed evaluation of these rocks suggests that the calc-alkaline parental magma was generated and emplaced during mature stages of arc building in Kohistan. The remarkable the Chilas Complex through its entire extent (approximately 8 km²) suggests a peculiar mode of emplacement prob rough a plume-like up rise of magma body in the core of the aruation indicating a component of extensional environments in later stages of arc building.

The second and youngest phase of magmatism is represented swarm of basic dykes which cut across all the other lithologies present the Chilas Complex. These basic dykes have a fractionation trend indicating greater iron enrichment than the host main-phase gabronorities. Comparatively tholeiitic magma character is also supported by rare-earth elements.

Magmatism in island arcs is normally tholeiitic in the initial stages building, switching to a calc alkaline composition in the mature stages. The reverse trend in the Chilas Complex i.e., from calc alkaline to tholeiitic composition in the successive phases of magma is suggestive of intra-arc rifting of compressional environments re with Kohistan Arc- Karakoram plate collision.

K/261. Khan, M.A. & Jan, M.Q., 1991. An interpretation of the Himalaya-Karakoram region of Pakistan in the light of plate tectonics and rock ages. *Pakistan Journal of Geography* 1, 1-23.

This paper presents a brief and simplified review of the concept of plate tectonics, continental drift, and methods of radiometric age determination. An attempt has also been made to present the tectonic and magmatic evolution of the NW Himalaya-Karakoram in the light of recent advances in earth sciences. North Pakistan has experienced a complex interplay of continental collision, magnetism, metamorphism, uplift and erosion. The region is envisaged as consisting of the Karakoram and Indo-Pak plates, both of which represent fragments of the Gondwanaland drifted towards north. Sandwiched between these ii the Kohistan- Ladakh tectonic zone, a late Mesozoic to Early Tertiary island arc.

Key words: Plate tectonics, Himalaya, Karakoram.

K/262. Khan, M.A. & Jan, M.Q., 1992a. Some fundamental field and petrographic aspects of the Chilas mafic-ultramafic complex, Kohistan arc, Northern Pakistan. *Acta Mineralogica Pakistanica* 6, 126-147.

Detailed field and petrographic studies of the Chilas Complex, especially around Chilas, suggest that it is principally made up of gabbro-norites with local pyroxenites, anorthosite, quartz diorites and tonalites. These contain, locally, up to 10 km² lensoid bodies of ultramafic rocks with associated anorthosites, troctolites, olivine gabbros, gabbros and gabbro-norites. These latter are commonly layered and contain excellent sedimentary structures. However, the main gabbro-norites are mostly uniform with only sporadic presence of igneous layering. The complex is remarkably coherent with rare evidence of multiple intrusions, suggesting that most of the crystallization took place in one or a few large, continuous magma chamber(s). The contact relations show that the Chilas Complex intruded into a basement comprising metavolcanic amphibolites and paragneisses. The close association of the Chilas complex with arc-related rocks both in space and time, details of mineral and whole-rock geochemistry (presented elsewhere) and the absence of cyclically layered successions negate the possibility for the complex to have developed in mid-oceanic ridge conditions. The Chilas complex may represent rocks of the magma chamber to the Kohistan Island Arc, more likely, it developed from a mantle diapir in an intra-arc rift, similar to that documented in a number of recent island arcs, e.g., Mariana, Fiji.

K/263. Khan, M.A. & Jan, M.Q., 1992b. Magmatic evolution of the lower island arc crust, Kohistan, N Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Deptt. of Earth Sciences, Oxford University, England, 47.

The Eocene obduction of the Kohistan island arc onto the Indian plate exposed a uniquely complete island arc crust in southern Kohistan. Much of the lower arc crust, exposed in the southern Kohistan, is ultramafic to mafic in composition, and is considered to have formed in an intraoceanic island arc setting. A detailed geochemistry, combined with a limited available radiometric age data, yields a three-stage magmatic evolution of the lower-arc crust in Kohistan.

Tora-Tigga, Jijal, Sapatgali, and Babusar ultramafic-mafic complexes occupy the immediate hangingwall of the Indus suture, and are all characterized by a low-K, high-Mg tholeiite geochemical composition. Rocks of this geochemical character are also encountered in the Kamila amphibolite belt as fine-grained metabasalts, and in the Chalt volcanics in the upper arc crust. This early-arc low-K, high-Mg tholeiitic magmatism took place between 120 to 110 Ma. and marks stage-1 magmatic phase in the Kohistan island arc.

The stage-2 magmatism in Kohistan is typically calc-alkaline and is represented by the Chilas Complex, Pattan garnet-granulites and several smaller plutons intrusive in the Kamila amphibolite belt. Trondhjemitic granites, equivalent to 102 Ma. old Matum Das pluton in Hunza valley intrude the stage-2 basic plutons. Some of the calc-alkaline volcanics in the upper arc crust may be equivalent of this stage-2 magmatic phase. An origin in mature island arc with a component of embryonic stages of intra-arc rifting is envisaged for this phase on the basis of trace-element geochemistry. The stage-3 magmatism in the lower-arc crust in Kohistan marks a reversal back to tholeiitic magmatism. It is represented by the intrusion of ultramafic-mafic-anorthosite association in the Chilas Complex, which is distinctly more depleted in incompatible trace elements than the stage-2 gabbro-norite, and is characterised by an enrichment in FeO and TiO₂. The later phases of stage-3 magmatism is also tholeiitic in character and is represented by a suite of ~80 Ma tholeiitic basic dykes which intrude both the Chilas Complex and the Kamila amphibolites. These dykes, representing the last phase of intra-oceanic magmatism in Kohistan, intruded immediately after a major deformation phase related with Kohistan-Karakoram collision. A tholeiite-calc-alkaline-tholeiite temporal evolution of magmatism in the lower arc crust in Kohistan suggests changing tectonic setting of magma generation, in an intraoceanic environment, from an early-arc, through mature-arc, to back or intra-arc rifting in a span of 40 Ma (between 120 and 80 Ma.), prior to Kohistan-Karakoram collision.

K/264. Khan, M.A., Jan, M.Q., Qazi, M.S., Khan, M.A., Shah, Y. & Sajjad A., 1995. Geology of the drainage divide between Kohistan and Kaghan, N. Pakistan. Geological Bulletin, University of Peshawar 28, 65-77.

This paper describes the geology of an area of about 1200 km² in the upper Kaghan valley. The area is traversed by Main Mantle Thrust, which juxtaposes the southern part of the Kohistan terrane in tectonic contact with the higher Himalayas of the Indian plate. The Indian-plate sequence in the study area comprises a basement of granitic gneisses (both ortho- and paragneisses) followed by the Domel unit (calcareous schist/paragneisses, garnetiferous marbles, calc silicates and amphibolites) and the Parla Sapat unit (graphitic quartz-mica to garnet staurolite schists). These rocks are in tectonic contact with the mafic-ultramafic rocks of the Sapat complex along the Main Mantle Thrust. The Sapat complex underplates metabasalts of the Kamila amphibolite belts (i.e., Niat metavolcanic unit) and comprises ultramafic cumulates (dunites, peridotites and pyroxenites) at the base, layered gabbros in the middle and isotropic gabbros in the upper levels. The complex is folded through two phases of folding and metamorphosed under greenschist/lower amphibolite facies. The restored thickness of the complex approaches in excess of 2 kms. The Main Mantle Thrust was mapped at several new locations during this study. Our observations show that the MMT at the base of the Sapat complex is younger than the melange /olistostorm preserved in the upper parts of the Parla Sapat unit. The thrust cuts upsection laterally, and to the east of Babusar, occurs at the base of the Niat metavolcanic unit.

K/265. Khan, M.A., Jan, M.Q. & Weaver, B.L., 1993. Evolution of the lower arc crust in Kohistan: temporal arc magmatism through early, mature and intra-arc rift stages. In: Treloar,

P.J. and Searle, M.P. (eds.), Himalayan Tectonics. Geological Society of London, Special Publication. 74, 123-138.

The middle to lower island-arc crust in southern Kohistan represents a 40 Ma life-span of subduction-related magmatism in an intraoceanic setting. The Kamila amphibolite belt comprises two varieties of metavolcanic amphibolites. One enriched in high-field strength (HFS) and heavy rare-earth (HRE) elements is transitional in character between N- and E-MORB with a minor subduction-related component, and represents the earliest arc basement in Kohistan. The other variety of the metavolcanic amphibolites, together with deformed and amphibolitised intrusive basic plutons, has a transitional tholeiitic to calc-alkaline nature marked by depleted HFS and HRE elements and a distinct negative anomaly for Nb, suggesting emplacement in the early to mature stages of arc growth. The subsequent magmatism in southern Kohistan took place in two stages. The extensive calc-alkaline gabbro-norites of the Chilas complex were derived from partial melting of a mantle diapir emplaced into a mature arc or, more probably, during the initial stages of sub-arc splitting. This intra-arc rifting, at its advanced stages, generated tholeiitic picrite to high-Mg basalts which crystallized the ultramafic-mafic-anorthosite (UMA) association and basic dykes of the Chilas complex. The Late Cretaceous accretion of the Kohistan island arc with the Karakoram plate in the north ceased the intraoceanic history of magmatism in southern Kohistan.

Key words: Magmatism, island arc, amphibolites, Kamila, Kohistan.

K/266. Khan, M.A., Jan, M.Q., Windley, B.F., Tarney, J. & Thirwall, M.F., 1989. The Chilas mafic-ultramafic complex; the root of the Kohistan island arc in the Himalaya of northern Pakistan. Geological Society of America special Paper 232, 75-94.

The Chilas Complex is a large mafic-ultramafic body closely associated with the Kohistan Arc sequence in the western Himalaya of northern Pakistan. The arc and the Chilas Complex occupy an area of 36,000 km², bounded on the north and south by major sutures. The arc formed close to the margin of Eurasia in response to the northward subduction of neo-Tethyan ocean lithosphere in Late Jurassic to middle Cretaceous time, and consists of intra-arc sediments, calc-alkaline volcanics, and diorite-tonalite-granite plutons. At its base is the Chilas Complex, which extends for more than 300 km and which has a maximum width of 40 km. Most of the complex consists of massive (although locally layered) gabbro-norites, which comprise variable amounts of plagioclase (An 64-40), orthopyroxene (En 76-48), clinopyroxene (mg = 75-55), magnetite, ilmenite, +quartz, tK-feldspar, hornblende, +biotite, +rare scapolite. In the central part of the complex, near the base, there are minor discordant dikes and intrusive bodies as large as 5 km² of a dunite-peridotite-troctolite-gabbro-norite-pyroxenite-anorthosite association that displays excellent layering, graded bedding, slump breccias, and syndepositional faults. These rocks contain olivine (Fo 94-71), relatively Mg-rich orthopyroxene (En 91-65), clinopyroxene (mg = 85-67), and calcic plagioclase (An 98-83), +/- hornblende, +/- chrome spinel, +/- pleonaste, and represent a more primitive magma batch emplaced into the base of the gabbro-norite magma chamber. The mafic complex is not an ophiolite. Rocks of the complex have more petrographic and compositional similarities with plutonic blocks from island arcs and with other major mafic complexes such as the Border Ranges Complex of Alaska and those from the Ivrea Zone in the Alps. Trace-element patterns of the gabbro-norites have marked negative Nb anomalies, positive Sr, Ba, and P anomalies, and high K/Rb ratios, features consistent with melting of a hornblende-bearing sub-arc mantle source. The Chilas Complex either represents the root zone magma chamber of the Kohistan island arc, or magma generated by diapirism in the early stages of intra-arc rifting during formation of a back-arc basin.

K/271. Khan, M.A. & Khan, I.H., 2001. Geothermobarometry of Oghi area, Mansehra, north Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.3.

The Mansehra area occupies the part of Indian plate south of the Main Mantle Thrust (MMT). The oldest rocks exposed belong to Tanawal Formation's schist, marble and quartzite of various grades. The Mansehra granite of Cambrian age has intruded the Tanawal Formation. The granitic gneisses, porphyritic granite and tourmaline granite are part of the Mansehra granite. The diabasic dykes of Siluro-Devonian age are emplaced into granite and rocks of Tanawal Formation. Some of these dikes are metamorphosed to amphibolite grade surrounding Oghi area and are aligned in an east-west direction. The major and trace element composition by XRF analysis have revealed SiO₂ contents ranging from 45-48% and represent mainly basic compositions.

The metamorphism of these rocks ranges from low to medium grade at relatively high pressure. The exposed lithologies belong to green schist facies and fall in the kyanite zone of the amphibolite grade. The area is affected by retrograde metamorphism and shows sericitized schists of variegated grades. The amphibolitized bodies are aligned east-west parallel to the Oghi shear. The geothermo-barometry was carried out to know the peak metamorphic P-T conditions. The garnet-hornblende-plagioclase geobarometer and garnet-hornblende geothermometer gave 10.8 to 11.9 Kb pressures and 5880C to 7050C temperatures. These amphibolite bodies may have equilibrated at high pressures and low to medium temperatures during the Himalayan collision times (?).

K/273. Khan, M.A, Khan, M.A. & Jan, M.Q., 1998. Trondhjemites in the southeastern part of the Kohistan Island-Arc Terrane, Pakistan: A product of partial melting. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 97-98.

The Kohistan terrane in N. Pakistan is sandwiched by two major thrusts, the Main Karakorum Thrust (MKT) in the north and Indus Suture or Main Mantle Thrust (MMT) in the south. Recent geological mapping in southeastern part of the terrane, along a N-S transect, provides new and important information about the geology of the area. Hence, the base of the terrane is occupied by a stratiform mafic-ultramafic complex (the Sapat complex), which overrides the crust of the Indian plate along. The complex was intruded into the base of a thick pile of metavolcanics of different environments (the Kamila belt). The Kamila belt is intruded by a suite of granitoid rocks divisible into

three groups. gabbroic association, gabbro-diorite/tonalite-granodiorite-granite association and trondhjemite association.

The trondhjemites occur as thin veins and dykes in the northern part of the Kamila amphibolite belt. Here, the belt is in contact with the Chilas complex along a strong shear zone known as Jal shear zone. Under the microscope the trondhjemites contain feldspar, quartz and amphibole with minor epidote, muscovite, biotite, sphene, garnet and ore, and show parallel alignment of mineral grains in one major direction. They show a very spiked pattern and are depleted in all HFSE, particularly strongly in Ti, P and Nb relative to the other granitoids of the area. The trondhjemites formed by the partial melting are depleted in these elements due to occurrence of amphibole and garnet as the residual phases in the arc basement.

Partial melting of a basaltic source material is considered to be the most viable mechanism for the generation of high-AI trondhjemites similar to those of the area studied by Drummond and Defant (1990). Basalts converted to amphibolites and eclogites when involved in subduction-zone setting are partially fused to generate trondhjemites (De Vore, 1983a, b., Windley, 1984; Martin, 1986, 1987). The geochemical modeling and experimental studies (Drummond and Defant, 1990) favour a hot oceanic crust (20-30 Ma old) subducting and melting to produce trondhjemites. The trondhjemites of the present study are probably a product of partial melting of Kamila amphibolites but a direct role of subduction is not observed.

Treloar et al. (1990) considered that the amphibolite-facies metamorphism and deformation in the Kamila belt is related to the Kamila shear zone of 80 Ma, suggesting a similar age for the trondhjemites. The emplacement of Chilas complex (90-80 Ma) might have played an important role in the genesis of the trondhjemites as a heat source. Field evidence, distinctive geochemical signatures and restricted distribution of trondhjemites close to the Jal shear zone and the lower contact of the Chilas complex support the idea but the exact petrogenesis of the trondhjemites cannot be properly evaluated without data on rare-earth elements.

K/274. Khan, M.A., Khan, M.A., Qazi, M.S., Khan, T. & Jan, M.Q., 1997. Chalt-Babusar transect across the Kohistan island-arc terrane, N. Pakistan. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 157.

Kohistan Island Arc terrane in N. Pakistan is a Cretaceous-Tertiary island-arc complex entrapped between collided Indian and Karakoram plates [1]. Several aspects of the crustal geology of the terrane have been refined in the light of our recent mapping along its eastern margin, i.e., Babusar-Chilas-Chalt transect (Fig. 1).

The base of the arc crust in SE Kohistan is occupied by the 2-km thick Sapat mafic-ultramafic complex [2]. Unlike the garnet-granulite facies Jijal Complex exposed in the Indus valley [3], the Sapat Complex is metamorphosed only to lower-amphibolite facies.

The Sapat complex underplates a sequence of amphibolite-facies metabasalts belonging to the Kamila amphibolite belt (KAB). Two compositional types are identified in the KAB. The volumetrically preponderant Niat metabasalts have a geochemical composition similar to the N-MORB, characterized by enriched HFSE and HREE relative to the LILE and REE [4].

These metavolcanics are locally intercalated with metabasalts, which are calc alkaline and have a composition typical of subduction-related magmas. Unlike the Indus-valley section [5], the part of the KAB in SE Kohistan is devoid of metagabbroic amphibolites.

To the north, the KAB is in tectonic contact with the Chilas complex [4]. Much of the northern contact of the Chilas complex is against the relatively younger Kohistan batholith, which more or less completely separates it from a sequence of metabasalts and metasediments exposed near Jaglot. The Chilas complex carries xenoliths of KAB in its southern marginal parts and those of the metasediments of the Jaglot group in its northern marginal parts, suggesting that it was emplaced at the interface of KAB and Jaglot group.

The Jaglot group [6] comprises Gilgit Formation (paragneisses, schists and pillowed metabasalts) at the base, pillowed metavolcanics similar to the Chalt volcanics in the middle and Thelichi Formation (slates, metavolcanics and marble) at the top. There is possibility the Jaglot group is equivalent to the Chalt-Yasin succession exposed adjacent to the Northern Suture, but more geochemical data are needed for evaluation of this aspects.

Key words: Ultramafics, metamorphism, Babusar, Chalt, Sapat, Kohistan, Himalaya.

K/275. Khan, M.A., Khan, M.H., Tahirkheli, T., Treloar, P.J. & Petterson, M.J., 2000. Tectonic Evolution of the Eocene Dosh-volcano-sedimentary basin NW-Kohistan island arc terrane,

Hindu Kush, N Pakistan. Abstract Volume, 15th Himalaya-Karakoram-Tibet Workshop, (Chengdu) China, 180-181.

In NW Himalayas, the suture zone between the collided Indian and the Karakoram Plates is occupied by crust the Cretaceous Kohistan Island-Arc Terrane (Tahirkheli et al., 1979). Late Cretaceous (about 90 Ma) accretion with the southern margin of the Karakoram Plate the site of the Shyok Suture Zone turned Kohistan to become an Andean-type margin. The Neotethys was completely subducted at the southern margin of Kohistan by Early Tertiary, leading to collision between Kohistan and continental crust of the Indian Plate at the site of the Main Mantle Thrust.

More than 90% of the Kohistan terrane comprised plutonic rocks of (1) ultramafic to gabbroic composition forming the basal crust of the intra-oceanic stage of the island arc, and (2) tonalite-granodiorite-granite composition belong to the Kohistan Batholith occupying much of the intermediate to shallow crust of the terrane mostly intruded in the Andean-type margin stage (Pettersen & Windley, 1985). Both these stages of subduction-related magmatism were associated with volcanic and sedimentary rocks formed in Late Cretaceous and Early Tertiary basins. This study addresses tectonic configuration of Early Tertiary Drosh basin exposed in NW part of the Kohistan terrane, immediately to the south of the Shyok Suture Zone.

Previous studies have shown that Shyok Suture Zone in its immediate southern vicinities comprises a sequence of Late Cretaceous sediments comprising turbidites and subordinate limestone, together constituting the Yasin Group, overlying a sequence of met volcanic rocks called Chalt Group. Recent detailed studies by us confirm that this configuration holds true for the area between the Hunza valley in the east to the Village of Shamran in the west, through the Chalt Volcanic Group increasingly becomes less deformed and more siliceous towards the west. West of Shamran, in the area around the Shandur Pass, there is sporadic presence of rhyolite-rhyodacite dominated green as well as pink volcanic rocks resembling closely with the Eocene Utror Volcanic Group. These rocks, known as the Shamran Volcanic Group. ⁴⁰Ar-³⁹Ar hornblende dating of the Shamran Volcanic Formation has yielded a 58 Ma age. Further west in the area near Drosh, occurrence of two volcanic units; Gawuch and Drosh formations is known previously (Pudsey, et al., 1985). The Gawuch Formation comprises highly tectonic greenschist metavolcanics, with common intercalation of limestone and marble in its upper (northern) part. The Drosh Formation consists of mildly deformed to slightly metamorphosed basalts of tholeiitic character, similar to the Chalt Volcanic group. Our recent mapping in Drosh area finds a third volcanic unit; this unit is andesite to rhyolite in composition, massive; aphyric to hornblende-and/or pyroxene and/or plagioclase phyrlic, undeformed and only mildly metamorphosed and is equated with the Eocene Shamran Volcanic Formation in strike to the east. All the volcanic units in the Drosh area are intruded by the Mirkhani granodiorite pluton. A sequence of red conglomerate, sandstone, siltstone, siltstone and shale of fluvial origin, termed Purit Formation is associated with all the volcanic rocks of the area. Previously this unit was considered to have an unconformable stratigraphic position above the Gawuch Formation and the Mirkhani granodiorite pluton but below the Drosh Formation. Detailed mapping and field-relation studies demonstrate that (1) Mirkhani Pluton is intrusive and thus younger than all the volcanic units in the area, implying that the Purit Formation that rests unconformably on top of the Mirkhani Pluton is the youngest in the area, (2) the occurrence of the Purit Formation unconformably on top of the Shamran Formation suggests a post Early Eocene age for the former.

A comparison between the Early Tertiary Drosh basin with the southerly located Dir basin (Sullivan, et al., 1993) of equivalent age shows a close match in the volcanic rocks in terms of composition and Andean-type setting of origin, but contrast in the sedimentary record. Sediments in the Dir basin are deep-water turbidites (the Baraul Banda Slate Formation) and are considered to have formed in an Andean-type fore-arc setting. In contrast the Purit Formation is typically fluvial and is relatively younger than the Early Eocene Shamran Formation. We equate the Drosh basin with the Reshun basin further to the north and suggest an Andean-type back-arc basin origin for these two basins.

K/276. Khan, M.A. & Khan, M.R., 1994. Evaluation of geotechnical properties and deformability of Jura granites, Neelum valley Azad Kashmir. *Kashmir Journal of Geology* 11 & 12, 89-95.

The geotechnical and deformability characteristics of Jura granites are presented. The middle and lower Jura granites are medium textured and takes excellent polish. The upper Jura is coarse textured and also take polish. From geotechnical variations it is apparent that upper coarse textured granites display a behavior markedly different

from lower granites. In the upper weaker rocks, the elastic range is limited to very low stress levels. The sensitivity of the strength to water content has also been discussed.

Microscopic characteristics in particular are outlined, in the areas of grain contact were successfully used to explain strength and deformability of granites: Evaluation of geotechnical properties shows potential as a compliment to the index test of saturated rocks and uniaxial load for weak and strong granites respectively.

The Aggregate Abrasion Value (4%), Aggregate Crushing Value (10%), soundness (1.3 to 6%), porosity (0.1 to 6%), compressive strength (2000-3500 PSI) and slake durability (75% retained) tests were conducted for economic exploitation of the rocks.

K/277. Khan, M.A. & Khan, M.S., 1989. Engineering characteristics of Nauseri Marble, Azad Kashmir. *Kashmir Journal of Geology* 6 & 7, 125-132.

White, gray and bluish gray marble and brownish gray to whit and dense marble occur in Nauseri area. The deposits were formed at southwestern margin of Kashmir landmass during Permo-Carboniferous times. They were metamorphosed to varying degrees. White crystalline limestones are calcite marbles of inferior quality comprising of a small part of the deposits. Most of these potential sources are not developed so far mainly for lack of technical information. However, on the basis of range of colors, good textures and quality a large and potential quarries could be developed. This paper describes the engineering characteristics of Nauseri Marbles.

A number of mechanical characteristics were determined and most of them are in confirmation to ASTM specifications.

The compressive strength of the marble varies from 3100 PSI to 8100 PSI. Taber Abrasion Index value range from 8.0 to 15.01. The soundness ranges from 0.1 to 5.0% absorption varies from 0.01 to 8%. Specific gravity ranges from 2.65 to 1.73. The porosity of the marble is 0.5 to 8.3%.

K/279. Khan, M.A., Khan, S.F. & Islam, F., 1999. Geology of marbles from District Buner, N.W.F.P., M.Sc. Thesis, University of Peshawar, 91p.

This study of marble deposits of the North West Frontier Province has been carried out in order to update the previous work on the commodity and also to investigate some of the new and the little known occurrences.

The project is located at the central part of Buner district which include areas of Yakh dara, Mirdara, Matwanai, Tursak, Bazargai, Nanser and Bampokha. These are the major marble producing deposits in North West Frontier Province, and different mining corporations are working in these areas.

The marble deposits under study are mostly associated with metasedimentary rocks of Paleozoic age. The marble deposits are located in Kashala, Nikanai Ghar and Saidu Formations. Variation in composition, texture, thickness, and structure displaying a wide array of color shades and grain sizes. The present study include general characteristics of the outcrop exposures, physical and chemical characteristics, petrography and geo-technical properties of these marble. The geology, petrography and geo-technical studies shows that the marble from these deposits has a pleasing appearance, take good polish and meet the standard specification for specific gravity, water absorption, flexural strength and other physical properties.

K/280. Khan, M.A., Khan, Z.A., Qureshi, M.S. & Nasim, S., 1994. Evaluation of geotechnical properties of Miocene shales of Muzaffarabad Azad Kashmir. *Kashmir Journal of Geology* 11 & 12, 97-104.

Geotechnical behavior of shale of Murree Formation of Miocene age was observed under static and dynamic tests. It include natural water content, absorption, specific gravity, plasticity, characters, slake durability, point load index, compaction and strength characteristics of mixed samples with varying proportions of shales and sills. This shows improvement in geotechnical behavior of the construction material.

The XRD analysis of the specimens shows montmorillonite and illite as the dominant clay minerals. Generally, the shales tend to have low absorption values, strength after compaction of the samples. Clayey shales showed the best compaction with the lowest void ratio. The void ratio increases with increasing proportions of siltstone in many cases. The unconfined compressive strength decreased with increasing proportions of siltstone (50-65%). The durability seemed to influence by the nature of cementation, degree of lithification and the proportion of silt.

K/283. Khan, M.A. & Petterson, M.G., 1992. Magmatic evolution of the Kohistan arc: Geochemical constrains. Abstracts, First South Asia Geological Congress, Islamabad, p.23.

The Kohistan sequence -in N. Pakistan comprises a diverse assemblage of rocks, emplaced during a wide span of time. The recently acquired radiometric ages and whole-rock geochemical data suggest that the sequential magmatism in the Kohistan arc was controlled by changing plate tectonic setting of the region. An early phase of magmatism was exclusively in an intraoceanic island arc setting and was mainly basic in composition (e.g., the Jijal and Chilas Complexes, the Kamila amphibolites, and high-Mg tholeiite volcanics in the Chalt area). The late Cretaceous accretion of the island arc with the Karakoram plate in the north resulted in a major change in the tectonic character of the Kohistan from an intraoceanic island arc to a continental margin. This led to generation of a predominantly acid magmatism which now makes bulk of the Kohistan batholith and volcanics in the upper parts of the arc sequence. Within this broad two-fold division of the arc magmatism, our geochemical data enables us to recognize changes in the tectonic character of the Kohistan arc from an interoceanic early to a mature stage, and from a continental margin to a continent-continent collision zone. In this paper we present geochemical data for these successive phases of magma, and identify changes in the magma character related with changes in the tectonic settings of the Kohistan arc.

K/286. Khan, M.A. & Qureshi, M.S., 1991. Landslide hazards in southern Muzaffarabad Azad Kashmir and southeastern Hazara Pakistan. *Kashmir Journal of Geology* 8 & 9, 121-on ward.

The Jhelum River Valley in southeast of Hazara and southern part of Muzaffarabad are the areas of high landslide hazards. Steep slope, silty, sandy and clayey soils, heavy rains, water seepages all contribute to the landsliding in the region. The instability of the area has been further increased by road widening and effect of the Main Boundary Thrust (MBT) resulting in the form of many major landslides, such as slumping earthflows, rockfall, sinkholes and combination of these.

The active Kohala and Rara landslides were investigated in detail because of their large size and proximity to roadways. Soil samples were collected to evaluate engineering properties of the materials involved in these failures. The investigated area lies in a structurally complex belt of folded and faulted sedimentary rocks which have been further deformed by the locally important Murree Thrust and regionally significant Main Boundary Thrust (MBT).

In addition landslide map of the area was prepared by performing fieldwork and using Ariel photographs. All slope failures were classified according to their movement and state of activity, with variation and change of water content (6.7-45%), liquid limit (22.6-41.5), plastic limit (6-23.7), swellability (8.9-55), compressive strength (2-15 MPa), shear strength (3-10 MPa) and pore water pressure (4-6 MPa). The results suggest that slope failure occur due to high swelling potential of soils, active faults and shear failures.

K/287. Khan, M.A. & Qureshi, M.S., 1992. Review of geotechnical characteristics of Neelum granites, Neelum valley, Azad Kashmir. *Kashmir Journal of Geology* 10, 141-146.

The Neelum granite of Neelum Valley Azad Kashmir has been investigated to evaluate its geotechnical properties. The geotechnical properties like compressive strength shear strength, soundness, porosity, water absorption and slake durability of the granite show their potential to be used as construction raw material. The compressive strength values ranges from 100-350 MPa. The shear strength varies from 150-950 MPa, soundness 0.1-2%, water absorption 14-20%, slake durability 99.5-99.8%, porosity 0.2-15% and degree of polish good excellent.

An evaluation of geotechnical properties of different granites suggest the rational use of the raw material, considering the deformability characters of the rocks.

Key words: Geotechnical, granites, Neelum, Azad Kashmir.

K/288. Khan, M.A., Rehman, I., Rehman, O. & Abbasi, I.A., 1990. Multiple detachment levels and their control on the deformation style of the Kalachitta Hill Range. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, p.2.

Detailed mapping in a part of the Kalachitta Hill Range, Attock District (I. Rehman, 1990) has shown two distinct styles of deformation, apparently controlled by two detachment levels. The lower detachment occurs at the base of the Mesozoic strata, and the upper in the Patala Formation of Paleocene age. The deformation in the Mesozoic-Paleocene sequence between these two detachment levels is controlled by thrusting, resulting in the formation of a duplex zone, in which the lower detachment is acting as a sole thrust while the upper detachment as roof thrust. The Mesozoic-Paleocene strata in this duplex zone is repeated, at one place, more than four times in the form of south-verging horses. No folding, except for that related with thrusts (open hanging wall anticlines) has been observed in the sequence between the two detachment levels. In contrast deformation in the Cenozoic strata overlying the upper detachment surface in the Patala Formation is controlled by large scale folds verging both to the north and south, in a fashion similar to that outlined by Cotter (1933) while presenting a model for the tectonic evolution of the Kalachitta Hill Range.

Key words: Deformation, Kalachitta range, Attock.

K/289. Khan, M.A. & Ristic, D., 2001. Swelling potential of sandstones and clays in Himalaya regions. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.47.

Swelling potential of rocks in Himalayan regions is a great problem for civil engineers for designing high rise buildings, bridges, highways, viaducts, overpasses, under passes and other civil engineering structures. This paper covers a broad mechanism of swelling potential of rocks and soils. The rocks were classified in different classes for identification and uses for civil engineering structures. The categories involve mudstone, shales, weakly cemented sandstones, and clays. The engineering aspects of swell are described by the influence of density, in-situ stress and availability of water. The identification of swell-shrink susceptible strata includes testing techniques and the design criteria for subsurface and surface structures in the Himalayan regions of Pakistan and are presented here.

Key words: Geotechnical, sandstone, clay, civil engineering, NW Himalaya.

K/290. Khan, M.A. & Stern, R.J., 1996. Polarity of the subduction system responsible for the Cretaceous Kohistan island arc terrane, N. Pakistan: geochemical and structural constraints. Geological Bulletin, University of Peshawar 29, 27-40.

The Kohistan island arc terrane of N. Pakistan has experienced multiple collisions, resulting in obliteration of the subduction system responsible for its creation. Indirect evidence, based on structural vergences and across-the-arc variations in trace elements (Ti, Zr, Nb, and P) have been combined to interpret the nature of the subduction zones responsible for Kohistan in terms of their location and polarity (i.e., dip direction). Geochemical investigations, from north to south, in the Chalt volcanics, the Chilas complex and the Kamila amphibolite belt indicate a systematic increase in high-field strength elements from north to south. These variations indicate an overall decrease in the degree of melting or degree of source-region depletion, which in either case, give a facing direction for the arc terrane towards north. The structural vergences in the northern parts of the Kohistan terrane are also consistent with a south dipping subduction zone located to its north. Using these observations, a tectonic model is proposed for the origin of Kohistan terrane on a south-dipping subduction zone located at its northern margin. The subduction switched to the southern margin of the arc terrane soon after the Kohistan-Karakoram collision with a reverse polarity (i.e., dip direction towards north). The model has been tested in the light of modern examples of arc-continent collisions in SW Pacific ocean.

Key words: Geochemistry, structure, subduction, Kohistan arc.

K/291. Khan, M.A. & Stern, R.J., 1997. Isotope composition of Sr, Nd and Pb in the Kohistan Intra-Oceanic Arc Terrane of Northern Pakistan. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 55-56.

The Kohistan terrane of northern Pakistan is a remnant of a Cretaceous-Tertiary island arc crust trapped between collided Indian and Karakoram plates. Two phases of evolution are recognized. Much of the arc crust (i.e., lower-crustal ultramafic-mafic cumulates of Sapat and Jijal complexes, intraoceanic phase. The collision with Karakoram took place at about 90 Ma accompanied by intrusion of the Chilas ultramafic-gabbro-norite Complex. Much of the Kohistan batholith was emplaced in the subsequent continental-margin setting.

We report isotopic composition of Sr, Nd and Pb for the principal units of the island arc crust, i.e., Kamila amphibolite belt, Chalt volcanics and the Chilas complex. Sr and Nd isotopic data for the Kohistan batholith has been published. The Kamila amphibolite belt in SE Kohistan comprises predominantly of metavolcanic rocks metamorphosed under lower-amphibolite facies. Two compositional types are recognized.

The predominant variety is E-type amphibolite, characterized by slight to moderate enrichment in HFSE and HREE over LREE, respectively. Overall composition is not far from type N-MORB. The D-type amphibolite are typically calc-alkaline in composition and show major and trace element composition consistent with a genesis involving strong subduction component. The distinction between the two varieties of the Kamila amphibolite is amplified by the isotope data; E-type contains more radiogenic Nd ($Nd_{120Ma}=+7.0$ to $+7.4$) and less radiogenic initial Sr ($^{87}Sr/^{86}Sr=0.7036-0.7039$) than the D-type ($Nd_{120Ma}=+2.9$ to $+4.7$; $^{87}Sr/^{86}Sr=0.7041-0.7047$). Pb isotope composition for the two varieties shows only subtle differences. The Kamila amphibolites, in SE Kohistan (Thak-Babusar valley), are intruded by a syntectonic suite of Gabbrodiorites-tonalites-granodiorites-trondhjemites. Within this suite three subgroups are identified based on geochemical and isotopic composition. The Gabbro-diorite-tonalite

suite is tholeiite to calc-alkaline in composition with rare-element characteristics common with subduction related rocks. They have highly radiogenic Nd ($^{143}\text{Nd}/^{144}\text{Nd} > 0.51290$), less radiogenic Sr (mean $^{87}\text{Sr}/^{86}\text{Sr} = 0.71380$), comparable to E-type Kamila amphibolites. The granodiorite suite, in contrast, has moderate radiogenic initial Sr and least radiogenic Nd (mean $^{87}\text{Sr}/^{86}\text{Sr} = 0.7037$, $^{143}\text{Nd}/^{144}\text{Nd} < 0.51280$). The trondhjemites have low initial Sr (mean $^{87}\text{Sr}/^{86}\text{Sr} = 0.7037$) and moderately low Nd ($^{143}\text{Nd}/^{144}\text{Nd} = 0.512840\text{--}0.512865$). The Chilas Complex comprises ultramafic cumulates, gabbro-norites and hypersthene diorites with a typical calc-alkaline composition and a strong subduction component [3]. It is characterized by a homogeneous isotopic composition for Sr, Nd and Pb ($^{87}\text{Sr}/^{86}\text{Sr} = 0.70396\text{--}0.70414$, $\text{Nd}_{120\text{Ma}} = 2.8\text{--}4.0$), which is closely comparable with that of the D-type amphibolites from the Kamial belt. The Chalt volcanics are compositionally heterogeneous comprising basalts, boninites and rhyodacites. These have homogeneous isotopic compositions for Nd ($\text{Nd}_{120\text{Ma}} = 6.3\text{--}7.3$) and Pb ($^{206}\text{Pb}/^{204}\text{Pb} = 18.1\text{--}18.4$; $^{208}\text{Pb} = 44\text{--}58$; $^{207}\text{Pb} = 5\text{--}10$), but have highly variable initial Sr ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7040\text{--}0.7055$), probably reflecting alteration accompanying submarine hydrothermal metamorphism. In the Kohistan batholith, Stage I tonalites have radiogenic Nd and low initial Sr ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7039$; $\text{Nd}_{120\text{Ma}} = +6.9$), Stage II granitoids have moderate initial Sr and less radiogenic Nd ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7041\text{--}0.7042$, $\text{Nd}_{120\text{Ma}} = +3.01\text{--}4.09$), and Stage III leucogranites have variable but high initial Sr and low Nd [2]. The isotopic composition of Sr and Nd for various units of the Kohistan arc terrane, when used together, identify two source types. The E-type Kamila metavolcanic amphibolites, Stage I (Matum Das) plutons of the Kohistan batholith, and Thak valley gabbro-diorite-tonalite suite are all characterized by more radiogenic Nd and less radiogenic Sr. The Chalt volcanics have comparable Nd but higher and variable initial Sr. Assuming that higher initial Sr is due to seawater alteration, the Chalt volcanics appear to have a source common with the above mentioned three suites of rocks. The early-arc crust in Kohistan, comprising these four units (and basal cumulates of Jijal and Sapat complexes), is envisaged to have formed from partial melting a mantle source similar to those of N-MORB, with slight but variable modification by subduction related metasomatism.

The mantle source responsible for the Chilas complex, D-type metavolcanic amphibolite and granodiorite and trondhjemite intrusives in the Kamila belt and the Stage-II Kohistan batholith is characterized by less radiogenic Sr and Nd. These suites of rocks formed in the later stages of intraoceanic phase or during Andean-type continental-margin phase, when the arc was in its mature stages of development. A mantle source with higher degrees of subduction-related metasomatism is considered responsible for this crustal component in the Kohistan arc terrane.

An interesting feature of the isotopic compositions of Sr and Pb in Kohistan rocks is the presence of DUPAL signature, suggesting that Kohistan formed at or to the south of equator prior to its northward drift and collision with the Karakoram plate. Independently acquired recent paleomagnetic studies confirm this conclusion.

K/292. Khan, M.A., Stern, R.J., Gribble, R.F. & Windley, B.F., 1997. Geochemical and isotopic constraints on subduction polarity, magma sources and palaeogeography of the Kohistan Arc, northern Pakistan. *Journal of the Geological Society, London* 154, 935-946.

Geochemical and isotopic data are presented for 18 representative samples from the intraoceanic phase of the Kohistan arc. A restricted range of initial $^{87}\text{Sr}/^{86}\text{Sr}$ ($0.7036\text{--}0.7066$) and $^{\circ}\text{Nd}$ ($+2.8$ to $+7.4$) along with measured $^{206}\text{Pb}/^{204}\text{Pb}$ ($18.0\text{--}18.6$) are consistent with formation of the arc complex in an intra-oceanic setting. The isotopic data demonstrate the involvement of enriched, DUPAL-type mantle, suggesting that the Kohistan arc formed at or south of the present equator. Subduction polarity inferred from geochemical and isotopic data indicate that the Chalt Volcanics and Kamila Amphibolites represent a forearc and backarc basin sequence, respectively. These inferences are most simply resolved with a tectonic model whereby the intra-oceanic Kohistan arc evolved over a south-dipping subduction zone, implying that Kohistan and India moved northwards on the same plate, although separated, during much of Cretaceous time. Collision of Kohistan with the Karakoram caused a new, north-dipping subduction zone to form on the south side of Kohistan, leading to collision with India in early Tertiary time.

K/295. Khan, M.A. & Thirlwall, M.F., 1988. Babusar amphibolites: arc tholeiites from the southern Kohistan arc, N. Pakistan. Geological Bulletin, University of Peshawar 21, 147-158.

An imbricate sequence of amphibolites, apparently in the form of a linear belt occurs in the hanging wall of the Indus Suture at Babusar Pass (SE Kohistan). Major-, trace- and a limited rare-earth element data classifies them to be arc tholeiite in composition, in contrast to the bulk of the Kohistan arc, which is predominantly calc-alkaline. Models are discussed about their position with respect to the rest of the Kohistan magmatic sequence, whereas there is a possibility that they represent early tholeiite phases of arc magmatism, a model is presented which considers them (together with a conformable basal ultramafic unit) as crust of a tholeiitic island arc, formed as a separate entity from a predominantly calc alkaline Kohistan arc to the north.

K/297. Khan, M.A., Treloar, P.J., Khan, M.A., Khan, T., Qazi, M.S. & Jan, M.Q., 1998. Geology of the Chalt-Babusar transect, Kohistan terrane, N Pakistan: implication for the constitution and thickening of island arc crust. Journal of Asian Earth Sciences 16, 253-268.

The Kohistan island arc terrane is sandwiched between the collided Indian and Karakoram plates in the Himalaya of North Pakistan. Structures related to collision, during which the arc was thrust onto the leading edge of continental India along the Main Mantle Thrust, have resulted in exposure of an almost complete section of arc crust. Mapping along a transect across the east end of the arc terrane provides new data concerning the magmatic emplacement of several of the principal units. The base of the arc here is occupied by a major stratiform ultramafic-gabbroic complex, the Sapat complex. This was intruded into the base of a thick pile of meta-volcanic rocks which make up the Kamila amphibolite belt, and which comprise a varied sequence of basalts some with MORB-type tholeiitic affinities and some with island-arc tholeiitic affinities as well as calc-alkaline andesites. Ultramafic and gabbroic rocks of the Chilas complex are intrusive into the top of the Kamila amphibolite belt. The upper part of the crust comprises meta-sediments and meta-volcanic rocks of the Jaglot and Yasin-Chalt Groups. These were formed in one or more arc-related basins, and host much of the Kohistan batholith. A three-stage history of crustal thickening can be documented for the Kohistan arc. From its initiation at *ca.* 125–120 Ma until *ca.* 90 Ma, the arc grew downward through magmatic emplacement, into its base, of stratiform ultramafic-gabbroic plutonic complexes, and upward through extrusion of volcanic sequences. In Stage 2, the focus of crustal growth shifted upwards from the base of the arc with emplacement of the Chilas complex along the interface between the Kamila amphibolite belt and the overlying volcano-sedimentary cover. This stage of crustal thickening was accompanied by shortening associated

with the 90–80 Ma Kohistan–Karakoram collision. Finally, in Stage 3 (80–45 Ma), the Kohistan batholith was emplaced into deformed cover rocks of the uppermost part of the arc crust.

The Main Boundary Thrust is a wide, complexly folded and faulted zone which uplifted the Kohat range, and tectonically emplaced the Mesozoic-Cenozoic shelf carbonate succession over the Tertiary molasse sediments. The MBT zone is characterized mainly by major thrust faults both imbricate and duplex type and tight folds. Tight folding along the MBT zone resulted in the formation of out-of the syncline faulting. Late stage (post folding and thrust faulting) development of normal faults at the base of the Paleocene succession further deformed the MBT zone in the Kohat area. The Paleocene strata in the hanging wall of southward propagating normal faults is subhorizontal to shallowly dipping northward, and lies discordantly over the Mesozoic succession. The normal faults are of localized nature in the MBT zone and are reported for the first time from the Kohat range. The normal faults may have exploited the weaker horizons generated during earlier thrusting such as out-of-syncline faults. Presence of thick fault breccia along the fault plane suggests that these structures may have formed close to near surface conditions during uplift of the Kohat range.

Part of the information contained in this thesis is presented in summarized form in the following three papers by M. J. Khan.

Key words: Magnetostratigraphy, sedimentation, Quaternary, Trans-Indus Salt Range, siwalik.

K/309. Khan, M.J., 1984a. Brief results of the paleomagnetic studies of the Siwalik group of the trans-Indus Salt range, Pakistan. Geological Bulletin, University of Peshawar 17, 176-178.

Thirteen stratigraphic sections were measured and sampled, from the Siwalik group rocks of the Trans-Indus Salt Range, for Paleomagnetic studies. After measuring Natural Remnant Magnetization (NRM) of all samples, a few were arbitrarily selected for Progressive Alternation Field (AF) demagnetization and Partial Thermal Demagnetization (PTD). The results of these studies show that AF demagnetization is not sufficient for the successful removal of the secondary component of magnetization particularly in case of samples collected from reddish-brown siltstone / claystone units. However, PTD successfully enables to isolate the stable and primary component of magnetization. Therefore, all samples were subject to PTD at 5000C to 6600C, to obtain the stable component of remnant magnetization. These stable directions of remnant magnetization were used to establish a magnetic-polarity reversal sequence of each section, respectively.

Key words: Paleomagnetism, sedimentation, Trans-Indus Salt Range, Potwar.

K/310. Khan, M.J., 1984b. Sedimentation and tectonics of the Trans-Indus Siwalik Group by paleomagnetic methods. Abstracts, First Pakistan Geological Congress, Lahore, p.11.

Paleomagnetic studies of thirteen stratigraphic sections from the Bhattani, Marwat, Khasor, Shinghar, and Surghar Ranges show that the Siwalik Group rocks in this area range in age from 12 Ma. to 0.5 Ma. The basal part of the Siwalik Group in the Bhattani Range could not be dated due to lack of exposure of lower part of the Siwalik Group.

These studies clearly indicate that onset of the Siwalik sedimentation, in the Trans-Indus area, started much later than in the Potwar Plateau, where basal part of the Siwalik Group is older than 15 Ma. Therefore, the Siwalik Group of the Trans-Indus area indicates westward transgression of the Potwar Plateau molasse facies.

Sediment accumulation rates calculated for the Trans-Indus Siwalik Group are generally higher than those calculated for the similar deposits of the Potwar Plateau. These higher sedimentation rates indicate faster subsidence of the Trans-Indus area, and consistent availability of detrital material. The entire stratigraphic sequence is conformable and suggests a lack of tectonic activity, except general subsidence of the basin of deposition, between 12 Ma. and 0.5 Ma. The Siwalik sedimentation was brought to halt at about 500,000 years BP, when the Trans-Indus area was uplifted during the Pleistocene phase of the Himalayan orogeny. Presence of uplifted recent alluvial deposits indicates that uplift is still an active process in this area.

K/311. Khan, M.J., 1987. Sedimentation and tectonics of the Siwalik Group of the Trans-Indus Salt Range, northwestern Pakistan. *Geological Bulletin, University of Peshawar* 20, 129-141.

Sediment accumulation rates calculated for fluvial sediments of the Trans-Indus Salt Range in northwestern Pakistan are generally higher than those of the Potwar Plateau. This indicates more rapid subsidence of the Trans-Indus area compared to the eastern Potwar Plateau area, as well as a continued supply of detrital material. The entire stratigraphic sequence, which covers a time span of 12.0-0.5 Ma, is conformable, suggesting that the only tectonic activity in this area over this period consisted of gradual subsidence of the depocenter. However, Siwalik sedimentation ceased at about 500,000 BP when the Trans-Indus region was uplifted during Pleistocene phase of the Himalayan orogeny. The uplift terraces of recent alluvial deposits show that uplift is still an active process in this area.

K/312. Khan, M.J. & Ahmad, W., 1987. Clay mineralogy of the Quaternary Lake deposits of Peshawar basin, at Jehangira, district Mardan, NWFP, Pakistan. *Geological Bulletin, University of Peshawar* 20, 143-152.

X-ray diffraction studies of Post-Siwalik Quaternary lacustrine clay deposits exposed near Jehangira suggest the presence of illite, chlorite and montmorillonite. Illite and chlorite show regular and well-formed structure suggesting detrital origin. Whereas montmorillonite may have detrital and/or authigenic origin, If authigenic the depositional environments were alkaline and "non-aggressive". Mafic, ultramafic metamorphites of the Kohistan sequence and Main Mantle Thrust (MMT) melange zone and the schists of the Indo-Pakistan plate south of MMT are inferred as the ultimate source for these clay deposits.

K/313. Khan, M.J., Arif, M., Awais, M. & Iqbal, S., 1987. Depositional environments of the Hissartang Formation Attock-Cherat Range, Peshawar. *Geological Bulletin, University of Peshawar* 20, 99-110.

Hissartang Formation forms the middle part of Silurian-Devonian stratigraphic sequence exposed in the Attock-Cherat Range. Detailed petrographic, textural and structural studies reveal that this formation consists of two facies described as follows.

Argillite facies:

Lower Argillite (99.12m) thin bedded, grey in color.

Upper Argillite (72.73m) thin bedded variegated in color.

Quartzose Sandstone facies:

Lower Quartzose Sandstone: (88.80m), thin to thick bedded, white to light gray in color.

Upper Quartzose sandstone: (105.99m), medium to thick bedded, white to light gray in color.

Only a few stratigraphic horizons of the upper quartzose sandstone show cross beds. Whereas thin to thick strata and thin laminae are commonly present in both, argillites and quartzose sandstone facies. Lack of various sedimentary and biogenic structures, fine grain size of quartzose sandstone and associations of argillites suggest the supratidal to

subtidal environments. Fine grain size of quartz and absence of barrier ridge sandstone suggest the large distance of transport of quartz particles and lesser amount of terrigenous material available.

K/315. Khan, M.J. & Hamidullah, S., 1994. Geochemistry of the seepage water from drain hole 0+53 Down, Adit RAA-2 of Tarbela Dam. Geological Bulletin, University of Peshawar 27, 117-123.

Geochemical parameters of the seepage water from drain hole 0+53 Down, Adit RAA-2 of Tarbela Dam are markedly in contrast with the similar parameters of the reservoir water. TDS and EC values are significantly higher and the amount of dissolved oxygen is lower in the drain hole seepage water than those of the reservoir water. The data suggest addition of soluble salts from the rocks of the right abutment into the seepage water while in transit from reservoir to drain hole. This clearly shows removal of soluble material from the country rocks and thus creation of voids in the right abutment. Lower values of dissolved oxygen in seepage water, as compared to those of reservoir water, indicate its consumption for the oxidation of ferruginous minerals during the transit period. Both gypsum and limestone are present in the country rocks with the former having higher oxidation potential and thus considered a preferred target of removal through dissolution, as compared to the latter. Therefore, proper future monitoring of the geochemical parameters of the seepage water in various drains is very important for evaluating the geotechnical hazards being posed by the dissolution of gypsum from the country rocks of right abutment of Tarbela Dam.

K/316. Khan, M.J. & Jan, M.Q., 1986. Last stages in the closing of neotethys and geotectonic evolution along the Indus suture zone. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, 20-21.

Geology of Himalayan mountain chain has been widely attributed to the closing of Neotethys. Permian rifting along northern margin of "Greater India" resulted in the opening of Neotethys and separation of several small continental blocks. Closure of Neotethys had been affected by Early Eocene. Mechanism and timing of various stages of evolution of the ocean basin are still strongly debated. Recent geological data enables us to constrain the evolution in the western and central Himalayas. The data indicate that subduction began earlier in the western Himalayas than along the southern margin of Tibetan block. This was due to late separation (Jurassic) of Lhasa block from northern margin of Gondwanaland. In conformity with the recent radiometric ages and field observations it is proposed that subduction began during Upper Jurassic-Late Cretaceous in the Kohistan-Ladakh Island arcs and simultaneously along a subduction zone north of Lhasa block, probably along the Bangong-Nujiang suture. The process of subduction continued in the western arcs and shifted to south of Lhasa block during Middle Cretaceous. This was accompanied by the development of Trans-Himalayan batholiths (Kohistan-Ladakh-Gangdese belt), rifting of the Indian plate from Gondwanaland and probably a change from steeply dipping to shallow dipping Benioff zone. During this transition the subducting slab intersected the base of magmatic arc and dragged a fragment of the stratiform Chilas complex to depths of more than 40 km. This resulted in the formation of Jijal garnet granulite complex around 103.9 mybp (Sm/Nd age). Continued spreading in the Indian ocean lead to an accelerated rate of subduction. Consequent compression in the island arcs resulted in the closure of the basins located north of the magmatic arcs between 90-75 mybp. The formation of this northern suture (Main Karakorum Thrust) resulted in a major phase of deformation affecting the early plutons of Kohistan-Ladakh batholith. Subsequent magmatism is due to the northward subduction of Neotethys and later anatexis. Contemporaneous formation of the blueschists of the Indus-Zangbo suture is indicated by available radiometric ages. Rapid northward drift of India between 80-55 mybp resulted in complete closure of the Neotethys. Subsequent thrusts and accompanied obduction of the island arcs

resulted in the formation of melanges and emplacement of the tectonic blocks to their present position along the Indus-Zangbo suture.

K/317. Khan, M.J., Jan, M.Q. & Humayun, M., 1986a. A new Neotethyan closure model in western and central Himalayas. Abstracts with Programs, Geological Society of America 18, p. 656.

Recent geologic data indicate that closure of the Neotethys began earlier in the western Himalayas than along the southern margin of the Tibetan block. The data indicate the subduction began during Upper Jurassic-Early Cretaceous epoch along a zone presently occupied by the Kohistan-Ladakh island arcs and probably the Bangong-Nujiang suture, north of Lhasa block. This was due to late separation (Jurassic) of Lhasa block from Gondwanaland and its middle Cretaceous suturing. This resulted in the shift of subduction to the southern margin of the Lhasa block and emplacement of Trans-Himalayan batholiths. Rifting of the Indian plate caused a change from steeply dipping to shallow dipping Benioff zone. During this transition the subducting slab intersected the base of magmatic arc and dragged a fragment of the stratiform Chilas complex to depths of more than 40 km forming the Jijal garnet granulite complex (103.9 mybp). Continued spreading in the Indian ocean led to an accelerated rate of subduction, compression in the island arcs and closure of the basins located north of the magmatic arcs between 90-75 nybp. The formation of this northern suture (Main Karakoram Thrust) resulted in a major phase of deformation effecting the early plutons of the Kohistan-Ladakh batholith. Subsequent magmatism is due to the northward subduction of the Neotethys and crustal anatexis. Contemporaneous formation of the blueschists of the Indus-Zangbo suture is indicated by 84-75 mybp ages. Rapid northward drift of India between 80-55 mybp resulted in complete closure of the Neotethys. Obduction of the island arcs resulted in the formation of melanges and emplacement of tectonic blocks along the Indus-Zangbo suture.

Key words: Neotethys, Himalaya.

Two sections were sampled in Bhattani range, the first at Bain pass consisting of 60 sites through 2200 m of section and the second along the North West Frontier province Road north of Pezu consisting of 25 sites through 100 m/ both sections are in rocks known to range in age from the late Pliocene and Pleistocene based on vertebrate fauna of Pijor age. After partial thermal magnetization a series of magnetozones were established, ten at Bain Pass and six at Pezu, which can be correlated to each other and to the standard magnetic time scale. The sediments from the long section at Bain Pass span the time from the middle Gauss to the upper most Brunhes Chron. The Jaramillo and Olduvai subchrons are present within the Matuyama Chron. A short normal magnetozones is present in the section preceding the Olduvai subchron which correspond in age to the Reunion subchron. Based on the rate of sedimentation during lower Matuyama time which would be 0.95 m/1000 y for Bain Pass section, the Reunion subchron would span at least 25000 y. the section at Pezu Pass begins within the Olduvai and ends between the Jaramillo and Brunhes/Matuyama boundary. The sedimentation rate determined at this section is 0.77m/1000 y. the rate of sedimentation in this region was much higher than over comparable time span previously determined from the eastern Salt Range. The folding of the Bhattani range must have occurred less than 730000 year ago, since Bruchhe age sediments have been deformed.

K/322. Khan, M.J. & Opdyke, N.D., 1987. Magnetic-Polarity stratigraphy of the Siwalik group of the Shinghar and Surghar Ranges, Pakistan. Geological Bulletin, University of Peshawar 20, 111-127.

Four stratigraphic sequence were measured and sampled from the Shinghar and Surghar Ranges, Pakistan, for detailed magneto-stratigraphic studies of the fluvial Neogene and Quaternary Siwalik Group. The samples were subjected to blanket thermal demagnetization at 500 °C. Some of the samples, particularly those from the pale brown siltstone/claystone units, were further subjected to 600 °C to isolate the stable primary component of magnetization used to establish the magnetic-polarity-reversal sequences. This sequence was correlated to the MPTS with the aid of fossils collected from the nearby Dawood Khel area (Hussain et al., 1977) and from the Shinghar Range during paleomagnetic sampling. This correlation suggests that deposition of the Siwalik Group in this area began during basal Chron 11 (11.8 m.y.B.P.) and continued till the late Matuyama Chron (0.85m.y.B.P.). These indicate that the Siwalik sedimentation in this area started later than that of the Potwar Plateau.

K/323. Khan, M.J., Opdyke, N.D. & Shroder, J.F., 1985. Bain diamictite: lithology, age and the origin. Geological Bulletin, University of Peshawar 18, 53-64.

The Bain diamictite is part of the Plio-Pleistocene Siwalik Group of northwest Pakistan. The type section is exposed in the Bhattani Range on the south edge of the Kurram river drainage basin near its confluence with the Indus. A counterpart section, reported here for the first time, occurs in the Shinghar Range north of the Kurram River. The unit in both areas is an unsorted, unstratified deposit that has heterogeneous lithology, including significantly large volcanic clasts and basal ash stringers. Cooling or drying cracks occur on the upper surface in at least one locality. Clast lithologies indicate a transport direction from the highlands of Afghanistan in the WNW. Previous workers have considered the Bain diamictite to be a tillite, but the low elevation of about 500m and lack of possible glacial

source area prior to main Himalayan orogenesis rule this out. Instead a debris-flow or volcanic-lahar origin from Dasht-i-Nawar caldera 300-400km away in Afghanistan is most likely. The probable volume of $30 \times 10^9 \text{m}^3$ of the deposit is compatible with most probable pre-caldera volcano topography and post- eruption caldera size, but is still perhaps the world's largest known lahar.

K/324. Khan, M.J., Opdyke, N.D. & Tahirkheli, R.A.K., 1988. Magnetic stratigraphy of the Siwalik Group, Bhattani, Marwat and Khisor Ranges northwestern Pakistan and the timing of Neogene tectonics of the Trans-Indus. *Journal of Geophysical Research* 93, 11773-11790.

Nine stratigraphic sections in the Siwalik Group, three from the Bhattani Range, five from the Marwat Range, and one from the Khasor Range, were measured and sampled for magnetostratigraphic studies. Progressive alternating field and partial thermal demagnetization of samples indicated the presence of two components of magnetization. These are a secondary component of low coercivity, which can be removed by alternating field demagnetization in fields up to 40 mT and/or temperatures to 400°C , and a stable primary component of magnetization which has blocking temperatures above 450°C . Therefore all samples were subjected to blanket demagnetization at 450°C and 500°C , and some to temperatures up to 600°C . Positive fold tests from the Bhattani and Marwat ranges indicate the successful isolation of a prefolding characteristic direction of magnetization. A magnetic polarity reversal sequence for each of the sampled sections is determined and correlated to the magnetic polarity time scale utilizing a fission track date and fauna from the sequences which have previously been shown correlated to the magnetic polarity time scale. This correlation shows that the Siwalik Group in the area of study ranges in age from the late Gilbert chron to the early Brunhes chron (about 0.5 m.y. B.P.). Deposition of the thick sandstone units of the Siwalik Group in the Marwat Range began at least by Gauss chron time. The correlation of observed magnetic polarity stratigraphy, of the Khassor Range, with the standard magnetic polarity time scale shows that the Siwalik Group of this area ranges in age from the early Gauss chron (about 3.2 Ma) to the Brunhes chron. The region of this study began to subside prior to 4 Ma and subsided at a rate of from 60 to 100 cm per 1000 years. The tectonism of the region began within the last 1 m.y. and may well be synchronous with folding in the Pabi Hill anticline on the other limb of the syntaxis near Jelum. This orogeny is therefore one of the world's youngest and is undoubtedly still in progress.

K/325. Khan, M.L. & Bangesh, I.H., 1983. Petrography of the Mahak area, Upper Swat. M.Sc. Thesis, University of Peshawar, 71p.

Mahak area in upper Swat lies in the southern amphibolites belt of the Kohistan island arc. The various rock types of Mahak are medium- to coarse-grained amphibolites, hornblendites, hornblende pegmatite, diorites, meta-gabbro, metapyroxenite and quartz-feldspathic veins and dykes. Amphibolites are most abundant rocks of the area. These are distinguished into epidote amphibolite and plagioclase amphibolite.

K/330. Khan, M.R. & Ali, M., 1994. Preliminary gravity model of Western Himalayas in Northern Pakistan. *Kashmir Journal of Geology* 11 & 12, 59.

The gravity modeling in western Himalayas along SW-NE profile from Fatehjang (southwest) to Kundul Shahi has been developed. Gravity model indicates 8-Km thick sedimentary wedge in the Fatehjang, which gradually increases to 20 km at Kundul Shahi. The thin skin metasedimentary wedge. These thrusts have brought in contact the different stratigraphic units of Precambrian to Mesozoic ages in the area of Hazara Kashmir Syntaxis. The stratigraphic units consist of Hazara Formation (mainly slates of Precambrian), Tanol Formation (pelites/psammities Late Cambrian), Panjal volcanics (Permo Carboniferous), Carbonate (Mesozoic-Tertiary) and Molasse (Miocene to Recent).

The western limb of the syntaxis moves southward over the decollement and formed the low angle thrust while in the eastern limb thrust nappes are uplifted in the absence of decollement and form the high angle thrust. Jhelum strike-slip fault developed by the differential movement marks a boundary between salt and salt areas.

The crystalline crust of 38 Km thick extending all the way from Fatehjang to Kundul Shahi is broken into blocks by the basement faults northeast of Taxila and Abbottabad. These faults are the Hazara lower Seismic Zone and the Bagh Basement Fault. The Main Central Thrust is not detected in the study area; it may be passing from the upper Neelum Valley Azad Kashmir. The results indicate that the differential movement because of the presence and absence of salt and anti clockwise rotation of transport direction are responsible for the formation of Hazara Kashmir Syntaxis. The average crustal thickness of 46 Km in Fatehjang gradually increases to 49 Km at Kundul Shahi.

Gravity data in the Hazara-Kashmir Syntaxis of northern Pakistan has been incorporated into interpretation of the gross crustal structure of the area. In this area, due to the continued northward migration of Indian plate, the Indian plate has been overridden by slices of its own northern margin and activity has caused the slight thickening of crust in the northeast and northwest of the Hazara-Kashmir Syntaxis. In the sedimentary wedge, the thinskin structures have been developed by the southward migration of the sedimentary wedge. In northern Pakistan, Late Precambrian to Early Cambrian strata constitutes the zone of decollement. It is absent in eastern side in Kashmir and India. In the eastern limb of the Hazara-Kashmir Syntaxis, the Main Boundary Thrust (MBT) and the Panjal Thrust (PT) are developed. Here the strong coupling between sediments and basement occurred due to the absence of decollement which caused the high topography of the Hazara-Kashmir Syntaxis range front. In the western limb the MBT and the Nathiagali Thrust (NT) are developed. These thrust sheets moved southward over this decollement. The thrust

system of eastern and western limbs are converging near the apex of Hazara-Kashmir Syntaxis. The differential movement resulted due to presence and absence of salt in the area developed the Jhelum fault. Jhelum fault cuts the PT, MBT and the Kashmir Boundary Thrust (KBT) in the Kashmir side and the MBT and NT in the western side in northern Pakistan. The sedimentary wedge of the western limb of the Hazara-Kashmir Syntaxis moves southward along this fault.

K/333. Khan, M.R. & Ali, M., 1997c. Tectonic modeling of western Himalaya in northern Pakistan based on gravity study. *Geological Bulletin, Punjab University* 31 & 32, 103-113.

Gravity data in the Hazara and its adjoining areas of northern Pakistan have been incorporated for the interpretation of the gross crustal structure of the Hazara-Kashmir Syntaxis in western Himalayas. In this region two types of deformation have been observed. One is in the crystalline basement and other is in the sedimentary wedge. The crystalline crust of 38 Kms thickness faulted into blocks in the northeast of Taxila and Abbottabad. These faults are Hazara Lower Seismic Zone and Bagh Basement Fault. These predeveloped faults have been reactivated after collision of Indian and Eurasian Plates. Some of the normal faults trending in the NE-SW, also appeared to exist in the upper crystalline basement near Rawalpindi. These faults were developed by the extensional stresses, which are caused by the bending of Indian crystalline basement.

In the sedimentary wedge the thin-skin structures have been developed by the southward migration of the sedimentary wedge. In the area under study the thin-skin structures consist of thrust faults, strike slip faults and the salt/incompetent state (decoulement). In the eastern limb of Hazara Kashmir Syntaxis there is strong coupling between sediments and basement consequently the materials is uplifted. In Pakistan Late Precambrian to Early Cambrian age strata constitute the uplifted zone of decollement. Over this decollement the western limb of Hazara-Kashmir Syntaxis move southward between Jhelum and Kalabagh strike slip faults.

K/334. Khan, M.R., Ali, M. & Ashraf, M., 1998. Crustal study in lesser and Sub-Himalayas of northern Pakistan based on gravity modelling. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 101.

In lesser and sub-Himalaya in Northern Pakistan the deformations have been observed in crystalline crust and sedimentary and metasedimentary wedge using gravity technique. The crystalline crust of 38-km thickness extended all the way in the study area and faulted into blocks under the western limb of Hazara-Kashmir Syntaxis. These faults are Hazara Lower Seismic Zone (HLSZ) and Bagh Basement Fault (BBF). These predeveloped faults have been reactivated after collision of Indian and Eurasian plate. The HLSZ has been associated with the basement fault under Northern Potwar trending NW-SE. Along this fault 6 Km relative movement of the blocks have been observed. In the gravity modelling best fit of the observed and calculated curves in the northeast of Abbottabad also suggested 4-km relative movement of the blocks. This fault has been named as the Bagh Basement Fault which is existing between HLSZ and Indus Kohistan Seismic Zone (IKSZ).

In the sedimentary and metasedimentary wedge the deformations have been developed by the southward migration of this wedge. The thrust faults have brought in contrast the different stratigraphic units in sedimentary and metasedimentary wedge of the Hazara-Kashmir Syntaxis. From north to south in Lesser Himalaya Nathiagali Thrust (NT) brings the Hazara Slates of Precambrian age over the Eocene to Cretaceous marine rocks. The Main Boundary Thrust (MBT) is the major southern most lineament along which the pre-collisional marine sediments are thrust over post-collisional molasse in the Sub-Himalaya. The fault plane of MBT is steeper near surface and becomes gentle in depth, and joins the low angle detachment. The fault plane of the NT does not join the MBT, which indicates that NT is not a part of MBT Zone. The MBT at present is active in the north of Kohat and in the eastern limb of Hazara-Kashmir Syntaxis. The present gravity investigations suggested the presence of the Panjal thrust between Panjal volcanics and Tanol Formation in the eastern limb and do not pick the Main Central Thrust up-to the Kundul Shahi. This may exist in the upper Neelum Valley. The thrust system of eastern and western limbs were converging near the apex of Hazara-Kashmir Syntaxis. The Jhelum Fault cuts Panjal Thrust (PT), MBT and the Kashmir Boundary Thrust in the Kashmir side and the Hazara Thrust System in the western side in northern Pakistan. The dips of the Hazara Thrust system increase towards northeast. The differential movement exists in the Hazara-Kashmir Syntaxis due to the presence and absence of decollement (salt). In the western limb thrust nappes

are thrusting southward over the decollement, whereas, in the eastern limb the thrust nappes are uplifted in the absence of decollement. These differential movements developed the Jehlum Fault. The sedimentary and metasedimentary wedge of the western limb of Hazara-Kashmir Syntaxis moves southward along the Jehlum Fault. The Kuldana Shales are acting as a secondary decollement, in the sedimentary wedge. The average crustal thickness or Moho depth in the area seems to vary from 46 km (southwest) in Fatehjang to 59 km in Kundul Shahi (northeast). It seems that the total crustal thickness from Potwar plain (Fatehjang) to the Neelum Valley (Kundul Shahi) Azad Kashmir increases by 13 Km.

K/335. Khan, M.R. & Khan, M.S., 2001. Study of shallow geological structures in the core of Hazara Kashmir syntaxis based on residual gravity data in Azad and Jammu Kashmir, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 69-70.

The residual gravity data has been incorporated for the interpretation of shallow geological structures in the core of Hazara Kashmir Syntaxis. In the western periphery of the area Jhelum fault is running along the river Jhelum. The contours trend on residual granite maps from Muzaffarabad to Tam follows the trend of Jhelum fault. The negative contours closure on the residual gravity map in Bagh area shows the low-density sedimentary basin of recent age. The modelling of residual gravity data indicates 1.3 km deep sedimentary basin. The contours trend from Bagh to Chikar and from Chikar to Muzaffarabad delineate the Kashmir Boundary Thrust (KBT). The KBT is running from Bagli to Chikar between the Murree Formation and the Siwaliks whereas on the northeastern side from Chikar to Muzaffarabad the Siwaliks have been eroded and the Murree Formation is exposed. The gravity modelling also envisages the KBT as a shallow thrust, which penetrates upto the depth of the Kuldana Formation. The shales of the Kuldana Formation are acting as decollement for the overlaying sedimentary wedge of the Murree Formation which is thrusting over the Siwaliks along the KBT.

K/336. Khan, M.S., 1986. Pleistocene sediments and chronology of Middle Indus and Lower Gilgit Valleys between Shatial and Dainyar. M.Phil. Thesis, University of Peshawar, 101p.

Thick valley-fill deposits preserved in deep valleys in Indus, Gilgit and Hunza river areas and a variety of age dates allow new definition of Quaternary events in Karakoram Himalaya. Three glacial stages of Pleistocene are recognized with several advances in Holocene. The early stage is indurated lower Jalipur tillites and heterogeneous upper Jalipur valley-fill sedimentary rock younger than 1 to 2 myr and folded, overturned or overridden by movement of Raikot fault associated with rapid overall uplift rates of Nanga Parbat-Haramosh massif. Middle stage is two tills intercalated with invariable sediments, including thick lacustrine units dipping upto 43° along fault. Indus-Shatial tills record the farthest advance down Indus of Pleistocene glacier at this time, Late stage consists of three or more separate advances that retain moraine topography; the Dianyor moraine near Gilgit was produced by a major longitudinal glacier from Hunza. Downstream at Jaglot, Nanga Parbat, Shatial and elsewhere, transverse glaciers blocked Indus to produce lake deposits now dipping upto 6° along the fault. Catastrophic breakout floods emplaced some Punjab erratics and sediments that was reworked into loesses in the Himalayan fore land.

Key words: Sedimentology, Quaternary, Pleistocene, Jalipur, Chilas.

K/337. Khan, M.S., 1997. Gold mineralization in the Carboniferous-Permian rocks in the Neelum valley, Azad Kashmir, Lesser Himalayas. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 2p.

The agglomeratic slates and the Panjal volcanics (lava flows) and associated carbonate rocks are sandwiched between the Main Boundary Thrust and the Panjal Thrust in the Neelum valley. Muzaffarabad, the Lesser Himalayas. The Panjal volcanics have been altered and metamorphosed to lower greenschist facies metamorphism. Major alteration minerals are chlorite, epidote, albite, actinolite, quartz and sphene. The Panjal volcanics are mainly tholeiitic to slightly alkalic rocks. They are dominantly basalts to basaltic andesites. The alteration has also been revealed from their high LOI values and high Na₂O and K₂O contents and by other mobile elements.

Reconnaissance geochemical “grab” sampling along two mapping and petrographic traverses across the strike of the volcanic sequence encountered Au and Ag mineralized units. The host rocks are dioritic and andesitic in composition exposed along and within the Panjal volcanics. The Panjal volcanics are closely associated with the Nauseri granite-granite gneiss terrain. The gold mineralization is located at two horizons. The lowest is a dioritic rock which is foliated and mylonitized. This rock is at the contact of the lava flows and chemically consists of SiO₂ 60.30, MgO 1.28, CaO 1.04, TiO₂ 0.80 Wt.%, Ni 1241ppm, Pb 1588ppm, Cu 49 ppm, Zn 80ppm and Au 11 ppm. The second horizon is a sulfide zone containing pyrite and chalcopyrite and located within the lava flows of the Panjal volcanics in an andesitic rock. The chemical constituents of this rock are SiO₂ 61.69, MgO 2.06, CaO 7.62, TiO₂ 1.4 Wt%, Ni 99ppm, Cu 5639ppm and Ag 8ppm. Both zones represent altered parent lithologies. Rocks have altered to chlorite, sericite, epidote and clay minerals. The foregoing results of only few samples in reconnaissance indicate that a follow-up comprehensive geochemical exploration programme in the areas comprising agglomeratic slates and the Panjal volcanics would be worthwhile.

K/340. Khan, M.S. & Ashraf, M., 1989. Panjal volcanics: geochemistry and tectonic setting in Azad Jammu & Kashmir & Kaghan valley NW Himalaya. Kashmir Journal of Geology 6 & 7, 61-80.

Panjal Volcanic rocks, with maximum upto 1400 m thickness, occur within a system of Main Boundary Thrust and Panjal Thrust in the NW Himalayas from Kahuta to Kaghan. The geotectonic evolution of these volcanic have been studied by field investigations, petrography and geochemistry. Petrographic study of the Panjal rocks show that they are basalts to basaltic andesites and are tholeiitic to slightly alkaline in character. They were formed mostly in submarine environments showing alteration of their minerals to epidote, chlorite and sodic Plagioclase.

Major elements data for the Panjal Volcanics are plotted on different tectonomagmatic geochemical discriminate diagrams, to infer their tectonic environment. The data largely plot in the oceanic fields. The geology of the area, geochemistry and inferred tectonic setting show that Panjal Volcanics were erupted in a rift to oceanic, environments.

Key words: Geochemistry, tectonics, Panjal volcanics, Azad Kashmir, Kaghan.

K/341. Khan, M.S., Ashraf, M. & Chaudhry, M.N., 1991. Geochemical evidence for an oceanic affinity of the Panjal volcanics in Kaghan valley, Pakistan. Kashmir Journal of Geology 8 & 9, 1-18.

The Panjal volcanic rocks in Kaghan area have been analyzed for major and trace elements. These rocks have been altered and spilitized considerably because Na₂O varies from 0.38 to 6.4 wt. %. In spite of alteration of these rocks the whole rock composition retains a strong igneous imprint (TiO₂ 1.28 to 2.34 % P₂O₅ 0.1 to 0.24 %, Zr 77 to 179 ppm and Y 19 to 39 ppm). The abundance of incompatible and immobile elements when plotted on discrimination diagrams of infer tectonic setting, indicate geochemical signature of ocean floor basalts. These rocks are transitional between within-plate to ocean floor basalts on major and trace element abundance.

K/343. Khan, M.S., Ashraf, M. & Chaudhry, M.N., 1997. Geochemical evidence for the tectonic setting of the Panjal volcanics in Azad Kashmir and Kaghan areas. Geological Bulletin, Punjab University 31 & 32, 43-52.

The Permian to Early Triassic age Panjal volcanics in Azad Kashmir and Kaghan areas are exposed along Main Boundary Thrust. Studies of the major and trace elements in the Panjal volcanic rocks indicate that they formed in a tectonic setting transition from within plate to oceanic conditions. These rocks show TiO_2 contents from 1.08 to 1.59 wt. %, SiO_2 from 47.93 to 51.24 wt. %, MgO from 5.05 to 9.07 wt. % and P_2O_5 from 0.09 to 0.19 wt. %. $\text{Mg\#}$ varies from 59.7 to 66.10 Na_2O contents range from 1.11 to 4.99 wt. %, K_2O from 0.11 to 2.67 wt. %. Major elements especially Na_2O and K_2O indicate alteration of these rocks.

Trace element contents of the Panjal volcanics also show variation. Zr contents range from 53 to 110 ppm, Ni 56 to 229 ppm and Cr from 54 to 677 ppm. Major and trace elements and $\text{Mg\#}$ of the rocks indicate that the Panjal magma has been evolved as tholeiitic to slightly alkalic in composition with geochemical characteristics similar to enriched mid ocean ridge (P-type) basalts or ocean island tholeiites. The interbedded chert, limestone and associated turbidite deposits indicate shallow marine environment during the time of eruption of magma. The volcanics represent range of the northern margin of Indian continent and development of shallow marine oceanic conditions during Upper Paleozoic.

K/344. Khan, M.S., Ashraf, M. & Raja, M.K.K., 1994. Petrology of the Nauseri granite gneisses in lower Neelum valley state of Azad Jammu and Kashmir. Kashmir Journal of Geology 11 & 12, 29-42.

The Nauseri granite gneisses occur in the lesser Himalaya of Azad Jammu and Kashmir. The granite gneisses are sheared, mylonitized, deformed and occur in the metamorphic assemblages of biotite to kyanite grades. The field relations of these rocks characterized by peraluminous and S-type nature. On the basis of available data i.e. their intrusive character in the field, petrography and major element chemistry, partial melting origin is envisaged and large scale subsequent granitization for the granitic rocks. These rocks have been resulted from the emplacement of the anatectic melt into the low-grade metasediments, which had been uprooted and transported southwards from their original place.

K/346. Khan, M.S., Mateen, A. & Tufail, M., 1997. Investigations of radioactivity in Hazara phosphate deposits for fertilizer applications. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 2p.

Natural radioactivity due to ^{40}K , ^{226}Ra and ^{232}Th has been investigated in the phosphate rock deposits of Hazara division of Pakistan. Gamma measurements of the radionuclides were carried out using a high purity germanium (HPGe) detector. Data acquisition and activity analysis was done by a PC based MCA. A common index, called Radium Equivalent Activity that incorporates ^{40}K , ^{226}Ra and ^{232}Th activity values, was found to be considerably higher than the permissible limit of 370Bq.Kg^{-1} . That can result in significant radiation exposure in the environment of fertilizer making plants and in its storage places where radon is accumulated. Radioactivity is also spread in the agriculture land along with fertilizers. Removal of radioactivity from the phosphate rock and ventilation of storage places of the fertilizers affect the economic value of the phosphate products.

The iron ore occurrence near Mazari Tang Payan village in Peshawar district has been investigated. The ore is hematite and is of sedimentary origin. It occurs in two to three lenticular beds in the lower part of Jurassic limestone. The hematite is good quality and contains more than 50% of Fe_2O_3 . The extent of the deposit is limited and its reserves, calculated to a dip depth of 400 feet, are 450000 tons.

K/353. Khan, M.Z., 1983-85. Geology and petrology of Burawai area upper Kaghan valley District Mansehra, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 125p.

Nearly 114 sq. km. in the vicinity of Burawai, upper Kaghan valley has been geologically mapped, at the first time. This thesis presents first time accounts of geomorphology, lithostratigraphy, petrography and economic geology of the area. The area constitutes rocks representing old Indo-Pak basement rocks, comprising pelites, calc-pelites and marbles have been metamorphosed to kyanite and sillimanite grades. These are intruded by para-autochthonous sheet granites also metamorphosed. Major structure comprises an open synform possibly part of a larger structural basin. The western part comprises the nose of a larger antiform. Marble, biotite mica and kyanite are important mineral deposits which deem further exploration and evaluation. This thesis also includes petrogenesis of the rock units as well as numerous sketch sections and photographs, illustrating the geology of the area.

K/354. Khan, M.Z., 1991. Petrology and Geochemistry of melange zone and southern amphibolite belt rocks from Gantar area. Allai-Kohistan, Hazara, N. Pakistan. M.Phil. Thesis, University of Peshawar.

Petrographic and geochemical study was performed for the Kohistan island arc (KIA) rocks, Main Mantle Thrust (MMT) mélangé zone and Indian plate rocks at Gantar and Kalalota, Allai Kohistan, Hazara, in order to envisage the petrogenetic history of these rocks. Field and petrographic data shows that the KIA is composed of amphibolites (mainly epidote amphibolite) together with hornblend pegmatite. The mélangé zone include blue schist, green schist, meta-gabbro/norite, ultramafic and pillow lavas while the Indo-Pak plate comprises quartz-muscovite-chlorite-carbonate schist, quartz-actinolite schist calcareous schist graphite schist and siliceous marble.

Amphibolites of the Kohistan arc are derived mainly from the basic magma of non-alkaline characters (transitional between tholeiitic and calc-alkaline) through crystallization differentiation of ferro-magnesian minerals with plagioclase. This protolithic material was the subjected to a metamorphism of amphibolites facies followed by retrogression into epidote amphibolite facies and green schist facies.

Mineral chemistry of amphibolites reflects maximum metamorphic temperature i.e. 600 c for tschermakitic hornblend and 500 c for the actinolite under a metamorphic PH₂O of 4-5 kb. The hornblend pegmatite appears to be of possible metasomatic origin.

It is concluded that the mafic/ultramafic rocks, meta-gabbro/norites, blue schist, pillow lavas and other basic rocks (metamorphosed to green schist) envision the normal ophiolitic sequence being offset by intensive multiple episodes of tectonic deformations (subduction and obducting environment).

K/356. Khan, N., 1990-91. Structure, stratigraphy and petrography of the western limb of the Hazara-Kashmir Syntaxis, Abbottabad and Manglaur areas, Northern Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 138p.

The Abbottabad and Manglaur area lies along the western extremity of the Hazara-Kashmir syntaxis. The area has been divided into two zones on the basis of structure and stratigraphy. Because the rocks of the blocks belong to different stratigraphic provinces and have become in contact with each other tectonically, these zones are Garhi Habibullah-Abbottabad (east of Panjal thrust) and Mansehra zone (west of Panjal thrust).

Rocks east of Panjal thrust in the area consist predominantly of Precambrian to Paleocene sedimentary and very low-grade metasedimentary rock units (Hazara Formation) that represents the first deformation and metamorphism in the Hazara area. Whereas, in west of Panjal thrust, the area consists of Cambrian granite gneisses and very low to low-grade metasedimentary (Tanol Formation) that represent D2 deformation and metamorphism associated with the Himalayan deformation phases. The grade of metamorphism varies from chlorite-grade in the south to biotite-grade in the north. The Mansehra zone is intruded by the Permian Panjal mafic dykes and sills of dolerite and basalts. These dolerite and basalts are mostly fresh. The sedimentary, metamorphic and intrusive igneous rocks of

these zones are classified and characterized by petrographic studies. The stratigraphy of the area has been developed in which the Abbottabad group has been divided into three formations which are Sobrah, Kakul and Sirban formations. The redivision was marked by an unconformity between Sangargali and Mahmdagali of the Sobrah and Kakul formations.

The rocks have undergone at least three phases of deformation (D1, D2 & D3) and have been metamorphosed to greenschist facies. The first deformation D1 took place as a result of Hazaran orogeny and produced first fabric (S1) in the Hazara Formation which is generally parallel or slightly oblique to the original lithologic layering S0. D2 is associated thrusting and folding phase. Himalayan orogeny folded S1 into open and closed F2 folds that range in size from small kink bands to larger map scale folds. It caused development of penetrative S2 foliation axial planar to F2 folds. D3 deformation phase associated with the formation of Hazara-Kashmir syntaxis and formed F3 cross folds.

K/358. Khan, N.A. & Khan, T., 1998. Geology of the Chilas quadrangle (Toposheet No. 43 I/3), Diamir district, Northern Areas, Pakistan. Geological Survey Pakistan. Information Release 548, 10p.

The mapped area lies within the southern Kohistan island arc terrane. The Kohistan arc terrane has been considered to form due to the northward subduction of the Neo-Tethyan oceanic lithospheric plate under the Eurasian plate during Cretaceous time. Two suture zones delineate the arc from the continental plates, viz., the Main Mantle Thrust (MMT) and the Main Karakoram Thrust (MKT). The Main Mantle Thrust (MMT) passes through the southeastern part whereas the MKT is exposed to the north" of the mapped area.

Rock formations ranging in age from Cretaceous to Recent include Thak amphibolites, Sunal greenstone, metasediments and metavolcanics of the Jaglot group, Chilas complex, Kohistan batholith and glaciofluvium, alluvium and colluvium deposits. Thak amphibolites occupy Jal shear zone which are sheared and deformed. Sunal greenstone include metabasalt and metaandesite with minor dacite and rhyolite, volcanic breccia and tuff. Amphibolites, metagabbroic and metadioritic in composition occur in Kiner Gah area. They have intrusive contacts with the Chilas complex and the Kohistan batholith. Metasedimentary and metavolcanic (amphibolites) of the Jaglot group occur as xenoliths within the Chilas complex. The Chilas complex comprises mafic, ultramafic and feldspathic rocks. The complex is dominantly composed of gabbro-norite and pyroxene quartz diorite. Dunite, peridotite, pyroxenite, anorthosite (ultramafic-mafic-anorthositic association; cumulates) are also characteristic of the Chilas complex. Blastomylonite diorite and tonalite are also present. Kohistan batholith includes tonalite which intrudes the Thak amphibolites.

Tectonically, the area is characterized by a number of northwest dipping high angle faults and shear zones which are truncated in the east by the Raikot fault. The ultramafics of Chilas complex have chromite, PGE and copper mineralization. Small patches of the sulphide zones occur within the Chilas complex and the Thak amphibolites.

Key words: Mapping, Chilas Complex, Kohistan Island Arc.

K/359. Khan, N.A., Khan, T., Mujtaba, G., Hussain, H. & Khan, R., 1999. Geology of the Kiner Gah quadrangle (Toposheet No. 43 I/2), Diamir district, Northern Areas, Pakistan. Geological Survey Pakistan. Information Release 684, 13p.

The mapped area lies within the southern Kohistan island arc terrane. The Kohistan arc terrane has been considered to form due to the northward subduction of the Neo-Tethyan oceanic lithospheric plate under the Eurasian plate during Cretaceous time. Two suture zones delineate the arc from the continental plates, viz. the main Mantle Thrust (MMT) and the Main Karakoram Thrust (MKT). The Main Mantle Thrust (MMT) passes through the southeastern part whereas the MKT is exposed to the north of the island arc.

Rock formations ranging in age from Cretaceous to Recent include Kiner amphibolite, metasediments and metavolcanics of Jaglot group, Chilas complex, Kohistan batholith and glaciofluvial deposits. Kiner amphibolites

(metagabbro and metadiorite) occur in Kiner and Hadar gah which are sheared and deformed in Dang Phhar area. They have intrusive contact with the Chilas complex and the Kohistan batholith. Metasediment and metavolcanics of the Jaglot group occur as xenoliths within the Chilas complex and Kohistan batholith.

They are schists and paragneisses interlayered with amphibolites. They are hybridized and at places migmatized. The Chilas complex comprises gabbro-norite, pyroxene quartzdiorite, hornblendite with minor ultramafic rocks. This sequence intruded by the Kohistan batholith which occupies about 70% of the northern part of the mapped area. It is composed of multiphases plutons of diorite, tonalite, quartzdiorite, granodiorite, adamellite, granite and leucocratic dykes. The diorite and tonalite show deformation whereas quartzdiorite, granodiorite and granites are partly deformed.

Tectonically, the area is characterized by a number of northeast dipping high angle faults and many shear zones are developed which accommodate the neotectonic uplift of the NPHM

Key words: Geology, Kiner gah, Diamir.

K/360. Khan, N.A., Latif, M., Bakht, M.S. & Fayaz, A., 1999. Geology of the Guner quadrangle (43 I/7), Diamir District, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 683.

The investigated area lies on the SSW of the Nanga Parbat Haramosh Massif (NPHM) and southern part of Kohistan island arc. The oldest formation is Nanga Parbat group of paragneisses, schists and orthogneisses of Precambrian age. These are polycyclic metamorphic facies which consist of garnet-microparagneisses, mica schists, migmatites, augen-gneiss, orthogneiss and retrograde chlorite schists. These rocks are intruded by granitoid of Cambrian age. These rocks updomed from a cover of thrust amphibolites/meta volcanic of Kohistan island arc and formed the Nanga Parbat syntaxis.

The Raikot shear zone is mostly amphibolite green schist and actinolite schist having faulted contact with Nanga Parbat group and Kohistan island arc. The Kohistan sequence has the oldest rocks of the Thak and Kiner amphibolites. They were formed from the early volcanics and plutonic rocks of calc-alkaline nature. The Chilas complex is a large mafic-ultramafic body intruded into the arc sediments and amphibolite and represent the root zone of magma chamber of the Kohistan island arc.

All these rocks are intruded by Kohistan batholith. Latest intrusions are tonalite stocks, garnet-tourmaline granitic sheets and granitic pegmatites after the collision during Miocene. Small deposits of molasse occur along the Indus River. However, the unconsolidated sediments are found along the Indus River and its major tributaries which are moraine, terrace and scree. Sulphide veins are associated with the Nanga Parbat gneiss and gneissic-schist, have mineralization of gold and silver. Detailed exploration may be carried out and geochemical studies are further recommended. The Indian plate collided with Kohistan island arc during 55 to 50 Ma along the Main Mantle Thrust (MMT). Later on due to reverse faulting the Raikot shear zone was formed and protruding of NPHM towards north. Many ductile and brittle shear zones are developed which accommodate the neotectonic uplift of the NPHM. The area is characterised by a number of high angle faults which are truncated the Raikot shear zone.

Key words: Geology, NPHM, Kohistan island arc.

K/361. Khan, N.A., Latif, M. & Shah, S.H., 1999. Geology of the Thurgoh-Gol quadrangle (43 M/15), Skardu District, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 687.

The mapped area lies within the Kohistan-Ladakh island arc near the Asian mass and separated by the Main Karakoram Thrust (MKT). The rock units are Katzarah formation, Shigar volcanics, Yasin group, mafic and ultramafic rocks, intruded by multiphase diversified plutons of Ladakh batholith. The Katzarah formation of Early Cretaceous age consists of intra-arc flysch deposit of various grade phyllite, schists, hornfels and para-gneiss interlayered with epidote amphibolite and marble lenses. The Shigar volcanics consist of basalt, basaltic andesite, andesite and pyroclastic volcanics which have turbidite beds and green schist. The Yasin group of Early Cretaceous age consists of slate, sandstone, green schist, massive algal limestone, marble and turbidite beds.

The mafic-ultramafic rocks comprise of layers of altered peridotites, changed into serpentinite near northern suture zone and the scattered outcrops of mostly metagabbro with pockets and patches of peridotite, gabbroic monzonite and diorite. Ladakh batholith of early Paleocene to Miocene consists of granodiorite and granite associated with

quartz diorite. It occupies southern and eastern parts of the mapped area. Leuco dykes and sills of aplite and pegmatite are also present.

The unconsolidated sediments consist of low and high altitude moraines and also terraces along the Indus River and its other tributaries. Shigar volcanics have faulted contact with the overlying Yasin group, the folds and faults of varying magnitudes are common in the mapped area, with major fold axis plunging toward west.

The gold showings are present in the quartz veins of Katzarah formation and Shigar volcanics. Some pockets and lenses of serpentinite occur in the remote areas of the Yasin group.

K/362. Khan, N.A., Mujtaba, G. & Khan, T., 1998. Geology and mineral investigations of the Gupis quadrangle (Toposheet No. 42 H/8), Northern Areas, Pakistan. Geological Survey Pakistan. Information Release 546.

The Gupis quadrangle 42-H/8 is bounded by latitudes 36° to 36° 15'N and longitudes 31° 4' to 73° 30'E. It comprises mainly the Kohistan batholith which contains xenoliths of Chalt volcanics and the metasediments. The Chalt volcanics are considered to be of early Cretaceous age and consist of basalt, andesite, rhyolite, tuff with marble and quartzite intercalation. It shows metamorphism from amphibolite to greenschist grades. The Kohistan batholith is composed of multiphased plutons of diorite, granodiorite, granite, pegmatite and aplite. The diorite shows deformation whereas granodiorite and granites are mildly deformed and undeformed. Economically the area is not so much promising except the occurrences of a small sulphide zone and quartz veins which contain at places some transparent to translucent quartz crystals.

Key words: Mapping, minerals, Kohistan.

K/363. Khan, N.A., Shah, S.H., Khan, F. & Laghari, A.L., 1999. Occurrence of gold in Garesh area, Gilgit District, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 692.

K/364. Khan, N.A., Shah, S.H., Laghari, A.L. & Mujtaba, G., 1987. A preliminary report on occurrence of sulphide mineralization in Singal area (42 H/16), Gilgit District, Pakistan. Geological Survey of Pakistan, Information Release 288.

Massive sulphide mineralization zone has been found in volcanic and metasedimentary rocks of lower Cretaceous age in Singal area about 50 km northwest of Gilgit (Toposheet No. 42 H/16). The mineralization occurs in Rakaposhi volcanic complex and is exposed in an area of 2.5 sq. km approximately. This sulphide zone can be recognized as an altered product of original rocks that weathers to pale, brownish, reddish and dark grey material in the superficial part of the outcrop. The mineralization is also observed in the form of dissemination in the volcanics and dolerite dikes mostly along the surface of joints and fractures. During the geological investigations of the area, 15 representative samples were collected and chemically analysed, Majority of samples show encouraging results of anomalous massive sulphide mineralization. The metallic content of analysed samples generally indicate the presence of Fe, Zn, Cu, Mn, Co and Mo in above-average quantities.

This report is based on field investigations and chemical analyses and may be suggested to be followed by a more comprehensive field and laboratory studies to prove the economic potential of sulphide mineralization.

Key words: Sulphide mineralization, Gilgit.

K/365. Khan, N.A., Shah, S.H. & Khan, M.S., 1988. Geology and mineral investigations of the Single quadrangle, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 362, 20p.

The investigated area is a part of the Kohistan island arc sequence lying adjacent to the south of the Main Karakoram Thrust (MKT), and falls in the Survey of Pakistan Toposheet No. 42 H/16.

The project area is typified by meta-volcano-sedimentary rocks which are intruded by multi phases intrusions of the Ladakh-Kohistan granitoids with subordinate gabbroic intrusions, acidic and hornblendic pegmatites. Magmatic segregation and differentiation are noted within the granitic rocks. The contact metamorphic effects are more pronounced along the marginal zones of the intrusive bodies thus resulting schist, amphibolite and gneisses. Owing to the presence of the collision boundary between the Asiatic mass and Island arc, the rocks of the investigated area are severely disturbed resulting a number of upright tight folds and faults.

Copper showings have been found in the Japuka and Hamuchal areas. Besides, altered massive sulphide mineralization and pyrite crystals as sparse dissemination are also located in the mapped area.

K/370. Khan, R., Hussain, H. & Saleem, M., 1984. Cement raw material around Muzaffarabad, Azad Kashmir. Geological Survey of Pakistan, Information Release 225.

During September, October and Novanber,1982, the investigation of cement raw materials around Muzaffarabad was undertaken by the authors on the request of the Government of Azad Kashmir and the Chairman, AKMIDC, to establish a cement plant near Muzaffarad, Azad Kashmir.

In the investigated area the metasedimentary and sedimentary rocks, ranging in age from Precambrian to Quaternary, are exposed. The sedimentary rocks are mainly limestone, shale and sandstone ranging in age from Cambrian to Pliocene. The metasedimentary rocks of the Hazara formation, probably of Precambrian age, consist of slate, phyllite, shale, limestone with lenticular bodies of gypsum are exposed in the west of Muzaffarabad.

Although the cement raw materials are available at different places between 2-8 kilometers around Muzaffarabad, but the most suitable deposits on the basis of quality and quantity are the Batmang deposits of the Chhalpani formation located at about 8 kilometers north of Muzaffarabad. During the course of investigation over sixty limestone, shale and gypsum samples were collected for chemical analysis on the basis of which a deposit was found to be suitable.

Key words: Limestone, cement, Muzaffarabad.

K/373. Khan, R.M.K., 1976-78. The geology and petrology of Jura-Bandi Area Muzaffarabad, Azad Kashmir. M.Sc. Thesis, Punjab University, Lahore, 97.

Jura Bandi, an igneous and metamorphic complex, is a part of Nanga Parbat-Haramosh zone. The area is highly disturbed being in the region of syntaxial influence i.e. involvement in Himalayan orogeny. The metamorphic rocks are the oldest marking of Salkhala series which includes granitic rocks (Quartz-o-feldspathic rocks) along with prominent foliated structure with development of augen gneisses at places. Lithologically the oldest metamorphic rocks present are as following:

i) Chlorite mica schist.

ii) Garnet mica schist.

The metamorphism extends up to garnet grade yet retrograde metamorphism is commonly observed especially in the chlorite mica schist. Among Quartz-o-feldspathic rocks two granites (Granite gneiss and granite porphyritic) lying side by side extending in NE and NW direction. Mineralogically both granites are rich in Potash feldspar. Pegmatites and Aplites are present as dykes. The basic rocks among the minor bodies are diorite and diabases dykes. The report submits a detailed map on scale 1pp-789 miles or 1:50,000 of about twenty seven square miles along with details of field and laboratory investigation, the petrogenesis of both the granites (Granite gneiss and granite porphyritic) is derived on the strelleson's triangle method. The Petrography is discussed slide wise.

K/380. Khan, S., 1965. Notes on the dolerite dykes in Northern Hazara. Zamaka, Peshawar University Geological Bulletin 2b, 1-4.

The northern regions of Hazara consist mostly of metamorphic and plutonic rocks of Palaeozoic and Mesozoic times. The plutonic rocks consist of granites and gneisses which are part of the great Himalayan batholiths. The metamorphic rocks consist of almost all grades from chlorite schists to staurolite schists passing further north into sillimanite gneisses in Hazara Kohistan. A little south of Oghi, big crystals of kyanite can be seen in a small portion of Susal Gali granite gneiss. These rocks of different metamorphic grades show all sorts of mineralogical, textural, and structural variation. Almost the whole of the region is isoclinally folded. Analysis of the structural data indicates that this area has been subjected to more than two phases of tectonic events. The granites and gneisses are also extremely variable, mostly have faulted contacts, and contain accessory minerals such as andalusite, sillimanite, kyanite, and garnet, etc., all of which are generally of metamorphic affinities. There is ample evidence that they are products of assimilation (Shams, 1961). Some granites are also very rich in tourmaline. These granites are of a later time and are generally very massive. Some of them for example the Hakale granite in Mansehra proper is extremely rich in volatile components and has intrusive relations with Mansehra granite. These rocks are profusely intruded by dolerite dykes and sills at different intervals of geological time. They have a tendency to be more abundant in plutonic than metamorphic rocks. The majority of these dykes and sills occurring in metamorphic rocks are regionally metamorphosed with well developed schistose planes striking parallel to the regional strike. The present notes are a short discussion of the various types of these dolerite veins, their optical characters and a review of their possible relation to the granites.

Key words: Metamorphic rocks, plutonic rocks, dolerite dykes, Hazara.

K/381. Khan, S.A., 1981-83. Geology of Para-Bela-Jared Area Central Kaghan Valley. M.Sc. Thesis, Punjab University, Lahore, 145p.

This report covers a comprehensive study of a part of central Kaghan Valley. The principal emphasis has been on detailed litho-structural mapping of the area of the scale 1:8333. The rocks range in age from Precambrian Salkhalas to Miocene Murrees. Stratigraphically, the geology is in many ways different from that in the Abbottabad-Murree-Tarbela-Attock area further south. Part of the Mesozoic and part of the Tertiary sequence is missing in the project area. Furthermore, the equivalents of Panjal Trap and associated limestone are not found in the above mentioned area southwards. Structurally except for some folding in the blocks and nearly all contacts are faulted. The succession in the area is overturned. A fairly detailed account of the stratigraphy is being given and the report also includes a detailed account of the Petrography of all units based on extensive sampling. Tectonically the area is very interesting and the Panjal Traps appear to represent Ophiolites while the Agglomerate Slates appear to indicate Volcano-sedimentary material with island arc affinities. There is thus some evidence of a Paleozoic subduction zone in this area. Numerous photographs and sketches have also been included to illustrate the geology of the area.

The detailed study of Rajdhawari pegmatites was completed on December, 30, 1961. In this study an attempt has been made to classify the pegmatites on the basis of their size, shape, internal structure, and mineralogy. An area covering 21 square miles around Rajdhawari has been geologically mapped. Longitudinal cross sections and radiometric grid maps of two productive pegmatites have also been prepared.

Out of a total of 74 pegmatite bodies studied in Rajdhawari area, less than three per cent contain traces of billibinitc and other unidentified radioactive minerals. Nearly fifteen percent pegmatites contain beryl. The two productive pegmatite bodies have an approximate reserves of 1500 pounds of beryl, 225 tons of mica, and 2500 tons of feldspar. Total reserves of feldspar to a depth ranging from 20 to 50 feet in five bigger pegmatites have been estimated as 6200 tons.

K/392. Khan, S.N., Khan, I.A., Abbas, S.G. & Khan, A.L., 1992. Coal resources potential of Pakistan. Geological Survey of Pakistan, Information Release 533.

Per capita power consumption is an indicator of the development stage of a country, and normally developed countries are using vast quantities of coal for power generation. In the USA 63 million tonnes of coal is used annually for power generation. In East Germany 220 million tonnes and in Western Europe 182 million tonnes of coal is used for power production every year. Pakistan, unfortunately has not been able to utilize its coal resources and the share of coal in the energy mix has declined from about 60% at the time of independence to less than 5% at present. Pakistan at present is using imported oil and natural gas for almost total thermal power generation. However, fast depleting gas resources and sharp increase in already scarce foreign exchange bill for import of oil are pressing hard to develop indigenous coal resources for generation of power.

GSP, from its own resources and aided by USAID and USGS, has continued its efforts to explore and establish the coal resources of the country. The efforts of the department have resulted in the recent discovery of two new large coal fields with coal quality suitable for power generation. The coal resources of the country are now projected at 22 billion tonnes.

Out of these 637 million tonnes are measured, 2440 million tonnes indicated 855 million tonnes inferred and 10646 tonnes hypothetical. Over ninety seven percent of these resources occur in Sindh Province, not very far from Karachi, the biggest industrial centre of the country.

The Pakistan coals are lignite A to Hv sub B and generally high in sulphur. However, the latest discovered coal field of Thar desert contains low sulphur coal. with the erection of two power plants of 50 M.W each, based on Lakhra coal, a beginning to utilize indigenous coal for large scale power generation has been made and it is expected that discovery of low sulphur coal in Thar will encourage the investment on development of huge coal resources of the country for power generation.

K/393. Khan, S.N., Khattak, M.U.K. & Ahmad, W., 1997. Significant gold base-metal anomalies associated with Tirich Mir Fault zone, Chitral, Northern Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 2p.

The Chitral region geographically occupies the eastern terminations of Hindukush ranges and geotectonically the western extremities of the Himalaya sedimentary rocks of Karakoram and Asia to the north and a dominantly Cretaceous volcano-sedimentary sequence of Kohistan arc in the south. The Paleozoic to Mesozoic rocks are strongly sheared, folded and faulted during the Cretaceous-Tertiary orogenesis and are subjected to subduction related ~oIcanopIutonic complexes.

This paper describes anomalous concentrations of gold and base-metal in the rock formations north and south of the Tirich fault zone. This research is part of a systematic regional exploration comprising drainage geochemical survey and remote sensing through the study of satellite imageries and aerial photographs together with use of information on ground geology (petrography. petrology and geochemistry) and mineral occurrences. Tirich Mir fault zone is typically associated with mafic-ultramafic rocks and probably represents a suture zone between the Karakorum and the Asian plates.

K/395. Khan, S.R., 1992a. Stratigraphy and structural set up of Swabi and adjoining areas, NWFP, Pakistan. M.Phil. Thesis, University of Peshawar, 42p.

The present work has resulted in the recognition of a well developed stratigraphic succession of the Tethyan Himalayas exposed in the mountain ranges fringing the northeastern Peshawar basin (Swabi, Mardan, and Buner districts of the NWFP, Pakistan). The rocks range in age from Precambrian through Paleozoic to Early Mesozoic and are composed of igneous, metamorphic and sedimentary rocks. A Precambrian succession comprising of Salkhala and Tanawal formations makes a basement to about 400 metres thick Paleozoic succession, comprising Ambar Formation (Cambrian), Misri Banda Quartzite (Early to Late Ordovician), Panjpir Formation (Late Silurian), Nowshera Formation (Early Devonian), and Jafar kandao Formation (Early Carboniferous). These metasedimentary rocks provide evidence for Late Paleozoic (Carboniferous Permian) intracontinental rifting, the onset of which is indicated by north derived clasts in the jafar Kandao Formation and together with extrusion of rift related volcanism in the form of alkaline acid porphyries and tholeiitic to alkaline basalt horizons. A much greater variety of hypabyssal and plutonic rocks including carbonatite, ijolite etc., are associated with this phase of magmatism. Post Permian thermal subsidence and marine transgression led to the deposition of the Early Mesozoic carbonate rocks which unconformably overly the Karapa Greenschist. The whole stratigraphic succession is considered to be developed in a northward dipping epicontinental basin while the magmatism is related to the rifting episode. Most of the rocks have yielded fossil evidences regarding their ages, while a few have been dated by radiometric determination. The present work describes some of the new evidences relating to the Paleozoic-Mesozoic rocks of the study area and their interpretation and implication in the reconstruction of the regional geological framework of this part of Tethyan outer Himalayas.

K/401. Khan, S.R., 2000. Petrology and geochemistry of part of the Waziristan Ophiolite Complex, Pakistan. Ph.D. Thesis, University of Peshawar, 253p.

This work presents for the first time a detailed geological mapping, petrologic, geochemical and stratigraphic synthesis of a part of the Waziristan Ophiolite Complex and part of shelf-slope sediments of the Indian plate in North Waziristan, northwest. Pakistan. The study area is presently sandwiched between the Afghan block to the west and Indian plate to the east and divisible into two blocks. These blocks from east to west are the shelf-slope sediments and Waziristan Ophiolite Complex. The shelf-slope sediments are thrust over by the Waziristan Ophiolite Complex to the west, whereas a thick pile of Tertiary sediments unconformably overlies the ophiolite complex.

The shelf-slope sediments based on detailed geologic mapping, section measurement and fauna discoveries are divisible into seven stratigraphic units. These units from older to younger are Raghzai formation of Middle Triassic, Kishai formation of Late Triassic, Zehe formation of Early Jurassic, Alexandra formation of Middle Jurassic, Zargar Khel formation of Late Jurassic-Early Cretaceous (?), Sinai formation of Early Cretaceous and Marni Rogha limestone of Late Cretaceous (Campanian) age.

The Waziristan Ophiolite Complex is also divisible into three thrust sheets/ nappes, each characterised by distinct lithologies and style of deformation. These nappes from east to west are the Vezhda Sar, Boya and Datta Khel. The Vezhda Sar nappe forms the eastern edge of the ophiolite complex, is composed entirely of pillow basalts and intermixed with the shelf-slope sediments. It contains exotic blocks of serpentinised ultramafic rocks. The central nappe called the Boya nappe contains an intact normal ophiolite sequence, starting from ultramafic cumulates followed by isotropic/homogeneous gabbros and pillow basalts and is capped by pelagic sediments. The central part of this nappe is strongly deformed and contains fault bounded blocks of all sort of ophiolitic rocks. The Datta Khel nappe forming the western part of the ophiolite complex is characterised by the presence of sheeted dykes and isolated outcrops of ultramafic-mafic cumulates and, pillow basalts. A thick pile of Tertiary sediments unconformably overlies this nappe. The Tertiary sequence is comprised of Ghazij Formation of Early Eocene and Kirthar Formation of Early to Middle Eocene age. The geochemical characteristics, such as LILE enrichment, HFSE depletion, and non-depletion of Nb indicate that the ophiolitic rocks are transitional between island-arc tholeiites and mid-ocean ridge basalts type affinities. Rocks displaying such a transitional characteristics are thought to have involvement of some sort of subduction component brought by fluids along subduction zone to the source region and interpreted to have formed above a subduction zone in a back-arc basin or suprasubduction zone setting.

The pelagic sediments intercalated and stratigraphically overlying the pillow basalts, contain radiolarian fauna of Late Jurassic to Early Cretaceous (Tithonian-Valanginian) age. Based on the age of the radiolarian fauna, the formation age of the ophiolite is interpreted to be Late Jurassic or older. The ^{40}Ar - ^{39}Ar isotopic dates on hornblende of an amphibolised gabbro from the Waziristan Ophiolite Complex indicate 93.57 ± 1.01 Ma. This - 93 Ma age may represent the first phase intraoceanic obduction of the Waziristan Ophiolite Complex. The ophiolite complex contains exotic blocks of Marni Rogha limestone of Late Cretaceous (Campanian) age and is also thrust over similar limestone, suggesting late Cretaceous or most probably Paleocene secondary obduction of the ophiolite over the shelf-slope sediments of the Indian plate. The K-Ar whole rock radiometric dates (- 75 Ma) of the gabbroic and trondhjemitic rocks further support this interpretation. The K-Ar whole rock radiometric dates ("" 60 Ma) of the Waziristan volcanics may suggest the accretion of the Indian plate with the Afghan block. The deformation of the Tertiary sediments overlying the Waziristan Ophiolite Complex, those of the Katawaz Basin and thrusting of the Mesozoic rocks of Kirthar and Sulaiman ranges over the foredeep molasse sediments, suggest collision between Indian plate and the Afghan block during Pliocene-Pleistocene.

Key words: Petrology, geochemistry, ophiolite, Waziristan.

K/402. Khan, S.R. & Fatmi, A.N., 1999. Discovery of Mesozoic fauna from Waziristan and its stratigraphic significance. Additional abstracts, IGCP 421 (North Gondwanan mid-Palaeozoic Bioevent/ Biogeography Pattern in Relation to Crustal Dynamics), Peshawar Meeting, 1p.

K/403. Khan, S.R., Jan, M.Q. & Khan, M.A., 2001. Tectonic evolution of the Waziristan ophiolite, NW Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.8.

The Waziristan ophiolite is located in the northwest Pakistan, demarcating a suture zone between the Indian plate to the east and Afghan block to the west. It is highly dismembered and divisible into three nappes. These nappes from east to west are: Vezhda Sar nappe entirely comprising of pillow basalts; Boya nappe, made up of ophiolitic mélange with an intact sequence in the basal part; and Datta Khel nappe, consisting of sheeted dykes along with variable proportions of other components. The intact Ophiolite sequence from bottom to top consists of i) the ultramafics (harzburgite, wehrlite and dunite), ii) the mafics (isotropic gabbros), and iii) the volcanics (pillow basalts), capped by pelagic sediments (limestone, shale and chert). The layered gabbros, sheeted dykes and trondhjemites are found as isolated fault bounded bodies in the highly dismembered central and western parts of the ophiolite suite. The ophiolite is unconformably overlain by sedimentary rocks of Early to Middle Eocene age to the west and thrust over the Mesozoic shelf-slope sedimentary rocks of the Indian plate to the east.

Major and trace elements geochemistry is used in specifying the petrogenetic and tectonic evolution of the Waziristan ophiolite. All the ophiolitic rocks are of N-MORB type and give a similar geochemical characteristics indicating to be comagmatic. These rocks are characterized by higher LILE/HFSE ratios and non-depletion of Nb. The various geochemical parameters based on high-field strength elements reveal that the ophiolitic rocks are transitional between island-arc tholeiites and mid-ocean ridge basalts. Their transitional characteristics, non-depletion of Nb, higher LILE/HFSE ratios and presence of sheeted dykes suggest that the Waziristan ophiolite may have originated in back-arc basin environment.

Based on the age of radiolarian fauna (Tithonian±Valanginian) recovered from the pelagic sediments (chert), the age of the Waziristan ophiolite is interpreted as Late Jurassic or older. The presence of tectonic blocks of Campanian limestone (Mami Rogha Limestone) in the ophiolite and thrusting of the ophiolite onto Maastrichtian shale, suggest post-Maastrichtian, most probably Paleocene, emplacement of the ophiolite.

Key words: Tectonics, ophiolites, Waziristan.

K/404. Khan, S.R., Jan, M.Q., Khan, M.A. & Khan, T., 2001. Geochemistry and petrogenesis of the sheeted dykes in Waziristan Ophiolite, NW Pakistan and their tectonic implications. 16th Himalaya Karakoram Tibet International workshop, Journal of Asian Earth Sciences 19, p.36.

This paper presents the petrologic and geochemical aspects of the sheeted dykes as well as isolated mafic dykes from the Waziristan Ophiolite, northwest Pakistan. The ophiolite occurs in the suture zone between the Indian plate to the east and Afghan block to the west. It is divisible into three main sheets or nappes which, from east to west are: Vezhda Sar nappe entirely comprising of pillow basalts; Boya nappe made up of ophiolitic mélange with an intact sequence in the basal part; and Datta Khel nappe consisting of sheeted dykes along with small proportions of other components. The sheeted dykes are an important component of the Waziristan Ophiolite and their excellent exposure is found in the hanging wall of the Datta Khel Thrust, ENE of Datta Khel. The ophiolite is thrust over the Mesozoic shelf-slope sediments of the Indian plate to the east and unconformably overlain by sedimentary rocks of Early to Middle Eocene age to the west. Major and trace element geochemistry indicate that the dykes (both sheeted and isolated) contain higher contents of Na₂O, FeO/MgO and LILE/HFSE ratios, and lower TiO₂ (0.1 wt%) and K₂O (Figs. 1 and 2). Non-depletion of Nb and high LILE/HFSE ratio negate an island-arc or mid-ocean ridge settings for these dykes, respectively. The enrichment of LILE rather suggests involvement of crustal components driven by fluids along a subduction zone. The various geochemical parameters used in specifying the tectonomagmatic setting of the Waziristan dykes reveal a transitional characteristic between mid-ocean ridge basalt and island-arc tholeiite. It is suggested that the Waziristan dykes may have originated in a back-arc basin tectonic set-up. Based on the age of the radiolarian fauna (Tithonian±Valanginian) recovered from the pelagic sediments (cherts), the age of the Waziristan Ophiolite is interpreted as Late Jurassic or older. The presence of exotic blocks of

the Campanian limestone in the ophiolite coupled with overthrusting of the ophiolite onto Maastrichtian rocks suggest post-Maastrichtian, most probably Paleocene, emplacement of the Waziristan Ophiolite.

K/405. Khan, S.R. & Karim, T., 1989. Geological map of Drazinda. US Geological Survey, Geological Map Series 775, 170A (39 I/2).

Key words: Mapping, Drazinda, D.I. Khan.

K/406. Khan, S.R. & Khan, M.A., 1994. Late Proterozoic stratigraphy of Swabi area, NWFP, N. Pakistan. Geological Bulletin, Peshawar University 27, 57–68.

A succession of weakly metamorphosed unfossiliferous sedimentary rocks has been described in terms of lithostratigraphy from an area north of Swabi. The succession unconformably underlies the Cambrian Ambar (Dolomite) Formation (=Abbottabad Formation) and represents the supra-crustal sediments of a probable Late Proterozoic age from the Indian- Plate basement. A WNW plunging cylindrical anticline controls the disposition of stratigraphic units. The succession is divisible into two formations; Salkhala and Tanawal. The basal part of the Sulkhala Formation, exposed at the west bank of the Tarbela dam, is classified as the Gandaf unit and comprises pelitic and graphitic schists, brown dolomite and white and grey-black marble. The upper part, exposed at the apex of the Kundal anticline, is predominantly argillaceous and contains black mud- and siltstone which grade upward into pebbly green phyllite. The overlying Tanawal Formation is conglomeratic at its base and comprises three units, two of which are quartzitic, while the one, in the middle, is argillaceous. It is suggested that the Tanawal Formation may be a time-equivalent facies change of the Hazara, Manki and Landikotal Slate formations, rather than being younger as suggested in the existing literature. This may explain some of the discrepancies in the existing regional tectonic framework of the Indian plate in northern Pakistan.

K/407. Khan, S.R., Khan, M.A., Jan, M.Q. & Khan, T., 1998. Trondhjemites from the Waziristan ophiolitic melange, NW, Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 98-99.

Small amounts of leucocratic intrusions composed of quartz, feldspar, and accessory ferromagnesian minerals are associated with most ophiolites. These, commonly called trondhjemite or plagiogranite, are soda-rich and potash-deficient as compared with normal granite. These rocks are generally found in the upper part of mafic cumulates of the ophiolite sequences, but the trondhjemites in the Waziristan Ophiolitic Melange are associated mostly with ultramafic cumulates and only locally with mafic cumulates. In both the cases they have sharp intrusive contacts with the host rocks. They occur in the form of veins, pods and plugs, ranging from a few centimetres to four metres in width and six to ten metres in length. The rocks are light-grey to milky-white, medium-to coarse-grained, equigranular, non-foliated, and composed of quartz, albite (An₈₋₁₀) and minor biotite and hornblende. The constituent minerals, especially plagioclase, show alteration to chlorite, calcite, sericite, epidote and muscovite.

The rocks are characterized by relatively high SiO₂ (60.47 - 79.70 wt.%), Na₂O (3.04 - 6.06 wt.%), CaO (0.52 - 6.95 wt.%), and low K₂O (< 1 wt.%), TiO₂ (< 1 wt.%), P₂O₅ (< 1 wt.%) and MgO (0.23 - 2.82 wt.%). They are sub-alkaline in composition and classify as trondhjemite on the basis of normative albite, orthoclase and anorthite contents [1]. The Rock/Primordial Mantle spider diagram pattern (Fig. 1) shows enrichment in LIL elements (K, Rb, Ba, Sr) relative to HFS (Ti, Y, Nb) elements [2]. The geochemical pattern for the trondhjemites is transitional between those of island arc and mid-oceanic ridge granites.

K/Ar whole rock ages of trondhjemites (77 ± 2 - 70 ± 1 Ma) are much younger than the overlying radiolaria (Late Jurassic to Early Cretaceous) found in the pelagic sediments lying on top of the ophiolite [3]. From these dates we conclude that the ophiolite was generated by the Late Jurassic and emplaced during the Latest Cretaceous-Paleocene.

Key words: Ophiolites, geochemistry, Waziristan.

K/408. Khan, S.R., Khan, M.A., Jan, M.Q. & Khan, T., 1998. Tectonic implications of major and trace elements geochemistry of volcanic rocks from the Waziristan ophiolitic melange, NW. Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, p.100.

Volcanic rocks are the most voluminous component of the ophiolite segments in the Waziristan Ophiolitic Melange (WOM). They are divided into two-groups, i) Vizhda Sar Complex volcanics (VSCV), and ii) Waziristan Ophiolitic Melange Volcanics (WOMV). The VSCV are erupted along the western periphery of the Mesozoic shelf sediments of the Indian plate, in Waziristan, Pakistan. Their most excellent outcrops are found between Vizhda Sar to the south and Baba shaga to the north. The name Vizhda Sar Complex is proposed after Vizhda Sar, the second highest peak in the area and is composed entirely of pillow basalts. The VSCV contain exotic blocks of limestone and shale ranging in age from Lower-Middle Triassic to Late Cretaceous. They are basaltic in composition, and are not associated with dykes. To the west they are obducted by the Waziristan Ophiolitic Melange (WOM). The WOMV form the uppermost segment of the ophiolite sequence overlying the mafic cumulate and underlying the pelagic sediments, respectively. In the normal ophiolite sequence they found as pillow lavas, while in the ophiolitic melange part, they are sporadically distributed over a considerable area and found as pillow lavas, sheet flows, agglomerates and breccias. Contrary to the VSCV, the WOMV are intruded by dolerite dykes, showing chilled margins. The WOMV have a wide range in composition varying from basalt to rhyolite. Geochemically, the VSCV are more primitive as evidenced by their higher content of MgO, Cr, and Ni than the WOMV, which are more fertile in LIL (K, Rb, Ba, Sr) elements. Both types are soda-rich, potash deficient, sub-alkaline and tholeiitic in composition. The VSCV are mid-ocean ridge basalt, whereas the WOMV are transitional between mid-oceanic ridge basalt and island arc tholeiite. Field and geochemical data suggest back-arc basin affinity for the formation of WOMV.

The radiolaria found in the cherts lying on top of the ophiolite sequence are of Late Jurassic to Early Cretaceous age, suggesting Late Jurassic age for the generation of WOM. The presence of tectonic blocks of Globotruncana-bearing limestone of Late Cretaceous age in the WOM, the K/Ar radiometric dates of gabbroic rocks ($77 \pm 2 - 75 \pm 1$ Ma) and trondhjemitic ($77 \pm 2 - 70 \pm 1$ Ma) and Early-Middle Eocene strata unconformably overlying the ophiolite sequence, suggest Latest Cretaceous-Paleocene as the time of emplacement of the WOM. This is consistent with the emplacement of Khost ophiolite to the north in Afghanistan and Muslim Bagh ophiolite to the southwest in Pakistan. The high scale deformation of the Tertiary (Early to Middle Eocene) sequence unconformably overlying the ophiolite sequence and the serpentinite splinters cross-cutting the Oligocene-Miocene flysch sediments of the Katawaz basin west of Muslim Bagh propose Pliocene age as the time of India-Afghanistan collision.

K/409. Khan, S.R., Khan, M.A., Nawaz, R. & Karim, T., 1990. Stratigraphic control for the age of Peshawar-Plain magmatism, northern Pakistan. Geological Bulletin, University of Peshawar 23, 253-263.

Recent mapping and stratigraphic analyses in the area at the north-eastern edge of the Peshawar plain has resulted in the recognition of a bimodal suite of basic and acidic volcanics. These volcanics occupy specific stratigraphic horizons in the Jafar Kandao Formation, whose age is well constrained between Carboniferous and Early Permian, on the basis of conodont studies. It is suggested that the basic volcanics are extrusive equivalents of the extensive suite of basic dykes and sills found in the internal zone of the Indian plate, while the acid volcanics are counterpart of the A-type granites of Warsak, Ambela, and Shewa-Shahbazgarhi. This study provides a stratigraphic control for the age of the Peshawar-plain magmatism.

K/413. Khan, S.R., Khan, R.N. & Karim, T., 1990. Field relationship: Stratigraphic and structural position of the Shewa-Shahbaz Garhi “porphyritic microgranite”. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 36-37.

Recent field studies carried out by the GSP in and around Rustam area in the Mardan District, NWFP, have shown, contrary to the previously thought structurally restricted extent (Martin 1962 & Kemp 1973)), that the “Porphyritic Microgranite” of the Shewa-Shahbaz Garhi area has a much larger areal extent showing cyclic intercalations with the host rocks.

The emplacement of the “Porphyritic Microgranite” and the deposition of the enclosing sediments seem to have taken place contemporaneously in an oscillating basin. The whole sequence is now treated as a separate, distinct and mappable time-rock unit. The name ‘Jafar Kandao Formation’ is proposed after the surveyed type locally at Jafar Kandao, about 5 km southeast of the Rustam village. In addition to the type locality and the better known Shewa-Shahbaz Garhi areas, the formation is also exposed in the Banda-Buner areas of the lower part of the Swat District. In most of these areas, it is found in the cores of the anticlines where the younger strata have been eroded.

The ‘Jafar Kandao Formation’ consists of argillites, limestone, quartzite, amphibolite, and “Porphyritic Microgranite”. The formation has been assigned Early Carboniferous age on the basis of conodonts found in the limestone lenses (Pogue, Pers. Commun.).

K/414. Khan, S.R., Nakagawa, M., Khan, I.H., Kausar, A.B. & Shirahase, T., 1996. PGE mineralization in the Jijal complex, Kohistan, north Pakistan. In: Kausar, A.B. & Yajima, J. (eds.), Geology, Geochemistry, Economic Geology and Rock Magnetism of the Kohistan Arc. Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad, 15, 103-125.

A GSP-JICA joint collaborative project for the investigation of PGE mineralization in the Jijal mafic-ultramafic complex, north Pakistan had been initiated in 1991, and carried out geochemical exploration, mineralogical and petrochemical investigations. During the course of works, restricted areas showing remarkable positive anomaly of Pt and Pd were found, and also merenskyite; (Pd,Pt)Te₂ hosted by pyrrhotite was discovered from massive sulfide ore of the Kolai stream which showed a considerable content of Pd (> 22 g/t). Follow-up petrochemical analysis revealed that the disseminated sulfide mineralization in the garnet pyroxenite and/or hornblendite of the Kolai area contained 1.4 g/t of Pt + Pd which is more than thousand times concentration compared to the host rock background. However, from the comparative study with sub-economical occurrence of PGE in the Ivrea-Verbano Complex, Italy, the tectonic setting of which is similar to that of the Jijal Complex representing a root of paleo-island arc, high grade (> 10 g/t) PGE mineralization would not be expected in the complex except the massive sulfide ore presumably in the garnet hornblendite located close to the Kolai stream.

K/418. Khan, S.R. & Suzuki, M., 1997. Geochemical exploration for gold mineralization in northern Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

The study area includes part of the Karakoram plate and the Kohistan arc terrane, which are separated from each other by the Main Karakoram Thrust (MKT). The Karakoram plate to the north of the MKT consists mainly of Paleozoic-Cenozoic sedimentary rocks, which are further intruded by Jurassic to Tertiary plutonic rocks. The island arc terrane contains metavolcanic and metasedimentary rocks intruded by Kohistan Batholith ranging in age from 102 to 30 Ma.

Detailed geochemical exploration, including stream sediments and panned concentrates as media, was conducted along the main streams of the Hunza and Gilgit rivers and their major tributaries. Sampling density was slightly enhanced in the neighbourhood of Gilgit where a number of alteration zones have been found. 120 samples of stream sediments were analyzed for gold, whereas 92 samples of panned concentrates underwent chemical assays for Au, Ag, As, Bi, Cu, Mo, Pb, Sb, and Zn in Chemex Laboratories, Canada. Gold contents in the study area are generally higher than the average of the earth crust, implying a high probability of some gold mineralization in this area. The univariate analysis demonstrates high concentrations along the MKT and on the northern side as a whole, except Cu and Mo. Gold shows particularly high concentrations along the MKT.

Factor analyses have led to the extract of the following two factors related to gold mineralization: i) a factor represented by a combination of Au-Ag-As-Sb (Factor 1) ~ their high factor scores are found along the MKT and ii) a factor represented by a combination of Bi-As-Ag-Au (Factor 2). High-scored points for the Factor 2 are distributed mainly around the glacier areas. The present survey succeeded in demarking areas showing high content of 11 ppm and 50.5 ppm Au as well as high scores for Factor 1 that suggest a follow-up survey on priority basis in these areas.

K/420. Khan, S.U., 1995-96. Structure, stratigraphy, micropaleontology and petrography of Dardhan, Narota & Karwali areas District Haripur Hazara (NWFP), Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 89p.

The Dardhan, Narota and Karwali area are part of Attock-Hazara fold-and-thrust belt of the northwest Himalaya of Pakistan. The lithographic units exposed in the area are mainly sedimentary in nature and range in age from Mesozoic to Cenozoic. The area is deformed by folding and faulting during the Tertiary-Himalayan collision. The Early Cretaceous Lumshiwal Formation has disconformable contact with the overlying Late Cretaceous Kawagarh Formation. The presence of glauconite in the Lumshiwal Formation reveals that the formation was deposited in marine condition during regressive as well as transgressive phases. The Late Cretaceous subduction of the Indian plate below the Kohistan Island arc caused the deepening of the Tethyan shelf in the subduction zone and initiated

the deep marine deposition of the Kawagarh Formation. The contact between Kawagarh Formation and Early Paleocene Hangu Formation is marked by break in deposition which is evidenced by the presence of laterite/haematite and sandstone. The abrupt change in facies from deep water marine environment of Kawagarh Formation to terrestrial deposition of Hangu Formation indicates the initial Early Paleocene collision of the Indian Plate and Kohistan Island arc.

The Lower Tertiary sequence exposed in the area is Early to Late Paleocene Lockhart limestone, Late Paleocene Patala Formation, Early Eocene Margala Hill Limestone, Early Eocene Chorgali Formation and Early to Middle Eocene Kuldana Formation. The Lower Tertiary sequence marks the complete cycle of transgression and regression of the Tethyan Sea. The presence of early Paleocene to Late Eocene foraminiferal assemblage like globorotalia, globogorina, lockhartia, assilina and nummulites in the limestones and shales of the Lower Tertiary sequence show the tropical sub-tropical open sea upper slope to outer shelf environments. The Kuldana Formation is composed of marine limestone, continental variegated clay, shales and evaporitic gypsiferous bands. These variegated lithologies show that the Early to Middle Eocene Kuldana Formation deposited in transitional environment. The Kuldana Formation marks the end of transgressive cycle and initiation of regression of the Tethyan ocean. The Paleocene-Eocene boundary cannot be marked due to the lack of microfossils in Patala Formation. However, a tentative Paleocene-Eocene boundary marked at the base of Margala Hill Limestone on the basis of first appearance of Early Eocene fossils in the Margala Hill Limestone. Two sets of folds have been recorded which indicate two separate phases of deformation. These deformation phases are D_1 and D_2 which are related to Himalayan orogeny. D_{1a} is associated with the southeast-directed thrusts and southeast vergent F_1 folds. D_{1b} is related with the backsteepening of the major thrusts and northwest overturning of the major F_1 folds. This phase is well documented by the northwest vergent Chak Jabbi syncline and Khui-Marl syncline. D_{1b} is also related with backsteepening of MBT due to folding. The D_2 deformation phase is related with the folding of earlier northeast-southwest trending D_1 structures along northwest plunging F_2 cross folds. The F_2 cross folds are antiforms and synforms. These F_2 cross folds are related with the development of the Hazara-Kashmir syntaxis.

K/422. Khan, T., 1986. Geology of the Pegmatite Belt in Chitral, North West Frontier Province, Pakistan. Geological Survey of Pakistan, Information Release 266, 16p.

The rock units of the investigated area are the metamorphites and granitoids, which range in age from Devonian to Tertiary. The pegmatite belt comprising simple and complex pegmatites, trending in northeast and southwest direction are the youngest intrusions (85-20 Ma) within the granites. Gemstone mineralization confined to the complex pegmatites has been found at several localities in the high altitudes. Beryl/ aquamarine, schorlite, indicolite, garnet, and mica may get economic significance. Sulphide mineral association, scheelite, graphite and fluorite mineralization has also been observed.

Key words: Pegmatites, Chitral.

K/423. Khan, T., 1991. Geochemistry of the Warsak igneous complex, N. Pakistan. M.Phil. Thesis, University of Peshawar, 103p.

The Warsak Igneous Complex (WIG) is a bimodal suite of granite and basic rocks, with no or little intermediate compositions. The field relations are ambiguous because of shearing and metamorphism, however, there are indications that the basic rocks are older than the granites. The granites, occurring in three petrographic varieties are closely similar in geochemical composition, in particular, in terms of incompatible trace elements. They have all the characteristics of A-type within-plate granites. The basic rocks are typically tholeiitic formed in intracontinental setting, probably in the initial stages of rifting event. The close similarity of the Warsak granites with Ambela and

Koga, suggests a Palaeozoic age of the WIC. The magmatism in the Warsak area (including both basic and alkaline acidic) was probably related with the Paleozoic fragmentation of the Gondwanaland and the separation of India.

Key words: Geochemistry, granite, alkaline complex, Warsak.

K/424. Khan, T., 1992. Geology and tectonics of the Hindukush Range in the north Pakistan. Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad 3, 84-90.

Hindukush (also called Nuristan) is a NE-SW striking range straddling parts of the countries including Pakistan, Afghanistan and the former U. S. S.R. The range is bounded by major faults except for in the NE where it may continue with the Karakoram Range (Figure 1: After Desio, 1979). The southern boundary of the Hindukush range is defined by the Main Karakoram Thrust (MKT) which separates the Hindukush range from the Kohistan arc. To the west the Hindukush range is bounded by the Sarobi fault which separates it from the Kabul block in the west. To the north the boundary of the Hindukush is defined by the Herat Fault that separates it from the Badakhshan block in the north. The Hindukush or the Noristan block is itself divisible into two structural domains, separated by the Reshun fault. The Reshun fault is a northward dipping thrust fault, which is locally defined along the Yarkhun River by a narrow belt of metavolcanics with (?) ophiolitic affinity (Pudsey et al., 1985). Thus there is a possibility that the Reshun fault is a palaeosuture between two continental blocks within the Hindukush range.

Key words: Tectonics, Hindukush.

K/425. Khan, T., 1994. Evolution of the “upper and middle crust in Kohistan island arc”, northern Pakistan. Ph.D. Thesis, Peshawar University, 225p.

This thesis presents a geological map of 4,000 km² area between Chilas and Gilgit on a scale of 1:250,000, together with details of geochemistry and petrology. The area is occupied by > 1 km thick basal turbiditic sediments (the Gilgit paragneisses), followed upward by > 0.5 km thick Chait metavolcanics and, finally the Thelichi formation = Yasin group comprising a volcanic base and > 1 km thick overlying turbidites with local intercalations of marble volcanoclastics and lava flows. Other lithologies in the area include, Chilas mafic ultramafic complex (8,000 km²), and the Kamila amphibolites. The Kohistan batholith of mostly Paleocene-Eocene age, consists of quartz diorites, tonalities, trondhjemites, gabbroic, diorites, quartz monzonites, granodiorites, granites, aplites and pegmatites. The batholith contains tholeiitic and calcalkaline mafic dykes; such dykes in the Chilas complex are tholeiitic. Metamorphism up to sillimanite grade has been recorded in the Gilgit paragneisses. The rocks of the Chait volcanic group, mafic dykes of the Chilas complex and early phases of the Kohistan batholith show amphibolite facies metamorphism. The Thelichi formation contains greenschist facies mineral assemblages. The geochemical signatures of the Gilgit paragneisses support passive continental margin setting for their deposition. The Chait volcanics demonstrate island arc and back arc type affinities, whereas the Kamila volcanics resemble back-arc tholeiites and mid ocean ridge basalts. These volcanics show transition from arc volcanism to back-arc spreading. The Kohistan batholith is calcalkaline, and gives island arc and continental margin types configurations.

The 36,000 km² Kohistan terrane is divisible in three tectonic zones, (i) the southern (Kamila) zone comprises principally amphibolitised basalts, underplated by cumulate mafic-ultramafic plutons which occupy the hangingwall of the Indus suture, (ii) the central zone comprises the Chilas complex, and (iii) the northern (Gilgit) zone, the Gilgit paragneisses and the overlying rocks. The Gilgit zone was welded to the Karakoram plate 90 Ma ago along the Shyok suture. The northern two zones are complexly folded and faulted (in a divergent pop up structure), while the southern zone is folded and imbricated with a persistent southward vergence. Much of the Kohistan batholith cuts across these structures in the Gilgit zone. Previous tectonic models for Kohistan consider the southern two zones as the basal crust and the northern as the upper crust of a Cretaceous island arc. The present investigation shows that in the Gilgit zone there are two stages of turbidite deposition intervened by basaltic volcanism, an assemblage probably formed in a back-arc basin. These findings have resulted in a completely new interpretation for the Kohistan terrane. It is suggested that only the southern or the Kamila zone represents an island arc crust, while the assemblage to the north of the Kamila-Jal shear zone, including the Chilas complex and the overlying sequence of metamorphosed turbidites and basaltic volcanics, represents a folded and imbricated back-arc basin.

K/427. Khan, T., 1998. Geochemistry, mineralogy and petrology of the sulfide mineralization and associated rocks in the area around Drosh, north Pakistan. Ph.D. Thesis, University of Peshawar.

Copper mineralization in the Drosh-Shishi area is localized in the upper crust of the Kohistan arc terrane in Chitral, northern Pakistan. It is confined to the Gawuch Formation in the area, comprising variably metamorphosed volcanics and sediments intruded by the plutons of diorite and granodiorite composition. The metavolcanics of the Gawuch Formation and the diorite-granodiorite minor plutons have calcalkaline compositional characteristics. In comparison, the metavolcanics of the Drosh Formation, occupying the top of the succession, are island-arc tholeiites. Copper mineralization in the area is related to hydrothermal activity and is mainly associated with altered diorites and quartz veins. It occurs in different forms; in the quartz veins, along the foliation planes, in dissemination and as supergene enrichment. Tetrahedrite, chalcopyrite, pyrite and galena are the dominant ore minerals along with subordinate amounts of sphalerite, magnetite, malachite and azurite. Fluid inclusion studies indicate that the salinity of the hydrothermal solution is <26 equivalent wt% NaCl and the homogenization temperature is in the range of 160 to 350°C. Oxygen isotope data suggest that the quartz in the mineralized quartz veins has $\delta^{18}O$ values ranging from 14.49 to 18.32 per mil. with mean value of 16.63 ‰. This, when combined with the homogenization temperature obtained from the fluid-inclusion studies, indicates involvement of magmatic fluids ($\delta^{18}O = 5.79$ – 9.42 ‰) in the formation of quartz veins and associated copper mineralization. The lead isotopic compositions of three galena samples suggest that $^{206}Pb/^{204}Pb$ ranges from 18.728 to 18.793, $^{207}Pb/^{204}Pb$ from 15.658 to 15.72, and $^{208}Pb/^{204}Pb$ from 39.040 to 39.285. These Pb-isotope ratios yield model ages of 42 – 142 Ma with the M values of 9.86 to 10.01. The minimum age (i.e., 42 Ma) is in close agreement with ^{40}Ar - ^{39}Ar age of the Lowari pluton, which is considered to be the source of hydrothermal solutions. The lead isotopic composition of studied galena samples indicate involvement of lead derived from older sources. These sources could be the arc volcanics or pelagic sediments of oceanic crust of Neotethys or the continental crust of the subducting Indian plate. It is concluded from these studies that the copper mineralization in Drosh- Shishi area was produced by the hydrothermal activity related with syntectonic dioritic magmatism.

K/434. Khan, T. & Kausar, A.B., 1996. Peridot occurrence with ferromagnetic mineral in the dunite of the Sapat ultramafics sequence, Naran-Kohistan, Pakistan. Extended Abstracts, International Seminar on Paleomagnetic Studies in Himalaya-Karakoram Collision Belt and Surrounding Continents, November 20-21, 1996, Islamabad. Geosciences Lab, Geological Survey of Pakistan, Islamabad, p.130.

We report for the first time the peridot occurrence associated with a ferromagnetic mineral in the sheared dunite body of the Sapat ultramafic sequence, Naran-Kohistan (Survey of Pakistan toposheet Nos. 43E and 43F). The Sapat ultramafic sequence comprises dunite-pyroxenite-gabbro- (anorthosite), thinly layered dunite pyroxenite, dunite with thin chromite layers, homogeneous dunite and serpentinized dunite. It is part of the Sapat layered complex, making the tectonic base of the Kohistan island arc. The ultramafic sequence occupies the Indus suture or the Main Mantle Thrust, with the Indian plate in the south. Peridot-magnetite-bearing dunite is sheared cataclastically, and as a result, the dunite is randomly and intensely jointed. Peridot occurs in the joints, and the cavities. Other minerals associated with the peridot include talc, serpentine, magnesite, chromite and ferromagnetic opaque mineral of which Curie temperature marks 585°C, and the specific gravity up to 5.08. The ferromagnetic mineral occurs as subhedral grains, black-coloured with metallic luster. Talc and/or magnesite is the host and cementing material for the peridot and the ferromagnetic mineral. Peridots of the Sapat area are green, and yellowish green. They are euhedral to subhedral, and transparent but translucent and opaque peridots are also mineralized. Hydrothermal activity is responsible for the mineralization of peridot, ferromagnetic and the associated minerals. Magnetic method is applicable for prospecting the peridot. The association of ferromagnetic mineral with peridot may indicate path finder signatures of the former with the latter. Due to the brilliance and green colour, the peridots of the Sapat ultramafic sequence can be used as gemstones.

K/436. Khan, T., Kausar, A.B. & Khan, I.H., 1997b. Peridot mineralization in the Sapat ultramafic sequence of the Indus suture zone, Naran-Kohistan area, Northern Pakistan. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 159-164.

The Sapat mafic-ultramafic complex of Jan et al. (1993) lies north of the Kaghan valley and to the northeast of Naran (N 34° 54' 17" and E 73° 38' 51") and north of Sochh village (N 34° 56' 29" and E 73° 42' 40") along the Naran-Babusar road. It comprises layered gabbro, gabbro-norite and massive to layered ultramafics with basal serpentinitic mylonites (Fig. 1). The layered ultramafics include dunite-pyroxenite-gabbro- (anorthosite) layers, thinly layered dunite pyroxenite, dunite with thin chromite layers, homogeneous dunite and serpentinized dunite (Fig. 2). The Sapat ultramafic sequence is part of the Sapat mafic-ultramafic complex, making the tectonic base of the Kohistan island arc, and marks the boundary, the Indus Suture with the Indian Plate to the south. Peridot mineralization has been spotted for the first time in the serpentinized dunite (minor), homogeneous dunite and the dunite with thin chromite layers (Fig. 2). Peridot occurrence has also been reported at the Zeberget, Island of St. John, in the Red Sea where the host rock is serpentinite dunite (McIntock, 1951; Reed, 1991), and Fo90 (Strunz, 1962; Wilson, 1976). In the Ross Island Antarctica the peridots occur in nodules in basalt with Fo92 (Wilson et al., 1974). Other localities where the peridot mineralization is known include Upper Myanmar (Burma), Australia, Brazil, China, Mexico (light green peridot, Fo91, and a more iron rich light greenish-brown variety, Fo88.6, Dunn, 1978), Norway (Fo90.6; Bank et al., 1970) and USA (Deer et al., 1982; Reed, 1991).

Peridots (Fo91 at the average, and occasionally Fo92 and Fo95) of the Sapat are green to yellowish green in color. They are euhedral to subhedral and 0.5 cm to 4 cm long. They are generally transparent, translucent, and occasionally opaque. The green-colored, transparent, and fracture-free varieties are used as good-quality gemstones. In the Sapat area peridot mineralization occurs in 250-m wide zone, bounded by a 3-m thick mylonite zone in the lower part towards the Indus Suture. They are mineralized in the crosscutting joints, joint cavities, and veinlets. The width of the cavities range up to about 7 cm (Fig. 3). Other minerals associated with peridots include clinochrysotile, antigorite, talc and magnetite (Curie temperature 585°C in heating curve and 595°C in cooling curve). Clinochrysotile is the main mineral wrapping the peridot crystals and magnetite grains (Fig. 4). As evident from the antigorite inclusions in peridots and the mode of occurrence of peridots, it seems that they are developed from antigorite, and the magnetite grains associated with peridots are inherited from the serpentinite, indicating high oxygen fugacity conditions during the progressive metamorphism of serpentinites or deserpentinization (Deer et al., 1982), and the processes related to the shearing along the Indus Suture.

K/438. Khan, T., Kausar, A.B., Takahashi, Y. & Takahasi, Y., 1993. Geochemistry of the mafic and ultramafics rocks of Chilas complex, Chilas, northern Pakistan. Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad 4, 51-61.

Chilas Complex is a layered magmatic complex of the Kohistan island arc which is 300 km long and 40 km wide. It comprises pyroxene quartz diorites, tonalites, gabbros, gabbro-norites, layered dunites, peridotites and amphibolites. Geochemical studies conducted on the ultramafic and basic to intermediate plutonic rocks of the complex reveal their island arc affinities. Various discrimination diagrams have been used to define these rocks. These are mainly gabbros and pyroxene quartz diorites, tonalites and peridotites. The basic and intermediate rocks are low-K to medium-K and calc-alkaline. The geochemical patterns identify the rocks as developed in the island arc environments. These rocks are depleted in Nb giving typical "V" shape pattern. Positive anomalies at Sr and Zr (in more acidic ones) are also significant. The geochemical pattern support the compatible behaviour of the HFS

elements in olivine, pyroxene and spinel. High degree of partial melting of the metasomatised mantle peridotite is considered the source for the Chilas Complex.

K/439. Khan, T., Khan, M.A. & Aziz, A., 1992. Petrogenetic comparison between the mafic dykes of Chilas complex and Kohistan batholith, Northern Pakistan. *Acta Mineralogica Pakistanica* 6, 118-125.

Kohistan Island Arc is formed due the northward subduction of oceanic plate in Cretaceous. The arc sequence contains two major magmatic complexes: the layered mafic and ultramafic Chilas Complex at the base, and the Kohistan Batholith in the middle part. Mafic dykes intrude the gabbro-norite and pyroxene diorites of the Chilas Complex, north of Chilas and the diorites of the Kohistan Batholith west and south of Gilgit. Petrography and geochemistry divided the mafic dykes into three distinct groups. The mafic dykes of the Chilas Complex are rich in plagioclase, hornblende and ilmenite and/or magnetite. These are metamorphosed to amphibolites except the dykes intruding the batholith at shallower part. The Chilas Complex dykes are picobasalt and basalt whilst in the batholith they are basaltic andesite and trachyandesite. Trace element geochemical patterns are similar for all the three type of dykes but the Chilas Complex dykes are more depleted in LIL elements with marked negative Nb and positive Sr anomalies. The Kohistan batholith dykes are comparatively enriched in the LIL elements and the trachyandesites are more enriched. The former is considered "D-type" and the later "E-type" dykes. They all show island arc affinities but the trachyandesite shows continental margin signatures. The three groups also reflect three different magmatic episodes, derived from the partial melting of less and more heterogeneous mantle sources, respectively.

Key words: Petrogenesis, mafic dykes, Chilas complex, Kohistan batholith.

K/440. Khan, T., Khan, M.A. & Jan, M.Q., 1993. Kohistan, a collage of island arc and back-arc basin assemblages in the Himalaya of Pakistan. *Geological Society of America, Abstract Program*, A-122.

Trapped between the collided Indian and Karakoram Plates, the 38000 km² Kohistan terrain in N. Pakistan is divisible into three tectonic zones. The southern (Kamila) zone comprises principally amphibolitized basalts, underplated by cumulate ultramafic-mafic plutons, which occupy the hangingwall of the Indus suture. The central zone comprises gabbro-norites, pyroxene diorites and ultramafics, forming a ~ 8000 km² coherent plutonic body. The northern (Gilgit) zone comprises > 1 km thick basal (turbiditic) sediments (the Gilgit paragneisses) metamorphosed up to sillimanite grade, followed by > 0.6 km thick Chalt (meta)volcanics (commonly pillowed) and finally > 1 km thick turbidites locally interbedded with marble of Albian-Aptian age (Yasin group). The Gilgit zone was welded to the Karakoram plate - 90 Ma ago along the Shyok suture characterized by up to 4 km thick olistostrome. The northern two zones are complexly folded and faulted in a divergent pop-up structure, while the southern zone is folded and imbricated with a persistent southward vergence. The Kohistan batholith of mainly Palaeocene-Eocene age cuts across the structures in the Gilgit zone.

Previous tectonic models for Kohistan consider the southern two zones as the basal crust and the northern zone as the upper crust of a Cretaceous island arc. Subsequently we suggested that the Chilas complex was probably emplaced during an episode of back arc rifting. Recent mapping, stratigraphic reconstruction and geochemistry in the Gilgit zone has resulted in the recognition of two stages of turbidite deposition intervarved by basaltic volcanism, an assemblage probably formed in a back-arc basin. These findings have resulted in a completely new interpretation for the Kohistan terrane. We suggest that only the southern or the Kamila zone represents an inland arc crust, while the assemblages to the north of the Kamila-Jal shear zone, including the Chilas complex and the overlying sequence of metamorphosed turbidites and basaltic volcanics, represents a folded and imbricated back-arc basin.

Key words: Kohistan, Island arc, Back arc basin.

K/441. Khan, T., Khan, M.A. & Jan, M.Q., 1994. Geology of a part of the Kohistan terrane between Gilgit and Chilas, northern areas, Pakistan. *Geological Bulletin, University of Peshawar* 27, 99-112.

More than 4000 Km² area of Kohistan terrane, exposed between Gilgit and Chilas, is mapped and described in this paper. A variety of plutonic and metamorphosed volcanic and sedimentary rocks are encountered in the mapped area, which have been classified into Kamila amphibolite, Chilas complex, Kohistan batholith and Jaglot Group. The Jaglot Group, comprising a succession of metasediments and metavolcanics, is divided into three stratigraphic units, which, from base to top, include Gilgit Formation [~ 1 Km thick succession of schists, paragneisses, calc-silicates and amphibolites (some derived from the pillowed basalts) and Thelichi Formation (comprising a volcanic basal part, overlain by >1 km thick turbidites with a thick marble unit in the middle). The rocks of the Jaglot Group are regionally metamorphosed in amphibolite-and greenschist facies; the highest grade is depicted by the occurrence of sillimanite in the paragneisses of the Gilgit Formation. A pair of crustal-scale anticline (the Gilgit anticline) and syncline (Jaglot syncline) control the structure of the area. These, together with their parasitic folds, repeat the stratigraphy of the area several times. The Jaglot Group is regionally correlated with the succession of metasediments and metavolcanics exposed along the Northern Suture (i.e., Yasin Group Sediments and Chalt Volcanics) and is considered to have been deposited in an oceanic basin (probably of a back-arc affinity) on the basis of the predominance of turbidites in the metasediments and pillowed basalts in the volcanics.

K/442. Khan, T., Khan, M.A. & Jan, M.Q., 1995. Back-arc basin assemblages in Kohistan, Himalaya, north Pakistan. Spec. issue, Mitt. Geol. Inst., Zurich, 4p.

The 36,000 km² Kohistan sandwiched between the Karakoram and Indian continental plates in the north and south, respectively. In the north the contact is defined by the Shyoke suture or Main Karakoram Thrust and in the south by the Indus suture or Main Mantle Thrust. The whole rock sequence of Kohistan is considered to represent an intra-oceanic island arc with a narrow marginal sea in the north (Pettersen & Windley 1985; Pudsey 1986). It was formed due to northward subduction of the Neo-tethyan Lithospheric plate (Coward et al. 1987; Honneger et al., 1982; Tahirkheli & Jan, 1979).

This manuscript includes a geological map of the investigated area together with a brief description of petrology and geochemistry. The area is occupied by >1 -km thick basal turbiditic sediments (the Gilgit paragneisses), followed upward by >0.5 -km thick Chalt volcanics and, finally the Thelichi formation = Yasin group of Ivanac et al. (1956), comprising a volcanic base and >1 -km thick turbidites with local intercalations of marble, volcanoclastics and lava flows. Other lithologies in the area include, Chilas mafic-ultramafic complex (~ 8000 km²), and the Kamila amphibolites (Bard et al. 1980; Jan et al. 1984; Jan 1988; Khan & Coward, 1990; Khan et al., 1993). The Kohistan batholith (Pettersen & Windley, 1985) mostly Paleocene-Eocene cuts across the structure in the Gilgit zone. The batholith contains tholeiitic and calc-alkaline mafic dykes; such dykes in the Chilas complex are tholeiitic.

Metamorphism up to sillimanite grade has been recorded in the Gilgit paragneisses. The rocks of the Chalt volcanic group, mafic dykes of the Chilas Complex, and early phases of the Kohistan batholith show amphibolite facies metamorphism. The Thelichi Formation contains greenschist mineral assemblages.

The geochemical signatures of the Gilgit paragneisses support igneous provenance, derived from mainly the oceanic island arc (Roser & Korsch 1988; Condie et al. 1992). Evidences for the existence of the continental basement and fore-arc basin are lacking for the Gilgit paragneisses. The metavolcanic rocks namely the Chalt, and the Majne volcanics are tholeiitic basalts, which show a composite trace elements geochemical signatures. The Chalt volcanics are mainly HFS elements depleted with Nb trough where as the Majne volcanics are HFS elements enriched with positive Nb anomaly. Both the island arc-and MORB-like signatures are found in these two volcanic formations (Alabaster & Storey, 1990). As evident from the stratigraphical setup the Chalt volcanics are older than the Majne volcanics, and enriched in the incompatible elements derived from the subducting lithospheric plate during the initial stages of back-arc rifting (Pearce et al. 1984; Saunders & Tarney, 1991). The Majne volcanics are MORB-like back-arc basin tholeiitic basalts, and are low in MgO and high in TiO₂ contents and FeO(total) / MgO ratio where as the Chalt volcanics are high-Mg tholeiitic basalts with low TiO₂ content and FeO(total)/MgO ratio at a given SiO₂ concentrations. Fractional crystallization and low degree of partial melting of the enriched mantle, and high degree of partial melting of the subduction modified mantle are the possible sources for the Majne and Chalt volcanics, respectively (Pearce & Norry, 1979; Wilson 1989). Moreover, these volcanic formations show transition between arc-like and MORB-like magmatism during back-arc rifting.

The establishment of a new stratigraphy in the middle Indus valley of Kohistan and the recognition of the sillimanite-bearing metasedimentary rocks and the back-arc basin tholeiitic basalts for the first time, divides the Kohistan in three tectonic zones. The southern (Kamila) zone comprises principally amphibolitised basalts, underplated by cumulate mafic-ultramafic plutons, which occupy the hanging wall of the Indus suture. The central

zone comprises the Chilas complex, and the northern (Gilgit) zone, the Gilgit paragneisses and the overlying rocks. The Gilgit zone was welded to the Karakoram plate-90 Ma ago along the Shyoke suture. The northern two zones are folded and faulted (in a divergent pop-up structure), while the southern zone is folded and imbricated with a persistent southward vergence. Much of the Kohistan batholith cuts across these structures in the Gilgit zone.

Previous tectonic models for Kohistan consider the southern two zones as the basal crust of a Cretaceous island arc. The present investigation shows that in the Gilgit zone there are two stages of turbidite deposition intervened by basaltic volcanism, an assemblage formed in a back-arc basin. These findings have resulted in a completely new interpretation for Kohistan. It is suggested that only the southern or Kamila zone represents an island arc crust, while the assemblage to the north of the Kamila-Jal shear zone, including the Chilas complex and the overlying sequence of the metamorphosed turbidites and basaltic volcanics represents a folded and imbricated back-arc basin.

K/443. Khan, T., Khan, M.A., Jan, M.Q. & Latif, M., 1996. The Kohistan between Gilgit and Chilas, northern Pakistan: regional tectonic implications. *Journal of Nepal Geological Society* 14, 1-10.

In this paper, we present geological description of an area located between Gilgit and Chilas within the Kohistan terrane. This terrane has been considered an intra-oceanic island arc, formed due to northward subduction of the Neo-tethyan lithospheric plate. At present, it is squeezed between the Karakoram-Asia and Indian continent plates. Both the contacts are marked by suture zones, that is, Shyok (MKT) in the north and Indus (MMT) suture in the south, respectively. The investigated area consists of plutonic, metamorphosed volcanic and sedimentary rocks, the Chilas Complex, and the Kamila Amphibolite. The metamorphosed volcanic and sedimentary rocks are packaged into the Jaglot Group. This group comprises basal turbiditic sediments, intercalated with amphibolites and calc-silicates (the Gilgit Formation), followed upward by the Gashu-Confluence Volcanic=Chalt Volcanic Group, and finally the Thelichi Formation=Yasin Group of Aptian-Albian age. The Thelichi Formation comprises a volcanic base (Majne volcanics) and overlying turbidites, local intercalation of marble, volcanoclastics and lava flows. Greenschist and amphibolite facies are common in the Jaglot Group, and particularly the sillimanite in the Gilgit Formation. A pair of anticline (the Gilgit anticline) and syncline (the Jaglot syncline) make up the structural scenario. On the basis of field geology, we conclude that the entire Jaglot Group and its equivalent, Yasin Group, Chalt Volcanic Group in Kohistan, and Burjila Formation, Bauma Harel Formation and Katzarah Formation in Ladakh show intra-oceanic back-arc basin rather than island arc affinities as suggested in the past.

Key words: Tectonics, Kohistan island arc, MKT, MMT, Himalaya.

K/444. Khan, T., Khan, M.A., Jan, M.Q. & Naseem, M., 1996. Back-arc basin assemblages in Kohistan, northern Pakistan. *Geodynamica acta* 9, 30-40.

The east central part of the Kohistan magmatic arc is made up principally of the Jaglot Group. From bottom to top it consists of I) paragneisses and schists intercalated with amphibolites and calc-silicates (Gilgit Formation), II) Gashu-Confluence Volcanics (GCV) and III) the Thelichi Formation comprising a volcanic base (Majne volcanics) and turbidites, marble, volcanoclastic sediments and lava flows. Metamorphic grade varies up to the sillimanite zone. The GCV are correlated with the Chalt volcanics and the Thelichi Formation with the Yasin Group. Other lithologies include the Chilas Complex, the Kohistan Batholith and part of the Kamila Amphibolite. Metavolcanics show a broad range in chemical composition. Geochemical parameters used to specify the tectonomagmatic regime suggest affinities of both island arc and MORB-like back-arc basin basalts. Kohistan can be divided into three tectonic zones, I) the southern (Kamila) zone comprises amphibolitized basalts, and mafic and ultramafic rocks, II) the central Chilas Complex, and III) the northern (Gilgit) zone i.e., the Jaglot Group. Previous tectonic models considered the southern two zones as the crust of a Cretaceous island arc. This investigation concludes that only the southern zone represents a true island arc. The Jaglot Group derives from back-arc basin assemblages and the Chilas Complex is a magmatic diapir emplaced in the back-arc basin.

Key-words: Island arc, back arc, geochemistry, Kohistan.

K/445. Khan, T., Khan, N.A. & Khan, M.S., 1988. A short note on the occurrence of turbidite at Sikanderabad, along Karakoram Highway, Northern Areas of Pakistan. *Geological Survey of Pakistan, Information Release* 387, 5(+8)p.

In the Hunza valley, rock units belonging to Kohistan Island arc, Main Karakoram Thrust zone and Eurasian continent are exposed along the Karakoram Highway. A turbidite unit has been identified at Sikandarabad in the melange zone of the MKT along with slates, phyllitic schist, calcareous schist, limestone, green schist pyroclasts, talc carbonate, serpentinite, peridotite, andesite/basalt and rhyolite as the melange constituents. The turbidite of the area is composed of interlayered siltstone, sandstone and mudstone. The mudstone is changed into schist, containing upto 25 cm long pebbles of sandstone, siltstone, limestone, quartz, slate and andesite. These pebbles are flattened and oriented in the northwestern directions. This turbidite of the melange zone may represent deep-seated sedimentary origin in the oceanic island arc environments.

Key words: Turbidites, Hunza, Shyoke suture, Karakoram.

K/446. Khan, T., Khan, N.A. & Shirahase, T., 1998. Geology of the Kohistan batholith in Kar Gah and Gor sectors, Kohistan arc terrane, Gilgit, North Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 102-103.

Kohistan arc terrane lies between the Asian and Indian continental plates (Fig. 1). Both the northern and southern contacts of the arc are marked by suture zones commonly known as Main Karakoram Thrust (MKT) and Main Mantle Thrust (MMT). The Kohistan batholith which is one of the major rock components of the arc and the Trans-Himalayan batholith extends for more than 2700 km along the length of Himalaya and Karakoram. The Kohistan batholith in Kohistan arc extends for 300x50 km between the Afghan border on the west and the western flank of the Nanga Parbat massif on the east (Fig. 1). The batholith is an ENE-SSW elongated body consisting of many plutons which intrude the Jaglot group and Chilas complex of the Kohistan arc. The Kohistan batholith, south of Gilgit, in Kar Gah and Gor sectors comprises multiphase plutons forming Shinghai and Gor plutonic belts. The Shinghai plutonic belt is basic to intermediate in composition comprising gabbro, gabbroic-diorite and diorite along with younger intrusions of granodiorite and granite (minor). The belt also contains serpentinite, pyroxenite? and paragneiss as xenoliths. The Gor plutonic belt is the principal occurrence of the Kohistan batholith along the drainage divide between the Indus and Gilgit Rivers. It is a coherent body of mainly quartz diorite composition but also contains intrusions of tonalite, granodiorite, adamellite and granite along with ample aplite and subordinate pegmatite. The main pluton contains abundant xenoliths and/or autoliths of basic composition. Both the northern and southern contacts of the Gor pluton are intrusive into the metasedimentary succession of the Jaglot group and the Chilas complex, respectively.

Major and trace element geochemical patterns and petrological characteristics of the Kohistan batholith in the study area reveal that (i) chemical variation seen in the batholith is not due to high level differentiation but can be better explained by partial melting, (ii) much of the Kohistan batholith appears to be the product of mantle wedge above the subduction zone, (iii) some of the leucogranite and aplite seem to be derived by partial melting of the crust of the Kohistan arc, and (iv) there are certain plutons which are alkaline in nature and contain a higher amount of K₂O over Na₂O which may be derived from crustal material such as Gilgit paragneisses and/or from a possible basement of the Indian plate crust underplating the arc. The Frequency of C twins in the Kohistan batholith is mostly 10 to 20% showing igneous features and shallow depth of emplacement for the batholith.

Key words: Kohistan batholiths, petrography, Gilgit, Kohistan arc.

K/447. Khan, T., Latif, M., Khan, N.A. & Shah, S.H., 1989. Geology and petrography of the rock outcrops in Shinghai Gah and Kiner Gah, Gilgit-Chilas Districts, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 446, 15p.

Reconnaissance geological investigation and petrographic study on the rocks of the Shinghai gah and Kiner Gah have revealed that the Kohistan Island arc in these nallahs is composed of plutonic, metavolcanic and metasedimentary rocks belonging to Ladakh-Kohistan granitic belt, greenstone complex, Chilas complex and Thelichi beds. Granodiorites and diorites are the dominant plutonic rocks with granite, pegmatite and aplite as minor associates with norite the bottom most unit exposed at Thak area in Kiner gah. The older granitoids are metamorphosed and mylonitized along the sheared contacts. Volcanics (greenstone/greenschist) occur in an elongated belt underlain by the marble beds, schists, andalusite slate and micaceous sandstone at Shinghai gah. The metasediments have sheared contacts. The older volcanics are metamorphosed into amphibolites and occur as

xenoliths and screens within the intrusive rocks. All the rocks units exposed in Shinghai gah and Kiner gah range in age from Recent to Jurassic and trend mostly in NW-SE direction.

K/448. Khan, T., Nakajima, T., Khan, S.R. & Sano, S., 1994. Occurrence of blueschists at Tuwa near Charbagh, NWFP, Pakistan. *Proceedings of Geoscience Colloquium (Geoscience Lab, Geological Survey of Pakistan, Islamabad)* 8, 94-99.

A new occurrence of blueschists within the Indus Suture near Charbagh has been reported. There is intermixing of blueschists and greenschists, representing single lithology. The coexistence of glaucophane- crossite, actinolite/tremolite and epidote may suggest high pressure intermediate series metamorphism of the rocks. Thus, blueschists melange and greenschists melange represent a coherent melange group extending from Shangla towards Tuwa.

K/452. Khan, T.M., 1992. Uranium distribution in graphitic metapelites in the Pre-Cambrian Formation of Azad Kashmir and NW Pakistan. M.Phil. Thesis, University of Peshawar, 133p.

The graphitic metapelites of NW Pakistan and Azad Kashmir are exposed in a zone of thrust tectonics, and are scattered in the form of continuous beds and lenses in various nappes. These are highly radioactive at places but the equivalent chemical uranium is found to be lower than its radiometric equivalents. This form of negative disequilibrium is produced due to the presence of daughter products of U, Th and K40. The chemical composition of the graphitic metapelites indicates that the rocks from Tarbela area are more siliceous and contain more organic carbon compared to the rest of the exposures of the graphitic-metapelites. Due to their fine grain-size, dark colour, and Fe oxidation along fractures, the rock types are classified as black shales. According to the classification of Stribny et al. 1988, the graphitic metapelites from Tarbela area are siliceous and those from other area are dominantly argillaceous, siliceous with high normative quartz. Uranium associated with other elements is concentrated in the upper part of the graphitic metapelites and unlike typical black shale deposits, do not indicate any correlation with organic carbon. The absence of relationship is primarily caused by the dissolution of some of the elements in ground water circulating freely in the otherwise impermeable rock made permeable by the structural movements in the region. Compared to metal rich black shale deposits these rocks are enriched in U, V, Ba and Pb. The enrichment of one of the elements took place in association with the detrital fraction of the rock while the rest of the enriched elements were concentrated from normal seawater in oxygenated transitional environment close to the continent. The graphitic metapelites were probably deposited in a basin fed by different source material.

Laboratory scale flotation studies were conducted on North Waziristan Copper Ore to enhance the copper content in the final concentrate product. Process parameters such as type of collector effect of activator/depressant, effect of pH were investigated. In the final product copper content was enhanced from 0.386% (in feed) to nearly 20 percent (in the concentrate) in a single stage flotation process.

K/455. Khan, W., 1986. Geology and petrography of the metamorphic and ultramafic rocks of Shergarh Sar area, Allai Kohistan, Hazara Division, N.W.F.P. Geological Survey of Pakistan. Information Release 254, 29p.

The area investigated, lies along the main Mantle Thrust and constitutes the southernmost obducted part of Kohistan Island Arc sequence, which developed due to the collision of the northward moving Indo-Pakistan continent with Eurasian plate. The area is occupied mostly by metamorphic and ultramafic rocks. The metamorphic rocks consist of epidote amphibolites, garnet-epidote amphibolite and garnet amphibolites. The ultramafics are peridotite, pyroxenite, dunite and their equivalent serpentinite. The amphibolites are the part of north east trending southern amphibolite belt of Kohistan and represent the metamorphosed Tethyan oceanic crust, while the ultramafics are considered to be the pieces of the underlying upper mantle and show the chromium mineralization.

K/457. Khan, W.M., 1965. The main Malakand granite. Geological Bulletin, University of Peshawar 2, 8-10.

The best exposures of this beautiful rock are seen along the main road from Malakand to Bat Khela. It is a dazzling white, coarse grained rock, mainly composed of quartz, biotite and alkali feldspar, but there are local variation in color, texture and composition. It is without foliation in the main part but where traced to the surrounding rocks, gneissic structures come in. the country rocks surrounding it are mainly slates and gneisses, but various kinds of schist may also be seen. Quartz, aplite and pegmatite veins are common, especially, where the adjacent rocks are slates. Rafts and xenoliths of slates are common in the granites.

K/458. Khan, Z.A., 1997. Nature and Genesis of India-Asia Suture. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 165-166.

The paper reviews the field data from the Chaman and the Indus-Tsangpo regions and points out that currently available evidence does not support the plate tectonic concept that these are sutures zones of the Indian and northern landmasses. Instead, it is suggested that the Indus-Tsangpo is a rift valley. Presumably it came into being in Triassic, which continue to deepen and receive sediments, became dormant in the Cretaceous after a spurt of volcanic activity long before the supposed suturing in the Eocene.

Attention is drawn on the occurrence of extensive Carboniferous fluvioglacial deposits in northern Tibet, and the presence of typical Gondwana flora and fauna bespeak unequivocally that there was a continuity from Peninsular India to northern Tibet in Carboniferous times. Tapponnier et al., (1980) and Acharyya (1990) admitted the existence of Carboniferous tillite with distinct Gondwana affinities underlying Permo—Carboniferous beds in the Lhasa block, but later, the former committed a somersault calling it a rift in—fill to continent to support plate tectonic data. Furthermore, consistent palaeocurrent-directions towards the northwest in Peninsular India, Lesser, and Tethys Himalayas (Sakai, 1991) indicate a continuity from Peninsular India to northern Tibet and may be beyond.

The ophiolite eruptions along the Indus-Tsangpo suture have yielded two different ages of emplacements i.e. emplacement took place about 100 Ma before the supposed collision in the Eocene-Miocene. Whereas, the Tibetan glacial indicate that India and Tibet were together in Carboniferous, Lystrasaurus fauna suggests for the Lower Triassic and the ophiolites for the Jurassic-Cretaceous. Thus, India and Tibet were together all the time.

Also, Indian plate is believed to have underthrust the Tibetan plate by about 500 km, however, if this is correct and if 500 km of shortening along the Himalaya is added to it there should be a displacement of about 1000 km on the Baluchistan coast. Instead, the coast is straight. Similarly, there is no explanation for the fact that, if this underthrusting has taken place, why did Himalayan uplift occur some 500 km from the Indus-Tsangpo suture instead of being along Collision zone itself The collision of suture is therefore, a consequence of misinterpreted evidence and distorted arguments offered by supporter of plate tectonic hypothesis. Likewise, the double thickness of crust in Tibet, is not unique in that it continue south of the so-called suture, as also in Pamir. It is of about the same order in Andes available evidence strongly suggests that the Tethys was entirely epi-continental. It may be noted that the

rivers flowing out of the Tibet area onto the Indian plate must have existed before the Himalaya rising, which means that India-Tibet area was a landmass, and Tethys did not exist. Evidence in support of the points indicated above is discussed in this study.

Along 10 miles long stretch of road, from lower Topa to Phagwari village has been surveyed to study the major landslides in detail, namely the so called Kasserli, Norgali, Seher Bagla and Aliot slides. The landslides have been mapped on contour map of scale 1:2400 and 1:4800 on basis of surface geology, characteristics of the slope, types of movement and the material involved. Majority of the failures mainly occurs due to lack of proper drainage facilities all along the road. Engineering properties like Atterberg's limit, specific gravity, density, cohesive strength, angle of friction and grain size analysis of the soil present on unstable slopes are tested to know behavior of the soil under different conditions. Suggestion for improving present conditions of the road and to minimize possibility of its failure are purposed.

The province is endowed with rich reserves of industrial minerals such as rock phosphate, magnesite, gypsum, limestone, soapstone, silica sand, etc. Selected minerals are discussed in terms of reserves and grade. Large deposits of silica sand occur in Pezu, Paniala in DI Khan contain iron, but it can be reduced to use the sand in colorless container glass. At Munda Kucha near Mansehra, 53 million tons of silica sand has been estimated. Very large deposits of limestone occur in the province. Large deposits of gypsum Karak-Kohat belt, and sizable deposits of barite, rock phosphate and magnesite occur in several places.

K/468. Khattak, M.U.K., Ahmed, I., Ahmed, J. & Ahmed, A., 1984. A note on the occurrence of blue quartz in Rustam, Mardan District, Pakistan. Geological Bulletin, University of Peshawar 17, 174-175.

The Swabi-Chamla sedimentary group of Martin et al. (1962) is generally borders the Ambela granite along its western and southern margin. The main lithologies include shales, quartzites, limestones and dolomites. The low grade regionally metamorphosed phyllitic rocks of Chamla are pelitic to semi pelitic in composition and contain the so-called quartzitic and graywacke layers and zones of elongate pebbles of generally psammitic composition (Martin et al., 1962). The rocks are locally schistose in character. We report here an occurrence of blue quartz in quartz-rich shaly lenses enclosed in the Chamla phyllitic shales. The lenses represent either a layer in the phyllitic country rocks as described by Martin et al. (1962), or quartz veins associated with the Ambela granite. Further data on detailed petrography, tectonic setting and correlation of the rocks in the area and the origin of the quartz will be given elsewhere.

K/469. Khattak, M.U.K., Ahmed, I., Parvez, M.K., Ahmed, J. & Ahmed, A., 1984. Carbonatite body near Khungai, Rustam area, District Mardan, north Pakistan. Geological Bulletin, University of Peshawar 17, 175-176.

A small carbonatite body is located on the eastern edge of the Ambela granitic complex at Khungai village in Rustam area of Mardan District. The Carbonatite is medium-coarse-grained and has a sharp contact with the Ambela granite. The granite is commonly medium-grained and is generally gneissose at the contact with the carbonatite. The granite is sheared along the contact with the carbonatite, however, in one occasion the contact between the granite and carbonatite contains enrichments of pyroxenes, pyrite, tourmaline, and garnet. At the eastern contact of the carbonatite the granite is very fine-grained and seems more felsic due to metasomatism. Fenetization seems to accompany the emplacement of carbonatite body.

K/470. Khattak, M.U.K., Jan., M.Q. & Khan, M.A., 1998. Nature of Indus suture (MMT) and Astak Fault east of Nanga Parbat-Haramosh Massif. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 103-104.

Recent studies have shown that in much of the Himalaya the Indus suture (IS) demarcates the boundary between the Indian plate and the "Asiatic" mass with local occurrences of ultramafic rocks and ophiolitic melanges. In the northwestern Himalaya, however, a more complicated scenario has been documented due to the presence of an extensive zone, the Kohistan-Ladakh island arc (KLIA), between the Indian plate and Asia. The contact between the Indian plate and the KLIA is an extension of the IS and locally (i.e. within Pakistan) named as the Main Mantle Thrust (MMT).

The MMT is quite variable in nature. It is razor sharp in some places (e.g. Sapat; Jijal; Timargara), consists of ophiolitic melanges (e.g. Shangla; Alai; N of Peshawar), or of melanges containing elements of the Kohistan arc and Indian plate with or without components of the neo-Tethyan crust-mantle (e.g. Babusar; E of NPHM). In some places high-P rocks have been reported in the MMT zone (Patan; Kaghan; N of Astak; Le Fort et al., 1997).

The IS on the eastern margin of the NP is a good example of a melange zone containing all three components. The Indian plate is represented by metasediments and gneisses, the KLIA by amphibolites, and the neo-Tethyan oceanic crust by mafic-ultramafic assemblages. Individual blocks range from a few to hundreds of meters in dimension and show varying degree of deformation and alteration.

West of the Astak river confluence with the Indus river (~3 km W of Astak police station), a series of pelitic and possibly some psammitic rocks, variably deformed and boudinaged, contain lenses of amphibolite (meta-gabbros), semi-pelites, calc-silicate and ultramafic rocks. The mafic-ultramafic assemblages include meta-gabbros (now garnet amphibolite), altered chromite-bearing dunite, peridotite and pyroxenite, and are enclosed in biotite-rich matrix. This biotite-rich matrix probably formed from a mud-rock. The pelites are garnetiferous and have streaky bands and veins of quartz and feldspathic material. Some muscovite pegmatite are highly boudinaged (upto 15 cm thick). Some amphibolite occurs in cm-scale bands. Amphibolite lens may contain 1/2 mm garnet porphyroblasts. The mafic-ultramafic lithologies are highly altered and mostly consist of ?tremolitic green amphibole with or without talc, boudinaged within biotite-rich band. The biotite-rich 'beds' are also boudinaged and in rare cases, reach ~1.4 m in width. These 'beds' consist of abundant biotite and subordinate green amphibole, with possibly a small amount of quartz. These green amphibole-bearing pockets in biotite-rich matrices, normally not more than a few meters across probably represent olistostromes formed at the surface of the neo-tethyan oceanic crust. The mafic-ultramafic lenses are upto a third of a meter in length and some 10-13 cm thick. One ultramafic lens (1/2 m x 20 cm) contains poorly defined layers as well as disseminated grains of chromite in an altered green ultramafic matrix. The outermost 1-2 cm crust of the 'nodule' is very dark, rich in amphibole, possibly some olivine and some orthopyroxene.

Also contained in the zone are lenses of a dense rock consisting of garnet, ?opx, ?cpx, and Qtz. One disc shaped, 2 x 3/4 m in size, ultramafic lens contains, from core outward, talc, talc+tremolitic amphibole, and ~1 cm rim of tremolitic green amphibole, enclosed in biotite-rich band. The largest ultramafic lens (~20 m broad), consists of grey/brown material in a greenish to yellowish serpentinitic matrix. In the interior of this lens, there is a biotite-rich zone ~1/2 m across which contains altered nodules of the ultramafic. These nodules may have talcose interiors surrounded by colorless and/or green fibrous amphibole. Adjacent to the ~20 m ultramafic lens, the biotite band passes into grey to white fibrous amphibole ± talc-bearing band with a green inner and a grey outer zone. Locally this ultramafic lens is grey serpentinitic. Alteration zones in the ultramafic main lens contain upto ~3 cm long green mica, prisms of upto ~2 cm long green amphibole, and ?magnetite. The ultramafic lithologies are hosted by metasedimentary rock which gets more and more gritty to conglomeratic westwards. Well-bedded siltstone and sandstone lithologies are exposed ~250-300 meters west of the eastern-most ultramafic lens. Some of these gritty rocks contain over 1 cm rotated garnet porphyroblasts. Local biotite-rich bands with greenish material continue westwards for at least several 100s of meters. This melange zone extends over ~2 km to the west from the Astak River confluence with the Indus river. Further west, associated with these rocks are greyish orthogneisses, garnet-kyanite gneisses and banded amphibolites and granitic sheets, all intruded by deformed quartzo-feldspathic material (aplites and pegmatite dikes). Similar melange zone has been found some 25-30 km to the south along Astore river east of Harchu, although the scale of the mafic-ultramafic 'pockets' here is several orders of magnitude smaller. Geochemistry is in progress to sort out details and tectonic locale of the various mafic-ultramafic lithologies.

Key words: Indus Suture, melange, petrography, Astak fault, NPHM.

K/471. Khattak, M.U.K., Khan, M.L., Bangash, M.I. & Jan, M.Q., 1985. Petrography of hornblendites and associated rocks at Mahak, upper Swat. *Acta Mineralogica Pakistanica* 1, 78-82.

An 8-km² area around Mahak consists of amphibolites, metamorphosed gabbros and pyroxenite, hornblendites, and minor dykes and veins of hornblende-plagioclase pegmatite and quartzo-feldspathic rocks. These are described here petrographically, with a brief discussion on their origin. The amphibolites are meta-igneous and essentially composed of amphibole, plagioclase and /or epidote; the gabbros and pyroxenites are relictual and partially amphibolitized; the hornblendites are essentially monomineralic, variable in grain size and may grade into amphibolites through a plagioclase-bearing variety.

Key words: Petrography, hornblendites, pyroxenites, amphibolites, Mahak, Swat.

K/472. Khattak, M.U.K., Khan, S. & Ahmed, W., 1997. Tirich Mir Fault zone of Chitral. Northern Pakistan. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, p. 167.

This paper describes geology of the Tirich Mir fault zone of Chitral in northern Pakistan. The fault zone follows a NE-SW direction from Arkari towards Tirich Gol, passes through Rich and Shah Jinali and enters Afghanistan. The fault zone is typically associated with mafic-ultramafic rocks and probably represents a suture zone between the Hindukush-Karakoram and the Asian plates. The mafic-ultramafic rocks form thin to thick lenticular bodies of fine to coarse grained, locally foliated to banded, gabbro-diorite, homogenous to banded amphibolites, hornblendite, and serpentinite. The serpentinite is strongly shattered, has a typical tectonized appearance and commonly contains veins of asbestos and locally pseudomorphs of pyroxene recognizable in hand specimen. The largest of the mafic-ultramafic bodies is ~20 km long and up to ~2 km thick and is exposed in the Arkari valley. To the northwest, the Wakhan Formation consists of Permian to Jurassic terrigenous sequence of dark gray slate to siltstone with less common fine grained quartzite and intercalations of calcareous schist, dolomite and marble. Drainage geochemical exploration along the Tirich Mir fault zone shows significant gold, nickel, zinc, cobalt, lead, copper, iron, and molybdenum values. Complex mesoscopic scale deformation (folding and faulting) is common along the fault. The fault zone is intruded by hornblende-biotite-granodiorite pluton of Tirich Mir and Kafiristan. No blueschists or eclogitic rocks have been found associated with the fault. To the southeast of the Tirich Mir fault zone is a thick sequence of dark gray slate-siltstone with minor gray argillaceous-arenaceous-calcareous schist, fine grained quartzite, and green metavolcanic and volcano-sedimentary rocks.

The occurrence of the typical alpine-type (as opposed to stratiform-type) mafic-ultramafic rocks along the fault zone on a regional scale probably indicates the existence of a major tectonic contact i.e. a suture between the Asian and Karakoram plates. This is supported by the fact that geochemical signature of the Tirich Mir fault zone resembles that of the Main Karakoram Thrust which is a well established suture between the Kohistan arc and the Karakoram plate in northern Pakistan. Another possibility is that the fault zone may have originated as an intraplate rift zone which probably developed as a result of extensional regime generated within the Hindukush-Karakoram plate and then gave way to a fault (suture) during the compressional phase developed by the northward subduction along the MKT and by the southward subduction along the Reshun Pshart suture in the Pamirs.

K/474. Khattak, M.U.K., Shervais, J.W. & Jan, M.Q., 1999. Petrology of the layered mafic-ultramafic lenses from the Nanga Parbat-Haramosh massif. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 85-86.

Recent studies have shown that in much of the Himalaya the Indus suture (IS) demarcates the boundary between the Indian plate and the "Asiatic" mass characterized by local occurrences of ultramafic rocks, ophiolitic melanges, and high-P metamorphism. In the northwestern Himalaya, however, a more complicated scenario has been documented due to the presence of an extensive zone, the Kohistan-Ladakh magmatic arc (KLMA), between the Indian plate and Asia. The contact between the Indian plate and the KLMA is an extension of the IS and locally (i.e. within Pakistan) named as the Main Mantle Thrust (MMT). The MNIT is quite variable in nature. It (a) is razor sharp at some places (e.g. Sapat, Jijal, Timargara), (b) consists of ophiolitic melanges (e.g. Dargai-Harichand, Shangla, and Alai, north of Peshawar), or (c) consists of melanges containing elements of the Kohistan arc and Indian plate with or without components of the neo-Tethyan crust-mantle (e.g. Babusar, E of NPHM). In some places high-P rocks have been reported in the MMT zone (Shangla, Allai, Kaghan, N of Stak). The IS on the eastern margin of the NPHM is a good example of a melange zone containing all three components. The Indian plate is represented by metasediments and gneisses, the KLMA by ortho-amphibolites and tonalites, and the neo-Tethyan sediments by biotite-rich gneisses containing lenses of rocks, which contain mafic-ultramafic assemblages. Individual blocks range from a few to hundred of meters in dimension and show varying degree of deformation and alteration/metamorphism (Fig. 1). This article presents data on the mafic-ultramafic assemblages along the eastern margin of the NPHM, which probably represent Tethyan shelf sediments caught up during subduction of the oceanic crust, subjected to elevated pressures and metasomatic changes, and finally thrust upward along with the rest of the sequence of the NPHM.

At the eastern margin of the NPHM, west of the Stak river confluence with the Indus River, there occurs a melange zone of strongly deformed and boudinaged biotite-rich bands with highly altered mafic-ultramafic lenses (Fig. 1). The mafic-ultramafic lenses consist of amphibolite, garnet amphibolite, pyroxenite, serpentinite, and carbonate- and talc-bearing ultramafic rock. The biotite-rich matrix probably formed from a mudstone, whereas the mafic-ultramafic lenses probably represent carbonate enclaves or portions of carbonate interlayers incorporated within the muds, which were later metasomatized and metamorphosed to their present state. Microprobe analyses of clinopyroxene from one banded pyroxenite lens show almost pure diopsides, characteristically impoverished in TiO₂ (<0.03 wt.%) Al₂O₃ (0.3 wt.%), Na₂O (0.3 wt.%), Cr₂O₃ (nil) and NiO (<0.06 wt.%) and enriched in MnO (0.4-0.6 wt.%), MgO (15.55-16.44 wt.%), and CaO (23.72-24.46 wt.%). The low Cr and high Mn content of Mg-Ca rich diopsides may be a consequence of metasomatic metamorphism. An iron oxide (hematite or magnetite) analysis contains appreciable amount of TiO₂ (0.8 wt.%), Cr₂O₃ (0.4 wt.%), and Al₂O₃ (0.4 wt.%), whereas an ilmenite analysis contains 2.5 wt.% MgO and 0.5 wt.% Al₂O₃, (Table I). The absence of chromite, the presence of Fe-Ti oxides and the occurrence of carbonate in some lenses further supports the view that the rocks may have been chemically modified during metamorphism.

Key words: Petrology, layered ultramafics, NPHM.

K/475. Khattak, M.U.K., Shervais, J.W. & Stakes, D.S., 1996. Counter-Clockwise P-T-t paths in garnets from the Nanga Parbat-Haramosh Massif and the Ladakh island arc terrane, Northern Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 79.

High pressure, upper amphibolite facies metamorphic rocks of the Nanga Parbat-Haramosh Massif (NPHM) in northern Pakistan record the Tertiary metamorphism and dynamics of the Himalayan collision, and subsequent overthrusting of the Kohistan-Ladakh island arc terrane onto the Indo-Pakistan plate. At the time of collision, the Kohistan-Ladakh island arc may have formed the southern margin of the Asia, or may have formed a separate terrane. In our study area, the NPHM is separated from rocks of the Ladakh island arc by the Astak Fault Zone, a NNE-trending high-angle fault that forms the eastern margin of the NPHM.

Metamorphic rocks of the NPHM are represented by an intercalated sequence of para- and orthogneisses, with minor metabasics, calc-silicate rocks, and post-metamorphic pegmatite dikes. Garnets from two gt-bi-sill paragneisses in the NPHM are characterized by three distinct textural zones: (1) an inclusion-free core (2) an inclusion-filled intermediate zone, and (3) inclusion-free rims. These garnets are characterized by distinct chemical zoning profiles from core to rim (Figure 1). Equilibration temperatures for these garnets, calculated with the garnet-biotite geothermometer, are ~650°C in the inclusion-free core, ~725°C in the inclusion-filled intermediate zone, and ~500°C

in the inclusion-free rim. Garnets in a paragneiss adjacent to the Astak Fault Zone and the Ladakh arc terrane are inclusion-free throughout, and have nearly flat, unzoned chemical profiles. Equilibration temperatures for these annealed garnets are ~700-684°C. The dominance of relatively high equilibration temperatures in all of these garnets is confirmed by oxygen isotope partitioning studies, which show that most grant-quartz, feldspar-quartz, biotite-quartz mineral pairs equilibrated at ~700°C in the NPHM (Khattak, 1995).

The Ladakh arc terrane, east of the Astak Fault Zone, consists largely of meta-volcanic rocks, but also contains minor paragneiss horizons. Garnets found in gt-bi-sill paragneisses from the Ladakh arc terrane contains minor inclusions in the core but have inclusion-free rims. These show a sharp step-like change in chemistry at the boundary between core and rim (Figure 1), with relatively high temperatures in the inclusion-filled cores (~720-650°C) and lower temperature rims (~580°C).

The chemical zoning, P-T estimates, and the textural features of these garnets are interpreted as indicative of the tectonic history of the area. The flat chemical zoning indicates annealing (re-equilibration) of the garnets during or after the peak of upper amphibolite facies metamorphism. The occurrence of inclusion coincides with the preservation of the original growth zoning under dynamic, rapid growth conditions. The following tectonic history is proposed: (1) the inclusion-free core of the NPHM garnets may represent collision of the Indian plate with the Ladakh arc; (2) the higher temperature inclusion-filled intermediate zone in the NPHM garnets and the inclusion-filled core of the Ladakh garnets indicates growth during collision of the India-Ladakh package with the Asian plate; (3) the outermost inclusion-free zones in garnets from both the terrains probably formed during unroofing/cooling. Annealed garnets of the NPHM adjacent to the Astak Fault Zone probably reflect heating by hot base of the over-riding Ladakh arc.

Key words: Garnets, metamorphism, NPHM, Ladakh island arc, Himalaya.

K/476. Khattak, M.U.K. & Stakes, D.S., 1993. New data on the metamorphism of the Nanga Parbat-Haramosh massif, and the adjoining Ladakh island arc terrain, northern Pakistan. *Geological Bulletin, University of Peshawar* 26, 1-16.

The Nanga Parbat-Haramosh Massif in northern Pakistan records the Tertiary metamorphism and dynamics of the Himalayan collision and subsequent overthrusting of the Asian plate onto the Indian plate. The massif consists of an intercalated sequence of paragneisses derived from the Precambrian Salkhala series, of orthogneisses from Precambrian and early-Paleozoic granites, of minor metabasites and calc-silicate rocks, and of post-metamorphic pegmatite dikes. The adjacent part of the Ladakh arc consists of metasediments intruded by younger massive tonalites. The massif and the Ladakh arc are metamorphosed under high pressure, upper amphibolite facies condition. P – T estimates and P – T paths have been determined for the metapelitic samples from the massif and from the adjacent areas of the Ladakh arc along two cross-strike transects (Indus and Astore rivers) through the massif. Results show that the massif followed a compressional (counter-clockwise) and the Ladakh arc a decompressional (clockwise) P – T path, consistent with the tectonic history of the Himalaya of northern Pakistan.

Geothermobarometry on garnet-biotite and garnet-plagioclase pairs from pelites in the massif indicates that the rocks started their metamorphic history at ~ 5.5 kb and ~ 625°C. During collision, the pressure and temperature rose ~ 9kb and about 725°C. The Ladakh garnets started to grow at ~ 10 kb and ~725°C with subsequent decrease in metamorphic pressure and temperature to ~8.5 kb and ~650°C. After the collision, the massif and the adjacent areas equilibrated at ~ 8 kb and ~ 700°C.

Key words: Metamorphism, P-T data, NPHM, Himalaya.

Key words: Isotopes, NPHM.

K/478. Khattak, M.U.K., Stakes, D.S. & Shervais, J.W., 1995. P-T-t paths of garnets from the Nanga Parbat – Haramosh massif, the Kohistan and the Ladakh island arc terranes, northern Pakistan. *Geological Bulletin, University of Peshawar* 28, 97-108.

Metamorphic rocks of the Nanga Parbat-Haramosh Massif (NPHM) are represented by an intercalated sequence of para- and orthogneisses, with minor metabasites, calc-silicate rocks, and post-metamorphic pegmatite dikes. Garnets from two gar-bio-sill paragneisses in the NPHM are characterized by three distinct textural zones: (1) an inclusion-free core, (2) an inclusion-filled intermediate zone, and (3) inclusion-free rims. These garnets are characterized by distinct chemical zoning profiles from core to rim. Equilibration temperatures for these garnets, calculated with the garnet – biotite geothermometer, are ~ 650°C in the inclusion-free core, ~725°C in the inclusion-filled intermediate zone, and ~500°C in the inclusion-free rim. Garnets in a paragneiss adjacent to the Astak Fault Zone and the Ladakh arc terrane are inclusion-free throughout, and have nearly flat, unzoned chemical profiles. Equilibration temperature for these annealed garnets are ~ 700-684°C, with thin rims ~ 610°C. The dominance of relatively high equilibration temperature in all of these garnets is confirmed by oxygen isotope partitioning studies, which show that most garnet-quartz, feldspar-quartz, biotite-quartz mineral pairs equilibrated at ~700°C in the NPHM (Khattak, 1995).

The Ladakh arc terrane, east of the Astak Fault Zone, consists largely of meta-volcanic rocks, but also contains minor paragneiss horizons. Garnets found in gar-bio-sill paragneisses from the Ladakh arc terrane contains minor inclusions in the core but have inclusion-free rims. These show a sharp step-like change in chemistry at the boundary between core and rim, with relatively high temperature in the inclusion-filled cores (~ 720-650°C) and lower temperature rims (~580°C).

The chemical zoning, P-T estimates, and the textural features of these garnets are interpreted as indicative of the tectonic history of the area. The flat chemical zoning indicates annealing (re-equilibration) of the garnets during or after the peak of upper amphibolite facies metamorphism. The occurrence of inclusion coincides with the preservation of the original growth zoning under dynamic, rapid growth conditions. The following tectonic history is proposed: (1) the inclusion-free core of NPHM garnets may represent collision of the Indian plate with the Ladakh arc; (2) the higher temperature inclusion-filled intermediate zone is the NPHM garnets and the inclusion-filled core of the Ladakh garnets indicates growth during collision of the India-Ladakh package with the Asian plate; and (3) the outermost inclusion-free zones in garnets from both the terranes probably formed during unroofing /cooling. Annealed garnets of the NPHM adjacent to the Astak Fault Zone probably reflect heating by the hot base of the over-riding Ladakh arc.

Key words: P-T-t path, garnets, metamorphism, collision, NPHM.

K/479. Khattak, M.U.K., Stakes, D.S. & Shervais, J.W., 1997a. Metamorphism of the Nanga Parbat - Haramosh massif - I: Stable isotope thermometry. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 169-170.

The Nanga Parbat-Haramosh Massif in northern Pakistan represents the northernmost exposure of the Indian plate that have been metamorphosed in the Late Tertiary subsequent to the Himalayan collision and overthrusting of the Asian plate onto the Indian plate. The massif is a complex mixture of para- and orthogneisses, of minor metabasites and calc-silicate rocks, and of post-metamorphic pegmatite dikes. The 180 geothermometry results indicate that these gneisses are metamorphosed under peak temperatures of upper amphibolite to granulite facies conditions (< 700°C).

The 180 isotopic compositions of the rocks and their constituent minerals in the massif and adjacent areas of the Kohistan and Ladakh arc along the Indus and Astore Rivers varies as following (Table 1): whole rock $\delta^{18}\text{O}_{\text{SMOW}}=7.4-15.3\%$; quartz =7.4-16.4%; feldspar =7-16. 10/ac; garnet 5.3-13.7%; biotite =3.9-12.6%; muscovite =6.7-12.7%; and hornblende amphibole =4.4-7.256g. 180 thermometry results were calculated from 180 fractionations among quartz, garnet, feldspar, biotite, muscovite and amphibole. Fifteen of the sixteen fractionations of Qtz-Gar pairs (aQG) vary from 2.89Gm to 3.8% giving a range of temperatures from 764°C to 599°C respectively. The 1.00/ac variation in fractionation is greater than the expected error and thus indicates a real variation in the maximum temperatures. Among the analyzed minerals, the feldspars, which are isotopically least stable, indicate isotopic resetting during a later metamorphic event.

Key words: Thermometry, metamorphism, stable isotopes, NPHM, Indian plate.

K/480. Khattak, M.U.K., Stakes, D.S. & Shervais, J.W., 1997b. ^{18}O fractionation in feldspars from the Nanga Parbat-Haramosh massif, Northern Pakistan. Geological Bulletin, University of Peshawar 30, 219-225.

The Nanga Parbat-Haramosh Massif in northern Pakistan represents the northernmost exposure of the Indian plate that has been juxtaposed against the Kohistan-Ladakh island arc along Raikot-Sassi and Astak faults. The massif is a complex mixture of paragneisses, orthogneisses, minor metabasics, calc-silicate rocks, and post-metamorphic pegmatite dikes. These gneisses are metamorphosed under high pressure upper amphibolite facies conditions (5.5-10 kb, 650-750°C; Khattak, 1990).

The ^{18}O SMOW isotopic compositions of the rocks and their constituent minerals in the massif and adjacent areas of the Kohistan-Ladakh arc along the Indus and Astore Rivers varies as following: whole rock $\delta^{18}\text{O}$ SMOW = 7-15.3‰; quartz = 7.4-16.4‰; feldspar = 7-16.1‰; garnet = 5.3-13.7‰; biotite = 3.9-12.6‰; muscovite = 6.7-12.7‰; and hornblende amphibole = 4.4-7.2‰ (Khattak, 1994). Feldspars isotopic compositions show maximum scatter indicating refractory nature of the minerals. ^{18}O thermometry results based on coexisting quartz-feldspar fractionation curves show disequilibrium in some of the samples. Calculation of the ^{18}O composition of fluids that were in equilibrium with different minerals in the temperature range of 500-700°C reveals that there is one pre-metamorphic and one post-metamorphic fluid activity affecting the isotopic composition of the rocks of the massif. The pre-metamorphic fluids probably originated from an igneous parent, depleting the rocks in -2‰, especially along the major faults. The post-metamorphic fluids probably originated from prograde metamorphic reactions and were heavy enough to enrich the feldspars up to ~1.8‰. Retrograde paths indicate that the massif was probably quick in its upward flight from depths of around 35 kms as shown by pressure estimates of Khattak and Stakes (1993).

Key words: ^{18}O fractionation, feldspar, metamorphism, NPHM.

K/481. Khattak, M.U.K., Stakes, D.S., Shervais, J.W., Arif, M. & Shah, M.T., 1995. Stable isotope thermometry of the Nanga Parbat-Haramosh Massif and the Kohistan-Ladakh arc, northern Pakistan. *Geological Bulletin, University Peshawar* 28, 109-126.

The Nanga Parbat-Haramosh Massif in northern Pakistan represents the northernmost exposure of the Indian plate that have been metamorphosed in the Late Tertiary subsequent to the Himalayan collision and overthrusting of the Asian plate onto the Indian plate. The massif a complex mixture of para- and orthogneisses, of minor metabasics and calc-silicate rocks and of post-metamorphic pegmatite dikes. The ^{18}O geothermometry results indicate that these gneisses are metamorphosed under peak temperature of 700°C.

The ^{18}O isotope compositions of the rocks and their constituent minerals in the massif and adjacent areas of the Kohistan and Ladakh arc along the Indus and Astor Rivers vary as following: whole rock $\delta^{18}\text{O}$ SMOW = 7-15.3‰; quartz = 7.4-16.4‰; feldspar = 7-16.1‰; garnet = 5.3-13.7‰; biotite = 3.9-12.6‰; muscovite = 6.7-12.7‰; and hornblende amphibole = 4.4-7.2‰. The majority of the mineral δ -values follow the "normal" sequence. ^{18}O thermometry results were calculated from ^{18}O fractionations among quartz, garnet, feldspar, biotite, muscovite and amphibole. Fifteen of the sixteen fractionations of Qtz-Gar-pairs (α_{QG}) vary from 2.8 ‰ to 3.8 ‰ giving a range of temperature from 764°C respectively. The 1.0- ‰ variation in fractionations is greater than the expected error and thus indicates a real variation in the maximum temperatures. Among the analyzed minerals, the feldspar, which are isotopically least stable, indicate isotopic resetting during a later event.

K/482. Khattak, N.U., Qureshi, A.A., Akram, M., Hussain, S.S. & Mehmood, K., 2001. Classification and petrogenesis of the Loe-Shilman carbonatite complex Khyber Agency, North West Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.4.

The Loe-Shilman Carbonatite Complex is the western extension of a 200 km long belt of alkaline rocks. The alkaline belt is situated on the northern side of the Peshawar Plain in an arcuate fashion. It consists of sills-like bodies of carbonatite and related alkaline rocks. These sill-like bodies have been emplaced along a fault zone in metasedimentary rocks of Palaeozoic to Precambrian age.

Using petrographic techniques the sedimentary and metasedimentary carbonate country rocks of the Loe-Shilman carbonatite were classified as dolomite and dolomitic limestone, while the carbonatites were classified into (a) calcite-carbonatites and (b) dolomite-carbonatites. The carbonatites were also classified into (a) calcio-carbonatites, (b) magnesio-carbonatites and (c) ferro-carbonatites on the basis of geochemical data. Field relationships, petrography and geochemical data indicate that the carbonatite magma originated by direct melting of the partly carbonated, metasomatized mantle peridotites. Calcite-carbonatite, the most widespread variety of the carbonatites

in the complex, appears to represent the first phase of carbonatitic magmatic activity, followed by dolomite (and ferroan dolomite)-carbonatite as a separate intrusion. Fission track dating on apatite crystals indicates that emplacement of the carbonatites took place prior to about 20 Ma, probably in the Oligocene (31 ± 2 Ma).

K/483. Khattak, N.U., Qureshi, A.A., Hussain, S.S., Akram, M., Mehmood, K. & Khan, H.A., 1998. Emplacement time and tectono metamorphic history of the Sillai Patti granite gneiss using fission track dating technique. *The Nucleus* 35, 159-162.

The Peshawar Plain Alkaline Igneous Province (PAIP) consist of a group of alkaline rocks. It occurs in the north of Peshawar from Tarbela in the east through Koga-Ambela, Shewa-Shahbazgarhi, Malakand, Sillai Patti, and Warsak up to Loe Shilman in the west. The alkaline rocks mainly consist of granites, syenites, gabbros, ijolites, carbonatites etc. The granitic rocks cover a major part of the Alkaline Province. This paper presents an account of fission track age data on zircon as a paleotemperature indicator, recognition of the emplacement time and tectonic uplift history of the Sillai Patti Granite Gneiss in combination with the other radiometric ages. The field relationships show that the Malakand Granite and Sillai Patti Carbonatites are younger than the Sillai Patti Granite Gneiss. However, our fission track age of the Sillai Patti Granite Gneiss is less than absolute ages of Malakand granite (U - Pb age approx. equal to 270 Ma) and Sillai Patti Carbonatite (K - Ar age approx. equal to 31 ± 2.00 Ma). Therefore, the fission track age of 24.32 ± 2.80 Ma on zircon from Sillai Patti Granite Gneiss, based on present work, represents a time of post metamorphic uplift history of the area, when these rocks pass through the 210 deg. C isotherm, corresponding to depth of about 6.7 km inside the earth crust from their present position

The project area has been mapped on 1:9000 scale and covers about 20 miles². Stratigraphic units from Dogra Slates to Siwalik Group have been identified studied and described. Micropaleontological identification reveals the presence of 18 species of foraminefera. Some invertebrate fossil encountered has also been recorded. It has been noted that unlike Hazara the unconformity has enlarged to bring Paleocene rocks in contact with Cambrian rocks. In this process some of the Lower Paleocene rocks are also absent with the result a new unit representing unconformity has been introduced. On the structural side, Main Boundary Thrust has been noticed passing through the southwestern part of the area. On the economic side minerals like fireclay, bauxite, soapstone, dolomite and coal have been recorded.

K/487. Khizr, K.M., 1979-81. Geology of Sawni Sheringal Area, Dir District, NWFP. M.Sc. Thesis, Punjab University, Lahore, 92p.

Sawni-Sheringal area is mainly composed of metamorphic rocks of sedimentary origin, with igneous intrusions. The main rock units in the area are calcareous quartzites, chlorite schists, biotite schists and amphibolites.

Calcareous quartzites are believed to be the oldest rock unit of the area. Chlorite schists, biotite schistose and amphibolites have formed as a result of progressive regional metamorphism of calcareous quartzites. The contacts of calcareous quartzites with the schistose and the contacts between chlorite and biotite schistose are gradational. Amphibolites are developed as formless patches in the schistose.

The area is tectonically highly disturbed being involved in Himalayan Orogeny. The report presents a detailed geological and petrological investigation of about 40-km² area. A detailed map of the investigated area on a scale of 1:10,000 are presented, along with its cross-section along X-Y line. Succession of Rocks of the area has been worked out. Detailed petrography of all the major units of the area is described. Petrogenesis of the rocks of the area is interpreted. Major and minor structures of the area are discussed in brief. Economic minerals found in the area are listed.

K/489. Khurshid, A., Yeilding, G., Ahmad, S., Davidson, I., Jackson, J.A., King, G.C.P. & Zuo, L.B., 1984. The seismicity of northernmost Pakistan. *Tectonophysics*, 109, 209–226.

A portable seismic network was operated in the Karakoram area of northern Pakistan for over two months during the summer of 1980. The principal objectives were to record possible subcrustal earthquakes beneath the Karakoram Range, and to monitor crustal activity throughout northernmost Pakistan. We confirm the existence of intermediate-depth seismicity (at a depth of about 140 km) beneath the Karakoram Mountains. Shallow crustal activity also occurs in the Karakoram Range, with events recorded from near the northwest end of the Karakoram Fault and near a number of smaller lineaments in Baltistan. Seismicity in Kohistan appears to be largely confined to the upper crust, though occasional earthquakes at 65 km depth (approximately the base of the crust) occur beneath areas of higher topography (Nanga Parbat, Rakaposhi). An area close to the Hamran (1972) and Darel (1981) earthquakes showed intense activity in the depth range 0–25 km, similar to that involved in the mainshocks themselves. Focal mechanisms for events in this area show thrusting on NW-trending planes, indicating NE-SW compression.

A belt of Siluro-Devonian limestone and quartzite, pink or yellowish-pink in color is exposed on either side of the Nowshera-Risalpur road. This belt was identified as a 'Reef Complex' in 1965, and is the first of its kind to be discovered in the Indo-Pak sub-continent. Prior to this discovery, the limestone belt had been erroneously assigned a Precambrian age and regarded as part of the Attock Slates.

The entire belt unconformably overlies the Kandar Phyllite and is divisible into four definite units: 1. Carbonate Rocks, 2. Reef Core, 3. Reef Breccia, and 4. The Misri Banda Quartzite. The first three collectively are known as the

Nowshera Formation. With the exception of the last, these units represent the characteristics structural layers of a reef.

The age of the reef complex on the basis of its fossil assemblage ranges between Upper Silurian and Devonian. However, there is no fossil present which may pinpoint an exact age. The uncertainty about the precise age of the reef is largely due to the destruction of many organisms by the process of dolomitization. In the opinion of the writers, the Nowshera Formation and the Misri Banda Quartzite were deposited in the southernmost extremities of the basin in which the Muth Quartzite, of Siluro-Devonian age, was formed. In their opinion, the Nowshera formation and the Misri Banda Quartzite, can be correlated with the middle and upper parts of the Muth Quartzite.

Rocks of Fatehpur Shin area (Lower Swat) are part of metamorphic hornblende complex. The area lies within the Southern portion of Lower Swat. These rocks are probably the extensions of rocks of Dir in the form of belt running approximately in East-West direction. The area given fieldwork comprises 30 miles in the North-West of Saidu Sharif. The area mainly comprises the main rock units are amphibolite, Norite, Diorite, Quartz-O-feldspar and pegmatite veins. Amphibolites have been metamorphosed basic rocks probably Norite gabbro. As the field evidences, and the laboratory study shows that the amphibolites were formed from basic magma, which has undergone regional metamorphism under the intense orogenic conditions. Quartz-O-feldspathic and pegmatite veins are extensively distributed all over the area indicating the evidence of Diorite magma. Major minerals are plagioclase, Hornblende, epidote and quartz with accessories as sphene and magnetite. These are products of regionally metamorphosed igneous rocks.

K/496. Kick, W., 1956. Chogo Lungma Glacier, Karakoram. Geographical Journal 122, 93-96.

I was expecting in the autumn of 1954 to accompany as topographer the expedition of Dr. K. Herrligkoffer, which had for its objective Broad Peak in the upper Baltoro region. But during the summer months of that year the scientists of Professor Desio's successful K2 expedition had been at work on the Baltoro glacier, and I decided to go to another region of the Karakoram. I chose the Chogo Lungma glacier, which had only once before been investigated, and that half a century ago.

Although it is one of the very big valley-glaciers, Chogo Lungma is not situated in the zone of the main crest, but southwards at the bifurcation of the Rakaposhi and Haramosh ranges in the Lesser Karakoram. From Skardu on the Indus, it self only four days by air from Europe, the valley can now be reached by a further four days journey. The

ease and relatively low cost of access may promote more activity by mountaineers and scientists in this region: last summer a Frankfort Himalayan Expedition went to Chogo Lungma, accompanied by the meteorologist Dr. Untersteiner.

Easy access was also the reason that this glacier was the first of all the big Karakoram glaciers to be discovered by a European, G. T. Vigne in 1835. He found the lower end "a short distance from the village Arindu," the height of the ice wall there being nearly 100 feet. The next explorer was Godwin Austen in 1861 who wrote from the small village of "Arundu at its (the 'Chogo Loombah's) termination, its fields touching the ice." As these statements are still roughly accurate, it would seem that the length of the Chogo Lungma has not changed much during the last 120 years.

However, although the glacier may not have changed much in its length, the thickness of the ice has varied greatly at different times. Godwin Austen carried out the first plane-table survey of this area in the space of only two days. But the result, a part of his "Sketch map of the glaciers of the Mustakh Range" on a scale of 1 / 506,880 (1 inch = 8 miles), shows the form of "Chogo Ganse" much better than the map on 1 / 150,000 of the Workman expedition of 1903. This second map was based on a "theodolite survey by B. H. Hewett, corrected and supplemented by the authors (Fanny B. and William H. Workman) from actual observation and photographs." They supposed, erroneously, that the given highest intersected point "Indus-Nagar-Watershed-Peak No.2" (= Peak 46/42L = Malubiting) was fixed wrong during the Kashmir triangulation, as they thought Pyramid Peak, which they had almost climbed to the top, was at least 300 feet higher than Malubiting. Meanwhile, during the triangulation of the Indo-Russian Connection Series in 1912/13 Malubiting (24,470 feet) was checked and found correct and a new point was intersected: this was Peak 68/42L (23,056 feet) for which the Karakoram Conference Report suggests the name Yengutz Har, because of the glacier with this name on the northern side. The peak which the Workman tried to climb is really Yengutz Har. Oestreich had already made this suggestion, and last year's triangulation confirmed it. The Workmans' mistake was quite understandable; it is very easy to be wildly out when comparing the height of peaks without instruments. In fact "Pyramid" is 1400 feet lower than Malubiting, not 300 feet higher. Indeed many sketch-maps of this region are wrong, some even make 2 Siebentauser (peaks over 7000 metres or about 23,000 feet) out of one, partly as a result of the many names existing for this mountain: Yenguta Har or Pyramid is the same as "Ghenish Chish" (Burushaski for "Gold Mountain") of the official quarter-inch map, and is the top of the ridge shown on Conway's map (1894) as the Golden Parri. The people of Arandu showed me the same peak as "Spantik," probably because of a highest single spot with grass at the foot of the south-eastern ridge of it (in Balti, spang = meadow, grass, tik = spot).

K/515. Kidd, W.S., Edwards, M.A., Schneider, D.A. & Khan, M.A., 2001. New geological map of the Nanga Parbat-Haramosh massif. Journal of Asian Earth Sciences 19, p.36.

We present a newly compiled detailed geological map (1:100 000 scale) of the Nanga Parbat±Haramosh massif based on our field work during the 1995-8 continental dynamics collaborative project, building from previous work by others (references on the map, and below), and supplemented by interpretation from an excellent cloud-free Landsat thematic mapper image taken in October 1995. Major geological features relevant to the young rapid uplift and denudation of the NPHM include the Raikhot fault and its precursor shear zone, first identified by Madin (1986), which is the main structure developed by the W- to WNW- directed thrusting and exhumation of the NPHM over the past 5±10 Ma. Our work has extended the identification and location of this fault and shear zone from Raikhot Bridge to the southwest through the Diamir valley, and shown the coincidence of this zone with the young Jalhari granite from the Diamir valley southwards (Edwards et al., 2000). Our work also documents the extent and shear sense of ductile shear associated with the Diamir± Raikhot shear zone (DRSZ) and distinguishes older ductile shear and mylonite zones, originally developed by S- to SW-directed thrusting, and some subsequent N-directed low angle normal sense motion, during the earlier 'Himalayan' events. The map also documents that the eastern NPHM-Kohistan contact is in most places only folded by the NPHM event, with local young faults in this zone being much

less abundant and not a continuous 36 Abstracts: 16th Himalaya-Karakorum-Tibet Workshop, Austria Fig. 1. N MORB-normalized spider diagram for the Waziristan dykes (after Pearce, 1983). Fig. 2. Primordial mantle-normalized spider diagram for the Waziristan dykes (after Wood et al., 1979) zone, unlike the Raikhot fault on the western margin. Our mapping shows that there is significant E- to NE- directed, mainly ductile displacement on the eastern margin of the main antiform of the Nanga Parbat part of the NPHM, expressed by a wide S/C ductile shear zone in the Chhichi and central Rupal valleys, which continues northwards as a narrower tightly pinched synclinal/shear zone structure at least to Shengus village in the Indus gorge (Schneider et al., 1999b). This Rupal±Chhichi shear zone (RCSZ) and its northward continuation is well within the NPHM, and does not directly affect the eastern NPHM-Kohistan contact. Some younger brittle faulting is associated with this zone in the Rupal valley, but it is not nearly as prominent as that associated with and defining the Raikhot fault on the western margin of the massif. The RCSZ forms the secondary part of a crustal-scale popup structure conjugate to the DRSZ and Raikhot fault. Besides the quaternary fault along surface trace of the Raikhot fault, some other active fault traces are developed in the Kohistan block to the west, up to as much as 15 km from the Raikhot fault. The map includes the newly discovered Himalayan leucogranite of Miocene age in southernmost Chhichi Nullah (Schneider et al., 1999a).

K/516. Kidwai, A.H. & Immam, A., 1958. Magnetite deposits of Dammer Nissar, Chitral state, West Pakistan geological Survey of Pakistan, Information Release 7.

Large bodes of magnetite are present three to four miles southeast of Dammer Nissar, Chitral state. The magnetite is massive, it is found in lenses ranging from 20 to 425 in length and from 5 and 75 feet in width.

A total reserve of 3.7 million tons of magnetite ore has been calculated on the basis of dimensions measured on the surface and on estimated extensions of ore to depths averaging 150 feet below outcrops of individual lenses.

The grade of the ore in general is high; near the contacts of the ore bodies iron content ranges from 45 to 55 per cent whereas main bodies contain 55 to 65 per cent. An alternate route of ore transport through Afghan territory is suggested.

Key words: Magnetite, Dammer Nissar, Chitral.

K/517. King, B.H., 1961. A new fossil locality in Swat. Geological Bulletin, Punjab University 1, p. 65.

The author has been engaged on the detailed mapping of the granitic gneisses, schists, amphibolites, and marbles of the Lower Swat Valley and adjoining area of Buner. It was *in* this latter area that, in November 1960, fossil remains were discovered in two outcrops on Nikanai (one of the two synclinal island mountain masses which rise abruptly from the Buner Plain) near the village of Tursak (34°31'; 72°22'). This is the first known .discovery of fossils in the crystallines of the region. The .fossils occur in the marbles which are wholly crystalline, usually well bedded, and with bluish-grey and white bands. Some parts, however, are more massive and bedding is obscure, or absent; here the marble tends to be lenticular in form, although often several hundred feet thick and up to one mile in length.

The fossils were found at the following two localities:-

1. on the crest of the spur directly above Tursak (43 B/6 grid 373533). They occur in several discontinuous bands which conform to the bedding of the well bedded marbles. Most of the fossils are highly distorted and only identifiable as such when referred to the few less distorted specimens.

Three types can be recognized;

(a) A small low-spined gastropod up to 1 cm. in diameter.

(b) A small pelecypod up to 2 cm. in diameter, with an oval valve.

(c) A larger pelecypod up to 10 cm. in diameter, with a more symmetrical valve than (b).

2. Just north of the summit of Nikanai (43 B/6 grid 346548). The fossils are less distorted than at the first outcrop, and are seen on a relatively small weathered surface. They display a coralline type of structure.

Thin sections of the collected material show only a mosaic of calcite crystals of two grain sizes and 110 internal structures, although the main outlines are fairly clear. No identification, even on a generic level, can be made of the available specimens. Therefore, it is only possible to put a very questionable Upper Palaeozoic (or possibly younger) age to the rocks. The evidence does, however, show that their age is not Pre-Cambrian, as had been generally assumed, previously.

Plate tectonics has successfully explained the behaviour of the major ocean Basins. However, it has proved to be less successful in describing the processes of continental collision and its associated deformation. Seismic studies proved crucial in providing information on which plate tectonics was established. Recent developments in the study of seismic signals recorded on distant instruments and on portable seismographs temporarily installed in the Alpine-Himalayan belt are beginning to reveal the relation between extension, sedimentation, compression and major strike slip faulting such as the Karakoram fault.

K/525. Klootwijk, C.T. & Conaghan, P.J., 1979. The extent of greater India, 1. preliminary palaeomagnetic data from the Upper Devonian of the Eastern Hindukush, Chitral (Pakistan). *Earth and Planetary Science Letters* 42, 167-182.

Samples of Upper Devonian sedimentary ironstones from the eastern Hindukush, Chitral (Pakistan), give a characteristic palaeomagnetic direction: declination $D = 318^\circ$, inclination $I = -6.5^\circ$; believed to represent the primary magnetization direction. The samples come from an area which lies north of a major ophiolite zone that recent workers suggest is the southwestern continuation of the Indus Suture. As the present palaeomagnetic results are in fair agreement with palaeomagnetic data from the Siberian platform but not with data from Gondwanaland they can be taken as additional evidence that this suture does indeed constitute the main collision zone between the Gondwanic Indian subcontinent and Asia. The palaeomagnetic data presented here from the Devonian of Chitral suggests additionally: (1) in excess of 100° of counterclockwise rotation of the area, associated most likely with the formation of the regional Hindukush-Pamir-Karakoram syntaxial bend; (2) more than 2000 km of crustal shortening between Chitral and the Siberian platform due to the northward indentation of the Indian Gondwanaland fragment subsequent to collision.

Key words: Paleomagnetism, Devonian, Hindukush, Chitral.

K/526. Klootwijk, C.T., Conaghan, P.J., Nazirullah, R. & DeJong, K.A., 1994. Further paleomagnetic data from Chitral (Eastern Hindu Kush): Evidence for an early India Asia contact. *Tectonophysics*, 237, 1–25.

The Eastern Hindukush forms part of an elongate belt ("Central Domain", collage of Cimmerian microcontinents) that encircles the northern part of the Indian subcontinent. A Gondwanan origin is commonly assumed for this belt, but a "Laurasian" origin for the Chitral region has been argued on palaeontological (Talent and Mawson, 1979) and palaeomagnetic (Klootwijk and Conaghan, 1979) grounds. The "Laurasian" view was based on a pilot study we undertook of Upper Devonian pisolitic ironstones from a thrust sheet at Kurāgh Spur in Chitral. Preliminary results showed a characteristic magnetization component [$D = 318^\circ$, $I = -6.5^\circ$, $N = 7$ (block samples), $k = 14$, $\alpha_{95} = 16.5^\circ$] indicating an equatorial palaeoposition. This component was thought to be of primary origin and was interpreted in terms of a Late Devonian "Laurasian" affinity of the Kurāgh Spur rocks. This controversial conclusion has been tested in the present more comprehensive study of the thrust pile of sedimentary rocks in the Reshūn-Kurāgh-Būni region of Chitral and the primary origin of the characteristic magnetization component refuted. Thermal demagnetization of 333 block samples from Middle to Upper Devonian variegated sediments, Permian quartz flysch, Permo-Triassic carbonates, and mid-Cretaceous redbeds showed two interpretable components. A softer component of recent origin (A); and a harder characteristic component (B) of both normal and reverse polarity whose mean direction [$D = 314.1^\circ$, $I = 6.0^\circ$, $N = 4$ (thrust sheets), $k = 198.2$, $\alpha_{95} = 6.5^\circ$] is comparable to the characteristic component observed in our preliminary study. However, the universal presence of this component throughout the thrust pile proves its overprint origin, which we attribute to initial India-Asia contact. Palaeomagnetic information pertinent to the controversy of a "Laurasian" versus a Gondwanan origin of the Chitral region has not been obtained in this further study because primary magnetizations could not be identified beyond doubt. Hence, we retract herewith our original conclusion of a Late Devonian "Laurasian" affinity of the Chitral region on the basis of the palaeomagnetic evidence. The secondary component (B) comprises a suite of secondary magnetizations, acquired at equatorial-to-low-northern palaeolatitudes, and is attributed to initial contact between Greater India and southern Asia. Component B has been observed previously in the Himalayan-Tibetan region, both north and south of the Indus-Tsangpo Suture zone. Identification is herein extended to the Hindukush region north of the Northern Kohistan (or Shyok) Suture zone, which is a western continuation of the Indus-Tsangpo Suture. Comparison of this suite of collision-attributed equatorial palaeolatitude data from the India-Asia convergence zone with new palaeolatitude constraints from the Ninetyeast Ridge on the northward movement of the Indian plate, constrained additionally by a recent minimal estimate of the palaeogeographic northern extent of Greater India, indicates that initial contact between northwestern Greater India and southern Asia was established at, or before, the Cretaceous-Tertiary boundary. The overprint origin of component B at about this time is further supported by observations by Zeitler (1985) on rocks from the sampled area in Chitral of partially reset zircon fission-track ages around 68-55 Ma. The NW-SE declination axis of component B indicates a $60-70^\circ$ counterclockwise rotation of the sampled thrust pile with respect to Eurasia and a counterclockwise rotation between 10 and 30° with respect to India. Some of the

recent field components (A) show a comparable rotation and indicate that the tectonic activity that led to the formation of the Hindukush-Pamir-Karakorum syntaxial zone has continued into recent times.

K/527. Kneneu, Ph.H., 1929. Petrographic description of the rock from the Hunza valley in the Karakorum. *Leidsce Geologie Mededeelingen* 3.

During his second Karakoram expedition in 1925 Mr. Ph. C. Visser collected some 70 rock specimens from the valley of the Hunza and its tributaries. The following is a petrographic description of these specimens and I gladly take this opportunity of thanking Mr. Visser for entrusting me with his valuable material. Geologists are much indebted to this energetic explorer for bringing together such a considerable number of samples under circumstances in which all carriage had to be reduced to a minimum and when so many other calls were being made on his time and energy. A collection made by a layman and therefore taken without many observations on mode of occurrence, must naturally be of limited value. When, however, it concerns a region that is almost terra incognita from a geological as well as from a geographical point of view, it may serve to give us an insight into the more salient features, especially petrographic and to some extent structural as well, and therefore constitute an important contribution to geological knowledge. Geologists will all hope that Mr. Visser will soon be in a position to add to the collections he has already made.

K/533. Kojima, J., 1965. Metamorphic and plutonic rocks of the Karakorum and Hindu Kush. In: *Geology of the Karakorum and Hindu Kush. Results of the Kyoto University Science. Exped. 1955*, VII, 93-119.

The specimens of metamorphic and plutonic rocks collected through the Japanese Expeditions of 1955, 1956 and 1957 have been studied petrographically. The results for 250 samples from Swat, Ghizar, Yasin, Ishkuman, lower

Hunza, Indus gorge east of NPHM and Braldu are listed in a useful and informative petrographic table in the Appendix. The principal rock types include acid to intermediate plutonic rocks, gneiss, basic igneous rocks, impure calcareous rocks, calcareous rocks, siliceous rocks, and psammitic and politic rocks. Based on petrography, the charts showing the metamorphic facies, type of anatexis, preservation of basement crystalline rocks in the area concerned have been constructed. From these charts the zonal arrangement of the terrains with different characters in the NW-Karakoram and East Hindu Kush, together with the northern extension of the Nanga Parbat gneiss dome, has been discussed. The distribution and the petrographic characteristics of the plutonic rocks show intimate relationship with the geotectonic division of the basement. The Nanga Parbat basement is considered to have passed through polymetamorphism.

K/535. Kordos, L., 1997. A comparative environmental and hominoid history in the Neogene of Carpathian basin and Siwalik. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, p.56.

Both Carpathian Basin and Siwalik region rich in Late Miocene Hominoid remains and have a great importance on the early phase of human evolution. The range of Hominoids in the Carpathian Basin 15-9 Ma, and in the Siwalik 12-7 Ma.

At the same time significant global and local environmental changes happened in the two areas, a transition from wet tropical-subtropical to dry temperate climate. However, the Late Miocene geological history of Carpathian Basin and Siwalik region are basically different. During the Early and Middle Miocene the Carpathian Basin was a member of the Paratethys (Central Paratethys) and separated as a large lake system (Pannonian Lake) during the early Late Miocene (11-10 Ma). The Pannonian lake and swamp gradually disappeared until the Mio-Pliocene boundary. The large body of water caused a long, generally warm and wet permanent environment. During this process the palynological data are showing two cooling periods during the Late Neogene. First is between 11 and 10 Ma, and the second between 8 and 7 Ma. Carbon isotopic analyses of 10 Ma old sediment of Rudabanya Hominoid site indicate purely C3 ecosystem. These climatic and ecological data are showing similar global environmental events at 7-8 Ma, both in Kenya, in Pakistan, and in the Carpathian Basin.

Comparative palaeoecology of Neogene terrestrial mammal faunas of the Carpathian Basin generally support previous analyses and help to answer one of the most interesting question, why Hominoids disappeared during Late Miocene from Eurasia?

In the Tien Shan, Pamir and Karakorum the southward migration of the mobile belts reflects the growth of the Eurasian continent during the Phanerozoic. Geosynclinal development in the mobile belts began with rifting and drifting of Pre-Baikalian continental crust during five periods: 1) in the Middle Tien Shan during the Proterozoic (Pre-Late Rifean); 2) in the North Tien Shan during the Late Proterozoic-Early Cambrian; 3) in the South Tien Shan during the Cambrian-Early Carboniferous; 4) in South Ghissar and North Pamir during the Early Carboniferous; and 5) during the Early Carboniferous-Triassic in Central and Southeast Pamir. The Caledonian orogeny occurred in the North Tien Shan, the Hercynian orogeny in the Middle Tien Shan, South Tien Shan, South Ghissar and North Pamir, and the Alpine orogeny during the Mesozoic and the Cenozoic in Central and Southeast Pamir and the Karakorum. The latest orogenic phase, which began in the Late Oligocene, is very widespread and is the result of the collision between the Eurasian and Indian plates.

New $^{40}\text{Ar}/^{39}\text{Ar}$ and U-Pb mineral ages from plutonic rocks help constrain the thermal and tectonic evolution of the Kohistan island arc terrane following its collision with India in early Tertiary time. Kohistan has experienced a prolonged tectonomagmatic history extending from the Early Cretaceous through the Tertiary. Thermal histories derived from multi diffusion domain analyses of K-feldspar within the Kohistan batholith reveal rapid cooling events (70–140°C/m.y.) distributed through space and time. The cooling histories show a systematic variation along the length of the batholith suggesting that Kohistan experienced differential unroofing. An episode of rapid cooling in the middle Eocene is recognized in western Kohistan, whereas rapid cooling occurs substantially later, during the middle and late Miocene, in eastern Kohistan. Rapid cooling in western Kohistan might have been caused by postemplacement cooling of hot magma against cold country rocks at relatively shallow crustal levels. Within the NW region of eastern Kohistan, rapid cooling at 13–12 Ma is recorded in K-feldspars ~60 km from the contact with

the Nanga Parbat-Haramosh Massif (NPHM), whereas cooling does not occur until 11 Ma only 2.5 km from the contact. This temporal and spatial variation in cooling histories may record differential unroofing in response to the development and propagation of the NPHM structure beneath Kohistan. The NPHM has experienced rapid cooling and unroofing over the last 10 m.y., and our results are consistent with this mid-late Miocene event.

Key words: Tectonics, Kohistan batholith.

K/544. Krol, M.A., Zeitler, P.K., Poupeau, G. & Pecher, A., 1996. Temporal variations in the cooling and denudation history of the Hunza plutonic complex, Karakoram Batholith, revealed by $^{40}\text{Ar}/^{39}\text{Ar}$ thermochronology. *Tectonics*, 15 (2), 403–415.

The $^{40}\text{Ar}/^{39}\text{Ar}$ thermochronology of the Late Cretaceous Hunza plutonic complex reveals an episodic cooling and denudation history for this regional-scale pluton. The $^{40}\text{Ar}/^{39}\text{Ar}$ analyses of biotites from a vertical relief section of >3200 m reveal a pulse of rapid cooling at ~20 Ma. In the interval of 110–27 Ma, age-elevation distributions suggest denudation rates of the order of 0.02 ± 0.003 mm/yr. At ~20 Ma, denudation rates increased significantly to 2.7 ± 0.7 mm/yr, then returned to much slower rates until 12 Ma. A second pulse of rapid cooling beginning at 12 Ma is revealed by inverse numerical modeling of multidiffusion domain alkali feldspars from a vertical section of 1700 m. Decreasing in elevation, these samples record the onset of rapid cooling at 12, 9, and 7 Ma, respectively. All of the alkali feldspars record a period of nearly isothermal conditions prior to the onset of rapid cooling when rates increased to $30^\circ\text{C}/\text{m.y.}$ Assuming a geothermal gradient of $30^\circ\text{C}/\text{km}$, these cooling rates translate into denudation rates of 1.0 mm/yr. Apatite fission track analysis indicates denudation rates of 0.7 ± 0.1 mm/yr over the interval of 6.6 Ma to 2.4 Ma in agreement with the alkali feldspar data. These data suggest denudation of 2.9 ± 0.4 km since the Plio-Pleistocene. Together, the alkali feldspar and apatite data indicate that a minimum of 10 km of overburden has been removed since the mid-late Miocene.

This account gives details of the water resources of NWFP. It comprises 1. Introduction, 2. Hydrogeology, 3. Groundwater behaviour, 4. Groundwater investigations, 5. Groundwater development, 6. Groundwater development potential, 7. Groundwater management: a look ahead, 8. The regional groundwater resources, which include 9. the intermontane basins of Dir, Swat and Chitral districts, 10. The left bank areas, 11. the intermontane basins of Peshawar and Mardan districts, 12. the intermontane basins of Kohat and Karak districts, 13. the Bannu basin, 14. The Dera Ismail Khan district, and 15. Groundwater in the Federally Administered Tribal Areas. At the end, references and glossary are given. The document is supported by 32 tables and 88 figures.

Key words: Groundwater, hydrogeology NWFP.

K/546. Kubo, K., Khan, T., Kausar, A.B., Sawada, Y., Takahashi, Y. & Takahashi, Y., 1998. Origin of ultramafic-felsic association in the Chilas Igneous Complex, Kohistan Arc, North Pakistan. Exotic block derived from oceanic crust. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 107-108.

The Chilas Igneous Complex is one of the major geologic units in the Kohistan Arc region, located in the western Himalaya of northern Pakistan. It is a huge gabbroic body, 300 km long, intruding the Kamila amphibolites which occur widely in the southern half of the Kohistan Arc region. The Chilas Igneous Complex is composed mainly of gabbro-norite with minor two-pyroxene quartz diorite and two pyroxene granodiorite. The complex contains several small xenolithic bodies of ultramafic-felsic association (UFA), layered two pyroxene gabbro and amphibolites. The layered two pyroxene gabbro is the cumulus facies of the gabbro-norite (Kubo et al., 1997).

Within the Chilas Igneous Complex, several bodies of UFA exist. Of these, the body cropping out along the Karakoram Highway (KKH) to the east of Chilas village (named as Thak body) is described in detail. The Thak body extends 2.8 km along the KKH, enclosed and intruded by gabbro-norite of Chilas Igneous Complex. The Thak body consists of cyclic units of layered cumulate rocks. The layered rock units are younging from west to east

throughout the body. The cumulates are classified into olivine cumulate and pyroxene-dominant cumulate. Olivine- dominant cumulate consists mainly of olivine cumulate (dunite), associated with minor amount of olivine-clinopyroxene cumulate (wehrlite). It occurs as 10 to 400 m thick layers, alternating with thin layers of plagioclase dominant cumulate. Plagioclase-dominant cumulate occurs as layers several meters to several tens of meters thick. It consists of plagioclase olivine-clinopyroxene cumulate, though the modal ratio of each mineral changes greatly within a layer. The amount of clinopyroxene occurring as primocryst is very low. At the basal part of plagioclase dominant cumulate, a trough structure develops. It crosscuts the underlying olivine dominant cumulate. The boundary between the top of the plagioclase-dominant cumulate layer and the overlying olivine dominant cumulate layer is generally straight, and is parallel to the rhythmic layering or lamina in the upper part of plagioclase-dominant cumulate. This suggests that the plagioclase-dominant cumulate was covered conformably by the olivine-dominant cumulate and the boundary plane represents a horizontal plane during the crystal accumulation.

Under the microscope, the plagioclase-dominant cumulate shows adcumulus texture. Plagioclase, olivine and clinopyroxene occur as granular primocrysts. Olivine is sometimes partly rimmed by clinopyroxene, orthopyroxene and/ or hornblende embedded by vermicular spinel. A similar texture is also recognized rarely in the olivine-dominant cumulate. The characteristics are as follows, i) frequently, olivine is in direct contact with plagioclase without the interception of other crystals, and ii) the rock has an igneous texture and keeps the normal compositional zoning of primocrysts though very weak. Effects of regional metamorphism are not recognized. These characteristics and mineral chemistry data indicate that the vermicular spinel within clinopyroxene, orthopyroxene or hornblende was formed by the reaction between olivine and plagioclase, under the condition of the inconstant existence of a liquid phase among the primocrysts, i.e., the reaction between plagioclase and olivine proceeded during the magmatic stage, instead of during the metamorphic stage.

Pyroxene-dominant cumulate occurs as a layer 18 m in thickness. The upper boundary of the layer is straight and covered concordantly by olivine-dominant cumulate, and the lower boundary is cut by gabbro. It consists of orthopyroxene-clinopyroxene cumulate (websterite) and clinopyroxene cumulate (clinopyroxenite). Pyroxene-dominant cumulate occurs also near the eastern margin of the Thak body as platy blocks, 20 m in thickness, intruded by gabbro. EPMA data show that the compositional variation of each mineral is very small within and among the layers, and systematic changes through the Thak body are not recognized, i.e., cryptic layering does not exist. The Thak body and gabbro of the Chilas Igneous Complex are very different in petrologic and mineralogical characteristics, indicating that these rocks have different origin. The crystallization process of UFA is summarized into, i) olivine and small amounts of clinopyroxene crystallized continuously near the central part of a magma reservoir and settled on the bottom. The settled crystals made up the homogeneous cumulate (olivine-dominant cumulate). During this process, the chemical composition of crystallizing minerals and the magma (liquid) above the cumulate was kept constant,, ii) at the same time, crystallization of pyroxenes and plagioclase occurred at other portions of the same magma reservoir. Some accumulated plagioclase and pyroxenes flew down along the bottom of magma chamber (like a mudflow in water) toward the place where olivine was accumulating. Thus the plagioclase-dominant and pyroxene-channeled or eroded olivine dominant cumulate, iii) plagioclase, olivine and interstitial liquid could not coexist stably, and a reaction rim was formed between plagioclase and olivine, and iv) as the downward flow of plagioclase and pyroxene occurred intermittently, plagioclase dominant and pyroxene-dominant cumulates were covered by olivine-dominant cumulates conformably until the next flow arrived. This magma reservoir is characterized by open system crystallization. That is, primitive magma is continuously supplied into the magma reservoir and differentiation proceeds from the center to margin of the reservoir. Such a magma reservoir is not known except for that supposed for the generation of oceanic crust. Therefore, the ultramafic-felsic association is considered to be derived from the oceanic crust.

K/553. Kummel, B., 1966. The Lower Triassic Formations of the Salt and Trans-Indus Ranges, West Pakistan. Museum of Comparative Zoology, Harvard University, Bulletin 134(19), 161-429.

The Triassic formations in the Salt Range of West Pakistan have played a particularly important role in the development of our Triassic zonal scheme, especially for the Scythian stage. In addition, interest in these formations is heightened because they conformably overlie late Permian formations, and the Triassic formations in the Salt Range have occupied the attention of nearly every student of the causes of abrupt faunal breaks. This great interest has not been matched by many modern detailed stratigraphic or paleontologic studies of these Permo-Triassic formations. Waagens (1895) great monograph on the Fossils of the Ceratit Formation was the first large scale report on a Triassic fauna from the eastern region of Tethys. In the same year Mojsisovics, Waagen, and Diener (1895) published their proposal for a classification of the Triassic System. In that paper the name Scythian was introduced for the lower series of the Triassic and the Salt Range sequence of zones presented as the type section. Later, Noetling (1901) reaffirmed the Pre-eminent importance of the Salt Range sequence in Scythian chronology, at the same time modifying somewhat the scheme of zones proposed by Waagen. It was not until 30 years later that it was

generally recognized that the Triassic fossilbearing formations in the Salt Range studied by Wynne (1878), Waagen (1895), and Noetling (1901, 1905) encompassed only the lower half or so of the Scythian. Waagen's Salt Range ammonites, however, have continued to play a dominant role in our interpretation of the evolution and systematics of Scythian ammonoids.

K/555. Kummel, B. & Teichert, C., 1970. Stratigraphy and Paleontology of the Permian- Triassic boundary beds, Salt Range and Trans-Indus Ranges, West Pakistan. In: Kummel, B. & Teichert, C. (eds.), *Stratigraphic Boundary Problems, Permian and Triassic of West Pakistan*. Geology Department, University of Kansas, Special Publication 4, 1-110.

It has been known for about a hundred years that the sedimentary series of the Salt Range and some of the Trans-Indus ranges of West Pakistan encompass a concordant succession of marine, fossiliferous rocks of Late Permian and Early Triassic age. After a brief introduction to geology and geography of the area, the history of research on this sequence and on the problem of the Permian-Triassic boundary is reviewed.

The detailed stratigraphy of the beds immediately above and below the Permian-Triassic boundary is described from nine localities in the Salt Range, two in the Surghar Range, and two in the Khisor Range. The uppermost lithological unit of the Permian Chhidru Formation ("Upper *Productus* limestone") is a white sandstone unit which is as much as 17 feet thick and in the Khisor Range has yielded brachiopods indicating a Late Permian age. It also contains conodonts, a rich palynological assemblage, and acritarchs.

The white sandstone unit is conformably overlain by a dolomite unit, about 5 to 14 feet thick, containing *Ophiceras*, *Glyptophiceras*, *Miocidaris*, and few other megafossils associated with rich assemblages of conodonts, acritarchs, and spores and pollen. This unit forms the base of the Triassic System. It is gradational with an overlying limestone unit that also contains *Ophiceras* and other fossils, including conodonts and palynomorphs. The dolomite and limestone units together form the Kathwai Member which represents the *Ophiceras* Zone, the lowest ammonoid zone of the Triassic System. This is overlain by thin-bedded limestone containing *Gyronites* and other ammonoids (the "Gyronitan" assemblage of Spath) the "Lower Ceratite limestone" of Waagen, which most previous observers believed to form the base of the Triassic System in the Salt Range.

The nature of the boundary between the Permian and Triassic systems in the Salt Range and the Trans-Indus ranges is discussed from the point of view of lithology, diagenesis, sedimentary structures, and fossil content. The abrupt litho-facies change indicates a sharp change of sedimentary environment. Sedimentary structures, such as mudcracks and capped ripple marks, in combination with dolomitization and dedolomitization patterns, suggest that a period of emergence intervened between the deposition of the white sandstone unit and the dolomite unit, and that the contact between the Permian and Triassic systems in the Salt Range and Trans-Indus ranges, therefore, is a paraconformity which may represent a gap equivalent to as much as, or more than, a stratigraphic stage.

Key words: Stratigraphy, palaeontology, Permian, Triassic, Salt Range, Trans-Indus Ranges.

K/556. Kummel, B. & Teichert, C., 1973. The Permian-Triassic boundary beds in Central Tethys. In: Logen, A. & Hills, L.V. (Eds.), *The Permian and Triassic system and their mutual boundary*. Canadian Society of Petroleum Geology, Memoir 2, 17-34.

The classical and most important areas for the study of Permian-Triassic boundary beds, with the exception of that at Kap Stosch, East Greenland, are in central Tethys. This report discusses the stratigraphy and paleontology of these boundary beds in the Salt Range and Trans-Indus ranges of West Pakistan, the Julfa region of northwest Iran, and at Guryul Ravine near Srinagar, Kashmir.

The Permian-Triassic contact in the Salt Range and Trans-Indus ranges is interpreted as a paraconformity reflecting a recession of the sea and an emergent condition in latest Permian time followed by a transgression in the earliest

Triassic as defined by the first appearance of *Ophiceras*. These earliest Triassic strata also contain a variety of Permian-type brachiopods which are interpreted as short-lived survivors from the underlying Permian.

The controversial strata of the Dzhulfa region of Soviet Armenia, and now known from the adjacent region of northwest Iran that contains the so-called mixed faunas, are considered to be of Late Permian age. New finds of ammonites, especially genera known previously only from the Changhsing Limestone of Kwangsi, China, are part of the basis for this interpretation. In Guryul Ravine are strata with *Claraia* that contain Permian-type brachiopods. We interpret these beds as of Early Triassic age.

L/3. La Fortune, J.R., Snee, L.W. & Baig, M.S., 1992. Geology and geochemistry of Indian plate rocks south of the Indus suture zone, Besham area, Northwest Himalaya, Pakistan. *Kashmir Journal of Geology* 10, 27- 52.

The Himalayan mountains are the geologic manifestation of continental collision, and in North Pakistan the Main Mantel Thrust (MMT) is major suture along which the collision occurred. The basement rock near Besham Village in southern Kohistan, adjacent to MMT, are bounded on the east and west by north-trending high-angle faults. These basement rocks that are significantly different from any of the other plutonic and metamorphic rocks of the southern Kohistan and that are not seen elsewhere in the Pakistan Himalaya west of the Nanga Parbat-Haramosh massif (NPHM).

Rocks of the Besham area are subdivided from oldest to youngest into five groups. The oldest rocks of the Besham area are; (1) the metasediments and heterogeneous gneisses of the Besham group. In conjunction with field evidence, major, trace and rare earth element analysis of Besham gneisses suggest that the quartzofeldspathic gneisses formed in situ from a sedimentary protolith. The presence of both quartzofeldspathic gneiss and sodic quartzofeldspathic gneiss in the Besham group may be attributable to variable protolith composition or more likely, the sodic gneiss was derived from intrusive protolith that was strongly transposed during deformation. These sodic gneisses are equivalent to the previously named Lahor granite. The Besham group was intruded by (2) mafic dikes that were subsequently metamorphosed to amphibolites. Geochemical data suggest that these tholeiitic dikes have island arc geochemical affinities. (3) The third group rocks comprise cogenetic, small granitic intrusions and associated pegmatites; the Shang granite, the Dubair granodiorite and the Shorgara pegmatite. Unconformably lying upon these three units is (4) the Karora group, which comprises conglomeratic, calcareous and carbonaceous sedimentary rocks. The Karora group provides evidence for more than one metamorphic event in the Besham area, i.e., the Karora group is metamorphosed to lowergreenschist facies, in contrast, the underlying Besham group is metamorphosed to epidote amphibolite facies. The youngest unit observed in the Besham area is (5) a relatively undeformed leucogranite that intrudes both the Karora group and the Besham group. The metamorphic and granitic rocks of the Besham area may be correlative with the basement rocks of the Nanga Parbat-Haramosh Massif. Specifically, the quartzofeldspathic gneisses of the Besham group may correlate with the Nanga Parbat gneisses and the amphibolites found in the Besham area may correlate with mafic dikes of the massif. Further study of both the Besham area and the Nanga Parbat-Haramosh Massif can provide a better understanding of Precambrian basement rocks of northern Pakistan.

Road alignment and related studies along Gilgit – Gupis roads were carried out during the field season of 1986. The road which 110 km long is jeepable in fair weather conditions. Geological mapping and study of seven bridge sites from the engineering geological point view was done. The entire road was divided into 20 sectors and a comparative statement showing the material exposed, problems, remedial measures and blasting pattern was prepared. At certain places realignment of road was also proposed. proper execution and implementation of recommendation made, may help to great deal in construction, of better road and bridges.

L/9. Latif, M. & Hussain, H., 2002. Limestone quarry sites around Islamabad and Kohat. Geological Survey of Pakistan Information Release 721.

The beautified and green Margalla Hills of Islamabad are being eaten up by limestone mining and crushing which in addition to the destruction of the natural landscape, is causing large scale environmental degradation and air pollution. To find out the alternate limestone reserves, the investigation in the surrounding areas of Islamabad was carried out in April, 2000. As a result of this investigation six different sites have been identified. These new sites are Khairi Murat, Kala Chitta Pathargarh Khanpur, Ganghar and Kohat ranges. The Margalla range which is already being mined has been studied as a reference site, The new sites have been selected in view of their relatively more favorable occurrences in sufficient quantity and their easy accessibility. Brief description of locations, accessibility, reserve estimates and geology of the six new sites and the existing mining area of the Margalla Hills range are given in the report.

The KarGah quadrangle (43 1/1) lying in the district Gilgit has been mapped on 1:50,000 scale. Mapped area shows variety of rocks including metasedimentary, metavolcanic and plutonic. Metasedimentary and metavolcanic rocks are classified as Gilgit formation (parapeisses and schists together with amphibolites), Thelichi formation (turbidites, marble, green schist and basic dyke) and Greenstone complex (metavolcanics and metatuffs). The plutonic rocks are named as the Kohistan batholith which consists of diorite, granodiorite, granites aplite and pegmatite.

Structure of the mapped area is depicted by a syncline which is occupied by the rocks of the Thelichi formation. The mapped area contains mineral showings of insignificant economic importance.

L/13. Latif, M.A., 1962. An Upper Cretaceous limestone in the Hazara District. Geological Bulletin, Punjab University 2, p.57.

In the Hazara District of West Pakistan, there occurs a limestone, 300 to 400 feet in thickness, above the Giumal Sandstone and below the un-doubted Tertiary sequence. It was described by Middlemiss (pp. 39-40) who was not sure of its age, but placed it at the base of his Nummulitic Series (Eocene), primarily for the convenience of mapping. At the base of the limestone is a bright orange yellow sandy limestone, about 6 to 10 feet thick, which contains a rich assemblage of definite Cenomanian fossils (op. cit. pp. 35 - 38). The top of the limestone is strongly lateritized, generally to a depth of 5 feet, and even more; and usually marks the small time-break to the overlying carbonaceous shales with inferior coal bands of early Tertiary age.

The limestone is very fine grained and pale grey on the freshly broken conchoidal fracture surfaces. It usually weathers creamy white, and occasionally dark grey. It is more thickly bedded at the base than the top, where it develops an uneven platy appearance due to the frequent alternations of limestone and very thin marly layers. This gives the rock a rather distinctive appearance compared with other limestones in the succession.

During the recent remapping of the region, a rich assemblage of small pelagic Foraminifera was found at a number of localities (Darband 33 56', 72 19' : Dungagali 34 3', 73 22': and Khan 34 8', 73 19').

Detailed work on these microfossils is in progress and the results will be published in full later. From the preliminary investigations of thin sections, however, the Foraminifera Globotruncana, Heterohelix, Rugoglobigerina and Pseudotextularia have been seen to occur, frequently, particularly in the upper part of the limestone. These genera are characteristic of the Upper Cretaceous, and, therefore, the limestone may be assigned definitely to this Series. It is interesting to note that the Parh Limestone of Baluchistan is of same age, and bears a striking similarity in the field.

L/18. Latif, M.A., 1970a. Micropaleontology of the Chanali Limestones. Upper Cretaceous of Hazara, West Pakistan. *Jahrbuch der Geologische Bundesanstalt (Wien)* 15, 25-61.

A sequence of limestones, considered as the basal beds of Eocene, have been identified as a mappable, lithostratigraphic unit and given a new formation name, the Chanali Limestone. The microfaunal studies of 5 samples, further reveal the presence of more than 30 species, 16 belonging to planktonic and 15 to benthonic foraminiferida and 3 to Ostracoda. An Upper Coniacian to Campanian age for the formation is established.

L/19. Latif, M.A., 1970b. Explanatory notes on the geology of southeastern Hazara, to accompany the revised Geological Map. *Wein Jahrb. Geol. Bundesanst., Sonderb. Austria* 15, 5-19.

This is a brief account of the stratigraphy of over 1000 square miles of south eastern Hazara, West Pakistan, supported by a geological map on a scale of one inch to one mile. The mapping is based on the recognition of lithostratigraphic units, which are briefly described with modernization of nomenclature. The rocks are divided into 7 groups and subdivided into 21 formations, some provisional. The strata range from Eo-Cambrian?/Cambrian to Recent. Diagnostic fossils evidence wherever available is given. A correlation with adjoining areas is attempted.

L/22. Latif, M.A., 1972a. Lower Palaeozoic (? Cambrian) hyolithids from the Hazara Shale, Pakistan. *Nature, Physical Science* 240(100), 92-93.

The age of rocks forming the Lower Himalayas of Nepal and of the Kumaon, Garhwal, Simla, Kashmir and Hazara areas in the northwestern part of the Indo-Pakistan subcontinent has long been the subject of considerable controversy. The rocks include the Simla Slates, the Chandpur and Nagthat beds, as well as the Hazara Group and Tanol Formation of the Hazara District in northern Pakistan, which are separated from the overlying clastic and carbonate sediments by a disconformity marked by a glacial conglomerate known as the Blaini boulder bed in Nepal

and India and the Tanakki boulder bed in Hazara, Pakistan. The post-Blaini or post-Tanakki sequence is known as the Infra-Krol and Krol beds in Nepal, Kumaon and Simla, and as the Abbottabad Group in Hazara^{1,2}. In the absence of fossil evidence, both the Blaini and Tanakki boulder beds have been correlated with the fossiliferous Talchir boulder bed and, accordingly, considered to be of Upper Carboniferous-Permian age.

L/24. Latif, M.A., 1973. Partial extension of the evaporite facies of the Salt Range to Hazara, Pakistan. Nature, Physical Science 244(138), 124-125.

The age of the Salt Range Formation (formerly the Saline Series of Wynne) has long been controversial. The problem of age has revolved around two factors-the fossil evidence and the contact with the overlying Palaeozoic sequence. A third factor-the presence of Slate Series in other areas of the Indo-Pakistan subcontinent-has not been considered, despite the fact that both the Salt Range Formation and the Slate Series mark the oldest known rocks of enormous thickness and with an unknown base^{6,7} in their respective areas of development.

Key words: Evaporites, Salt range, Hazara.

L/25. Latif, M.A., 1974a. A Cambrian age for the Abbottabad Group of Hazara, Pakistan. Geological Bulletin, Punjab University 10, 1-20.

The Lower Himalayas all along are dominantly composed of a thick sequence of quartzites, sandstones and dolomites overlying what are known as Slate Series named variously at different localities. One such sedimentary sequence mapped earlier (1970) by the author as Abbottabad Group is the subject of study in this article. Like similar other rocks sequences in other parts of Indo-Pakistan the age has been unknown for want of fossil evidence. The majority of previous workers have for reasons of glaciated Tanakki conglomerate proposed a post carboniferous age for the problematic sequence. The rock sequence has been described starting with the Hazara Group followed by the Tanol Formation. These are considered to be from Eo-Cambrian to Basal Cambrian. Abbottabad Group follows after a break marked by Tanakki Conglomerate followed by Sangargali Member, Mahmadagali Member and Mirpur Member all belonging to Kakul Formation. These are followed by a dolomite sequence, the Sirban Formation, which in upper parts is cherty and phosphatic. After a break, said to be gradational in few sections, (?), the Abbottabad Group is followed by Tarnawai Formation composed of Galdanian and Hazira members, known to be facies equivalents of each other. Galdanian Member is composed of red haematitic mudstones, clay-stones etc. and Hazira Member of yellowish sandstone and siltstone rich in glauconite in lower parts. The Tarnawai Formation is followed by the Thandiani Group of Jurassic age.

Fossil, Hyoliths and Chencelloria have been recorded from the Hazira Member and a Cambrian age is assigned to the rock sequence lying above Tanol Formation and below Hazira Member. The sequence has been correlated partly with the Cambrian sequence of Salt Range and Iran. The lithologically similar sequence in other parts of Indo-Pakistan are suggested to be the possible equivalents of Abbottabad Group.

Key words: Cambrian, Abbottabad, Hazara.

L/27. Latif, M.A., 1974c. A new evidence to solve the controversy of paleo-glaciation in Indo-Pakistan. Geological Bulletin, Punjab University 11, 1-6.

Evidences show that unconformity is not restricted to Tanakki Member horizon; the conglomerate occurs at levels other than Tanakki Member; the Tanakki Member is composed entirely of rocks of local origin, mainly sedimentary, as against Talchir Boulder Bed where these have been transported from far off distances and are mainly composed of crystalline rocks; the red and purple sandstones, quartzites and dolomites always occur younger than Tanakki Member whereas lithologically identical rock units always occur older than Talchir Boulder Bed; fossil Hyolithes, Chancelloria etc. of Cambrian age are found to occupy a younger position in sequence than Tanakki Member and there is a possibility of the presence of globular organisms of Algonkian affinities in the Blaini Beds of Simla India. It is suggested that Tanakki Member and Talchir Boulder Bed belong to two different phases of glaciation, the former being older, possibly Cambrian or topmost Pre-Cambrian.

Key words: Paleo-glaciation, Tanakki conglomerate, Cambrian.

L/28. Latif, M.A., 1976. Stratigraphy and micropaleontology of the Galis Group of Hazara, Pakistan. Geological Bulletin, Punjab University 13, 1-64.

The Galis Group is composed of 6 distinct mappable units recognized as formations. The gray limestone considered as Eocene by Middlemiss (1896) in fact of Upper Cretaceous age and has been separated as Kawagarh Formation at the top of the Hothla Group. The contact between Hothla and Galis groups is marked by a break in deposition followed by laterite/limonite/hematite/ and coal/bituminous shales. The group contains 75 species of Foraminifera and genera of Ostracoda, recorded and described from Hazara for the first time. The Group ranges in age from Lower Paleocene to basal Middle Eocene. The southeastern parts of the area indicate relatively shallower conditions of deposition. During the deposition of the Galis Group, intermittent phases of transgression and regression are recorded with a tendency towards a complete withdrawal of marine conditions upward in the succession.

Key words: Stratigraphy, micropaleontology, Galis Group, Hazara.

L/29. Latif, M.A., 1980. Overstep by Thandiani Group, Jurassic over older rock sequences in Hazara. Contributions to the Geology of Pakistan 1, 1-8.

Of the seven unconformities recorded in the sequence of rocks in Hazara the lower three disconformities merge into one composite unconformity. This leads to an overstep by Toarcian rocks over, the Eo-Cambrian rocks. An attempt has been made to elaborate the varied effect of various unconformities on the underlying sequences in various parts of Hazara which led to the formation of the composite unconformity.

Indian plate movement after the deposition of Cretaceous Kawagarh Formation and prior to the Paleogene deposition created conditions suitable for the formation of Hangu Formation which the product of lateritization of old limestone surface. The laterite beds exposed near Changlagali, on Murree-Abbottabad road were measured and sampled for this study. The samples dominantly consist of gray colored pisoliths embedded in a gray to creamish brown matrix. Mineralogically, goethite and boehmite are the two distinct phases in laterite. Geochemical analyses show that the percentage of alumina decreases in the upper parts of the beds, whereas, the percentage of iron increases with the decrease of alumina in the beds. The general trend is desilicification in the middle of the beds. In the upper part of the beds the percentage of silica is increasing because of leaching out of the elements due to weathering phenomenon. The firing of samples at above 900 °C produces beautiful red colors. It is deduced that materials are suitable for the manufacturing of surface tiles.

L/37. Laurs, B.M., Dilles, J.H. & Snee, L.W., 1996a. Geologic origin of gem-bearing pegmatites, Stak Nala, Haramosh massif, Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 83-84.

Gem-bearing pegmatites and associated leucogranite bodies are widely distributed in rocks of the Pakistan Himalaya, within both the Nanga Parbat-Haramosh Massif of the Indian Plate and in the Asian Plate to the north. The Stak Nala pegmatites are located (ca. 35°59'; 75°02'E) near the eastern portion of the massif, where late tectonic

Himalayan leucogranites (U/Pb zircon ages of 2 to 13 Ma) were emplaced during late Neogene uplift (Zeitler and Chamberlain, 1991). The pegmatites are hosted by granoblastic-textured ortho- and para-gneiss (Shengus gneiss of Verplanck, 1986) metamorphosed at granulite facies (8 to 13 kb, 650-700°C) (Pognante et al., 1993). In the mine area, cm- to m-scale banded biotite-muscovite±garnet granitic gneiss dominates.

The Stak Nala pegmatites contain the only known economic concentration of gem quality pink-green tourmaline in the region. The pegmatites are mined west of and 400 m above the Stak Nala valley over a 0.5 km distance, but similar pegmatites extend 3 km south. Pegmatites are typically <1-m thick and locally up to 5-m thick. Most pegmatites are emplaced along the gently dipping S1-foliation (& F1 folds with top-to-south shear) of the Shengus gneiss, but in detail are slightly discordant sills. The pegmatites also cross-cut a series of N60°W striking, 60°N-dipping monoclinical F2-flexural shears with gneissic layers attenuated within the dipping limbs. These fold-shears are interpreted to be deep, ductile normal faults related to Neogene uplift of the massif. The pegmatite emplacement locally deforms gneissic wall-rock foliation and hence occurred while the gneiss was hot enough to allow ductile deformation of quartz (>300°C). Late brittle normal faults reactivate the F2-shears, offset pegmatites, and contain local sericite-pyrite hydrothermal alteration inferred to have formed at ca. 250°C. Two ⁴⁰Ar/³⁹Ar plateau ages on white micas (closure temperature ca. 325°C) yield 5.80±0.05 Ma for wall-rock gneiss and 4.63±0.12 Ma for the pegmatite. If the micas have the same structural state, these data suggest the gneissic wall-rock cooled to 325°C at 5.8 Ma slightly prior to pegmatite emplacement.

In the mine area, at least six pegmatites separated by 3 to 20 m occur within a 100 m section of gneiss. All these pegmatites have complex mineralogic zonation, microlitic cavities, coarse grain-size, and quartz, orthoclase, sodic plagioclase, muscovite, and schorl tourmaline. The most productive pegmatite has been mined in a zone 100 m by 60 m. The thickest portion of the pegmatite (1.0 to 1.2 m) is most productive; the northern thin (<0.7 m) portion is non-productive. The productive zone is bounded on the north by an F2 fold, which forms an anticline that may have trapped volatile components to produce gem tourmaline. The pegmatites display a simple internal zonation from the wall-rock contact inward; border and intermediate zones symmetrically enclose a central core zone (Fig. 1). The border zone is ca. 10 cm thickened characterized by coarse-grained (1 to 7 cm) albite, orthoclase, and quartz, and medium-grained schorl, garnet, and loellingite. Large (15 to 30 cm) perthite crystals nucleate within the border zone and flare into the intermediate zone, accompanied by locally abundant schorl prisms. Schorl, albite and quartz form irregular coarse-grained intergrowths which are rarely graphic in texture; loellingite (<0.1 vol.%) is widespread. The core zone is at or slightly above the pegmatite centerline, and is marked by an abrupt increase in blocky, commonly albitized, and perthite crystals. Albite, quartz, schorl, muscovite (rare lepidolite), and green fluorite of variable grain size (1 mm to 10 cm) are essential.

Gem tourmaline-bearing pockets occur sporadically within the core zone. The pockets range in size up to 2*3*0.5 m, and are lined by albite (wedge-shaped crystals and cleavelandite), topaz, green fluorite, and pink-brown fluorapatite; columbite-tantalite, pyrochlore, and hambergite form rarely. A thin layer of hypogene fine-grained illite partially covers pocket minerals, and together with soil fills the remaining pocket cavity. Associated with some pockets are irregular bodies of sugary albite, garnet, and tourmaline, which locally extend into the surrounding intermediate zone. These may be pressure-quench aplite derived from abrupt fluid escape during pocket rupture, as described at pegmatites in San Diego County, California (Ford, 1976).

The wall-rock is bleached up to 7 cm from the pegmatite and contains metasomatic albite, muscovite, and tourmaline. Wall-rock alteration increases with pegmatite thickness and amount of pocket mineralization, and is most extensive in biotite-rich gneisses where tourmaline extends up to >50 cm along foliation. Pegmatite-derived fluids have added, B, Fe, Rb, Zn, Zr, and Nb, and leached K, Ba, and Sr from the wall-rocks.

We conclude that pegmatite gem mineralization at Stak Nala formed during the late Neogene uplift of the Nanga Parbat-Haramosh Massif, probably after the granulite-facies host rocks have cooled to 300 to 350°C at pressures of <2 kb (based on microlitic cavities). The pegmatites are derived from leucogranite magmas enriched in Si, Al, Na, K, B, F, Li, Rb, and H₂O that formed from low degrees of partial melting of a metapelite source during decompression (?). The high concentration of rare elements in the narrow pegmatite dikes is probably due to extreme fractionation of vapor-saturated magma.

Key words: Gems, pegmatites, granites, Stak Nala, Nanga Parbat-Haramosh.

L/38. Laurs, B.M., Dilles, J.H. & Snee, L.W., 1996b. Emerald mineralization and metasomatism of amphibolite, Khaltaro granitic pegmatite-hydrothermal vein system, Haramosh Mountains, northern Pakistan. *Canadian Mineralogist* 34, 1253-1286.

Emerald mineralization is found within 0.1- to 1-m-thick hydrothermal veins and granitic pegmatites cutting amphibolite within the Nanga Parbat-Haramosh massif, in northern Pakistan. The amphibolite forms a sill-like body within garnet-mica schist, and both are part of a regional layered gneiss unit of Proterozoic (?) age. The $^{40}\text{Ar}/^{39}\text{Ar}$ data for muscovite from a pegmatite yield a plateau age of 9.13 ± 0.04 Ma. Muscovite from mica schist and hornblende from amphibolite yield disturbed spectra with interpreted ages of 9 to 10 Ma and more than 225 Ma, respectively, which indicate that peak Tertiary metamorphism reached 325 to 550 degrees C prior to 10 Ma. Pegmatites were emplaced after peak metamorphism during this interval and are older than pegmatites farther south in the massif. At Khaltaro, simply zoned albite-rich miarolitic pegmatites and hydrothermal veins containing various proportions of quartz, albite, tourmaline, muscovite, and beryl are associated with a 1- to 3-m-thick heterogeneous leucogranite sill, that is locally albitized. The pegmatites likely crystallized at 650 to 600 degrees C at pressures of less than 2 kbar. Crystals of emerald form within thin (<30 cm) veins of quartz and tourmaline-albite, and more rarely in pegmatite, near the contacts with altered amphibolite. The emerald-green coloration is produced by Cr and Fe. The Cr and total Fe contents, expressed as Cr_2O_3 , and Fe_2O_3 , respectively, decrease systematically from emerald (>0.20, 0.54-0.89 wt%), to pale blue beryl (< or = 0.07, 0.10-0.63%), to colorless beryl (<0.07, 0.07-0.28%). The amphibolite is metasomatized in less than 20-cm-wide selvages that are symmetrically zoned around veins or pegmatites. A sporadic inner zone containing F-rich biotite, tourmaline, and fluorite, with local albite, muscovite, quartz, and rare beryl, gives way to an intermediate zone containing biotite and fluorite with local plagioclase and quartz, and to an outer zone of amphibolite containing sparse biotite and local quartz. The inner and intermediate zones experienced gains of K, H, F, B, Li, Rb, Cs, Be, Ta, Nb, As, Y and Sr, and losses of Si, Mg, Ca, Fe, Cr, V and Sc. The outer alteration zone has gained F, Li, Rb, Cs, and As. Oxygen isotope analyses of igneous and hydrothermal minerals indicate that a single fluid of magmatic origin with $\delta^{18}\text{O} = 8$ per mil produced the pegmatite-vein system and hydrothermal alteration at temperatures between 550 and 400 degrees C. The formation of emerald result from introduction of HF-rich magmatic-hydrothermal fluids into the amphibolite, which caused hydrogen ion metasomatism and released Cr and Fe into the pegmatite-vein system.

Key words: Emerald mineralization, amphibolites, metasomatism, pegmatites, granites, Stak Nala, Nanga Parbat Haramosh.

L/39. Laurs, B.M., Dilles, J.H., Warraich, Y., Kausar, A.B. & Snee, L.W., 1998. Geological setting and petrogenesis of symmetrically zoned, miarolitic granitic pegmatites at Stak Nala, Nanga Parbat-Haramosh massif, northern Pakistan. *Canadian Mineralogist* 36, 1-47.

Miarolitic granitic pegmatites in the Stak valley in the northeast part of the Nanga Parbat-Haramosh Massif, in northern Pakistan, locally contain economic quantities of bi- and tricolored tourmaline. The pegmatites form flat-lying sills that range from less than 1 m to more than 3 m thick and show symmetrical internal zonation. A narrow outer or border zone of medium-to coarse-grained oligoclase--K-feldspar-quartz grades inward to a very coarse-grained wall zone characterized by K-feldspar-oligoclase-quartz-schorl tourmaline. Radiating sprays of schorl and flaring megacrysts of K-feldspar (intermediate microcline) point inward, indicating progressive crystallization toward the core. The core zone consists of variable mixtures of blocky K-feldspar (intermediate microcline), oligoclase, quartz, and sparse schorl or elbaite, with local bodies of sodic aplite and miarolitic cavities or "pockets". Minor spessartine-almandine garnet and lollingite are disseminated throughout the pegmatite, but were not observed in the pockets. The pockets contain well-formed crystals of albite, quartz, K-feldspar (maximum microcline+ or - orthoclase overgrowths), schorl-elbaite tourmaline, muscovite or lepidolite, topaz, and small amounts of other minerals. Elbaite is color-zoned from core to rim: green (Fe^{2+} and Mn^{2+})-bearing), colorless (Mn (super 2+) -bearing), and light pink (trace Mn (super 3+)). Within approximately 10 cm of the pegmatites, the granitic gneiss wallrock is bleached owing to conversion of biotite to muscovite, with local quartz and albite added. Schorl is disseminated through the altered gneiss, and veins of schorl with bleached selvages locally traverse the wallrock up to 1 m from the pegmatite contact. The schorl veins can be traced into the outer part of the wall zone, which suggests that they formed from aqueous fluids derived during early saturation of the pegmatite-forming leucogranitic magma rich in H₂O, F, B, and Li. Progressive crystallization resulted in a late-stage sodic magma and abundant aqueous fluids. Two late stages of volatile escape are recognized: the first stage caused pressure-quenching of the last magma, which produced aplite and caused albitization (An 3 to An 8) of earlier crystallized K-feldspar and oligoclase. The second stage, released during the rupture of miarolitic cavities, produced platy albite ("cleavelandite," An 1) locally associated with F-rich muscovite and elbaite. Albitization is likely due to cooling of alkali-fluoride-dominated fluids at less than 2 kbar pressure. The pegmatites are derived from Himalayan leucogranitic magma emplaced prior to 5 Ma into granulitic gneiss that was at 300 degrees to 550 degrees C and 1.5

to 2 kbar. The pegmatites were emplaced during uplift of the Haramosh Massif, since they cross-cut ductile normal faults but are cut by brittle normal faults. Economically important pink tourmaline mineralization formed in pockets concentrated near the crest of a broad antiform, as a result of trapping of late magmatic aqueous fluids that had become Fe-poor owing to the prior crystallization of schorl.

Key words: Petrogenesis, zoned pegmatites, granites, Stak Nala, Nanga Parbat-Haramosh.

L/40. Lawrence, L. & Malinconico, Jr., 1989. Crustal shortening in the west Himalaya. *Geological Bulletin, University of Peshawar* 22, 55-64.

The main collision between the Indian and Asian lithospheric plates occurred during the late Eocene (40 million years ago) and continued closure at the rate of 5 cm/yr has resulted in approximately 2000 km of crustal shortening between the two plates (Molnar and Tapponnier, 1975; Molnar, 1984). In northern India it has been suggested that while some of the shortening is by underthrusting (Molnar and Tapponnier, 1975) much may be the result of diffuse deformation in China (Tapponnier, 1982). However, in northern Pakistan the problem is complicated because there is no Tibetan plateau analog and no evidence of strike-slip structures that could have removed significant amounts of crustal material.

In order to place tighter constraints on tectonic models for the Indian-Asian collision in the western Himalaya it is important to be able to estimate the amount of crustal shortening that has occurred. Current estimates of 500 to 700 km of convergence in northwestern Pakistan (Butler, 1986), are calculated from balanced cross-section methods. This is significantly less than the 2000-km required by closure models based on paleomagnetic data (Powell, 1979, Molnar and Tapponnier, 1975; Molnar, 1984).

An important step in estimating the amount of shortening that has occurred is to determine the volume of crust that remains in the orogen. The crustal models based upon observed gravity profiles presented in this paper suggest that there may be enough crustal volume to account for between 550-1100 km of shortening. This is still significantly less than the 2000 km of closure that has presumably occurred. The balance of the closure might be account for by erosion and/or diffuse deformation or it might suggest that less than 2000 km of closure has occurred in the northwestern Himalaya.

Key words: Structure, tectonics, collision, Himalaya.

L/41. Lawrence, R.D., 1982. West and Tibetan collision zone in Pakistan. *EOS* 63, p1112.

The northwestern margin of the subcontinental India in Pakistan is characterized by two major suture zones. The one on the west juxtaposes the Afgan block with India. That in the north (commonly referred to the Indus Suture) juxtaposes the Kohistan island arc terrain against India. These are described in this note. Major tectonic features record the transition from convergence in the Himalaya and Tibet to transform on the Chaman fault system in northern Pakistan. The Main Boundary thrust can be traced to the south side of the Safed Koh where it overrides the Sulaiman fold belt. It ends abruptly where the Sarubi tear fault abuts the Heart fault. The Main Central thrust becomes obscure in eastern Kashmir. Beyond the Hazara-Kashmir Syntaxis (HKS) its only possible expression is a deep seismic zone (IKSZ) under "flack tectonic" thrust sheets of Kohistan & Swat (Kohistan flakes). The Indus suture continues as the Main Mantle thrust to the Kunar fault, reappears around the Kabul block, and into the Quetta line; all marked by latest Cretaceous/Paleocene obduction. The Kabul block is a fragment of Lesser Himalayan terrain of the Indian subcontinent displaced by interactive motion on the Herat & Chaman faults. Significant stratigraphic contrasts subdivide the Lesser Himalayan terrain. The HKS & Nanga Parbat loop are neotectonic features on the eastern border of the Kohistan flakes with centers of rotation at their apices. Microplate line of Afghanistan-Nuristan-Pamirs-South Tibet is wrapped around the Kohistan flakes by rotation in the west, thrusting in the north (Pamir thrusts), & right-lateral translation in the east (Karakorum fault). Unscrambling of tectonic development requires (1) reverse translation and rotation of relatively rigid blocks, (2) unfolding and thrusting of marginal belts, and (3) reconstruction of areas concealed by over-thrusts. Key is reversal of motion on Chaman & Herat faults and reversal of rotation of Kohistan flakes.

Key words: Collision zones, tectonics, Tibet, Pakistan.

L/42. Lawrence, R.D., 1984a. An expedition to Pakistan. *Science* 226, p.1414.

This gives a brief account of the two volumes of the International Karakoram Project (K.J. Miller editor, 1984). Papers in these are annotated at appropriate places in this work.

The International Karakoram Project, K. J. Miller, Ed. Cambridge University Press, New York 1984. In two volumes. Vol. 1, xxx, 412 pp., Vol. 2, xxviii, 635 pp., From two conferences, Islamabad, June 1980, and London, Sept. 1981.

This two volume set contains papers delivered at conferences which that took place before and after the International Karakoram Project (IKP). The IKP was a major expedition into the remote Karakorum Mountains of northern Pakistan using the recently completed Karakorum Highway, which follows the old silk road between India and China. The project was undertaken, in a two-month period, during the summer of 1980s as part of the Royal Geographic Society's 150th anniversary celebration. It brought together earth scientists mainly from three cooperation nations, the United Kingdom, Pakistan, and the People's Republic of China. The principal studies involved glaciology, topography, seismology, housing as it relates to natural hazards, geomorphology, and geology. The first volume contains papers delivered at the conference preceding the expedition. About a third of the volume is thus devoted to descriptions of techniques for gathering desired data. About a fourth is devoted to descriptions of the results of studies in distant areas that used techniques intended to be used in the IKP. The remainder of the book mainly describes projects planned in Pakistan and neighboring areas. Six papers report new results from previous work in Pakistan that are of lasting value. Four papers report the results of glaciological studies by Chinese scientists. Israr-ud-Din of Pakistan reports the results of his studies of house construction in Chitral in relation to the geographic setting. H. M. Rendell reports new work on the Quaternary history of the Potwar plateau. This volume is largely superseded by the second volume.

The second volume contains the results obtained by the IKP, Much information is published here for the first time and not all of it can be reviewed. One of the most ambitious efforts of the IKP was a resurvey of the 1913 triangulation connection between India and Russia in an effort to detect tectonic deformation across the Karakoram. This effort entailed major mountaineering, for the stations to be reoccupied were mostly mountain peaks between 4000 and 6000 meters high. The survey itself was successfully accomplished, but significant tectonic deformation was not detected. A substantial effort was made in glaciology, and many new data were obtained that will be increasingly useful as these baseline studies are replicated. A micro-earthquake survey was made with a portable seismic network. Most of the seismicity was under the Hindu Kush to the west. However, important seismicity was observed for the first time in the Kohistan area of northern Pakistan (south of Karakorum) and will provide guidance to future neotectonic studies. A large part of the volume is devoted to the study of housing and natural hazards. Many data on house construction and family use of homes were gathered that will interest ethnologists and anthropologists. A key element of the success of these studies was the presence of a female, F. D'Souza, for non-family males are not allowed inside the homes in this area. The housing team devoted considerable effort to attempts to determine the role of natural hazards in locating houses. Surprisingly in this area of very great natural hazard, they found that agricultural considerations, specifically preservation of cultivatable land and availability of irrigation supplies, essentially exclude natural hazards such as rock-fall, mudflow, flood, and earthquake from consideration when new houses are located.

The longest part of the volume deals with geomorphology. Extensive data on current processes are reported. Perhaps the most unexpected result here is that a dissolved load yielding sediment of 90 tons per square kilometer per year was measured on the Hunza River, indicating that substantial chemical weathering occurs even in a high, cold, arid area where it had always been considered to be negligible. One of the best papers in the collection deals with the Quaternary history of the Hunza Valley. Eight separate glacial phases are recognized, the older of them more than 139,000 years old. The oldest stages are recorded by remnants several thousand meters above the Hunza Valley floor. The sole weakness of the study is a failure to consider the effects of tectonic uplift interacting with glacial episodes. With uplift rates of over 1' centimeter per year recorded in the area, the interaction must be significant. This is the first modern study of glacial chronology in northern Pakistan and will be of great value to other workers.

The IKP was an ambitious undertaking. Much was accomplished, but the project has the inherent weaknesses of short-term projects. In numerous instances previous work is not adequately recognized. Little effort was apparently made to assist Pakistani colleagues to continue the studies, particularly those that established baseline data. These proceedings volumes are not as tightly edited as one would wish, but they do contain substantial amounts of valuable information.

Key words: Reconnaissance, expedition, Karakoram.

L/43. Lawrence, R.D., 1984b. Suture tectonics in Pakistan. Abstracts, First Pakistan Geological Congress, Lahore, p.49.

In Ladakh the Indus suture divides. A minor northern suture, the MKT, records a back arc basin north of the Kohistan-andesite arc. The major suture, which records the location of the Neotethys, is south of the arc. It is made up of a complex set of terrains and structures. Ultramafic rocks of three derivations can be distinguished in this suture, namely: (1) those emplaced by obduction, (2) those imbricated into subduction zones, and (3) those basal to the arc complex. Obducted material is present as an infolded klippe at Dargai and associated with emerald mineralization from Mohmand to Mingora. Subduction complex with blueschist, serpentinite, piemontite schist, and phyllite is preserved at Shangla. Fossils of probable early Cretaceous age are present in subduction material near Mingora. Initial emplacement of subduction and abduction material in Swat occurred prior to continental collision. Ophiolite material of diverse origin is mingled by collision and its complex earlier history is obscured. This is demonstrated better in Pakistan than elsewhere in the world. As the suture is followed west and south from Swat, the subduction and obduction complexes become separated by the Khojak flysch. Subduction melange occurs at Khost, in the Altimur Range, and in the southern Ras Koh. Obduction masses occur at Waziristan, Muslimbagh, and Las Bela. The enormous Khojak flysch mass separates these, and collision has not gone to completion as is the case in the Himalayan Ranges.

Key words: Structure, tectonics, ultramafics, MKT.

L/44. Lawrence, R.D., Baig, M.S., Dilles, J.H., Lafortune, J.R., DiPeitro, J., Huges, S.S., Palmer, Rosenberg, P.S., Pogue, K., Snee, L.W., Tahirkheli, R.A.K., Ghauri, A.A.K., Jan, M.Q., Ahmad, I., Rafiq, M., Kazmi, A.H. & Hussain, A., 1989. Tectonics south of the Suture, northern Pakistan. *Geologique Internationale Resumes – 28th International Geological Congress Section 2*. No. 28, p.265.

In Pakistan the Indus suture zone is known as the Main Mantle Thrust zone (MMT) and separates the Kohistan andesitic arc complex from rocks of the Indian subcontinent portion of Gondwana. The latter, south of the MMT, are the hinterland of the Himalayan thrust system in Pakistan. In Swat and Besham areas pre-Himalayan deformation and early Himalayan metamorphism complicate interpretation of these rocks.

The MMT zone contains three separately mappable melanges in the Swat region. Mingora melange consists of ophiolite blocks and slabs in or on a metamorphosed talc-carbonate or serpentinite matrix that is tectonically interleaved with graphite schists at the base. Klippe of Mingora melange may be found 40 km south of the MMT. Charbagh melange is composed of greenschist of possible andesitic arc origin. The Shangla melange contains blueschist, serpentinite, and other exotic blocks in a sheared matrix of low grade metasediments and metavolcanoclastics. On the Indus River north of Besham the MMT is a fault at the base of the Jijal complex (peridotites and pyroxene granulites of the base of the Kohistan arc); suture melanges are absent. In Allai Kohistan east of the Indus River, blueschist and serpentinite melanges similar to those of southern Swat reappear in southern Swat the rocks under the MMT are stratigraphically divided by a significant unconformity. Below the unconformity are quartzofeldspathic and calc-silicate metasediments, Manglaur schist (MS). Above the unconformity are the members, quartz-mica schists, amphibolites, calc-schists, marbles, graphite schists, etc. of the Alpurai formation (AF) of late(?) Paleozoic age. Member 5 maps south to stratigraphically overlie conodont-bearing lower Carboniferous rocks near Rustum. This Rustum Paleozoic section is fossiliferous from Ordovician to Carboniferous. The Paleozoic section of the SE Peshawar basin margin overlies with angular unconformity Precambrian Tanawal formation, a largely quartzose sequence probably correlative with MS. Granitic rocks of the Swat region were intruded at several different times. The Swat porphyritic granites (SPG) are unconformable beneath AF and intrude MS. These are peraluminous coarse-grained granites containing biotite, muscovite, garnet. SPG correlates (?) with Mansehra granites east of Indus River (516 My Rb/Sr isochron). Small bodies of syntectonic Swat tourmaline granite (STC) intrude mainly along major contacts. These are peraluminous non-porphyritic rocks containing muscovite, tourmaline, epidote group minerals. STG REE patterns are similar to those of the SPG, but a factor of 5-10 less enriched; this is compatible with partial melting of the SPG to form the STG. About 20 km south of SPO outcrops, the Ambela granite (AG), associated with numerous small bodies of alkaline granites (Rb/Sr isochrons of about 300 My) intrudes Carboniferous sediments. These granites may reflect late Paleozoic rifting along northern Gondwana. Major and trace element chemistry confirm that the STO, AO, and STG are distinct magmatic entities. The youngest granites include the small post-tectonic Malakand biotite granite whose intrusive contacts cross cut Himalayan age metamorphic foliation. The upper rocks of Swat probably form a roof thrust 75 km. Marker units can be traced in overlapping sequence from the MMT to the Swabi region. AF Member 2 forms a regional marker

allowing detailed analysis of folding within this unit. The first two fold sets are synmetamorphic at or before Ar closure in hornblende at about 40 My. and have north-south or northwest-southeast axes. The first set is recumbent and west verging; the second set upright and west verging. Neither comprises sheath folds or other structures rotated into the direction of elongation; their axes do not define a stretching lineation. They occur only in the 20-30 km wide zone of high grade metamorphism, are associated with initial collision, and suggest left lateral strike slip along the suture with limited west-directed overthrusting (50 - 30 My). The youngest set of folds in the Swat area has eastwest axes associated with the onset of major south-directed thrusting. Folds of this pattern are present from the MMT south to the Salt Range. East of the Indus River stratigraphy and intrusive history are similar to Swat, but an imbricate pattern of south-directed thrusts developed in the Hazara Hills east of the Indus River. The most probable interpretation is an extensive roof thrust in Swat that overlies the imbricate duplexes revealed by deeper erosion to the east in Hazara. The Besham block is a stratigraphically and structurally distinct block along the Indus River. North-south, steeply dipping faults separate this block from its neighbors. Reconnaissance mapping suggests 'that these faults also cut the MMT itself and separate the portion of the MMT marked by the Jijal complex from the Swat and Allai Kohistan melange-bearing portions of the MMT.

Besham block stratigraphy consists of heterogeneous quartzofeldspathic banded gneisses and metasediments, the Besham Group (BG), representing early Proterozoic(?) crystalline basement. Major and trace element variability in the gneisses suggests both paragneisses and in situ anatexitic melts of pelitic sediments as the origin of these rocks. The BG is intruded by Labor granite (LG) which is clearly crustal melt. Pegmatites of LG intrude all lithologies of the BG. BG gneissic foliation and LG pegmatites are truncated by an angular unconformity at the base of marine metasediments of the Karora Group (KG). Fragments of all basement lithologies are found in the Karora Group (KG). Fragments of all basement lithologies are found in the basal conglomerate of the KG. Above this unit the KG consists of graphitic phyllite overlain by siliceous dolomite. Metamorphic grade of the KG is middle greenschist. The higher metamorphic grades and anatexitic events of the BG developed before the unconformity between these units. The KG can probably be traced into equivalent Precambrian phyllites unconformable under the Tunawal near Turbela. A common structural history for Besham and Swat blocks probably began with the younger north-south fold set. Recently the entire area was arched on a north-south axis to form the syntaxial bend of the MMT. The limbs of this structure are partly formed by brittle motion on steeply dipping north-south trending faults. Some of these faults contain mafic and ultramafic slivers derived from suture melanges. In summary the Swat and Besham regions record different structural and metamorphic histories: in the former, late Precambrian to Paleozoic granites and sediments are deformed and intruded by tourmaline granites during Himalayan metamorphism and deformation; in the latter, an earlier Proterozoic metamorphism and magmatism are preserved below the suture.

L/45. Lawrence, R.D. & Ghauri, A.A.K., 1983a. Observations on the structure of the Main Mantle Thrust at Jijal, Kohistan, Pakistan. *Geological Bulletin, University of Peshawar* 16, 1-10.

Structures in the lower plate of the MMT at Jijal include a blastomylonite zone, Z-folds in the blastomylonite, and abundant slickensides in a breccia block. Blastomylonite foliation is cross-cut by intermediate granitic intrusive. A multi-stage history of the MMT involving (1) SE thrust motion on a deep shear zone, (2) uplift and granitic intrusion, (3) renewed thrust faulting and breccia formation at a shallow crustal level, and (4) folding of the MMT and cessation of thrust motion is suggested.

L/46. Lawrence, R.D. & Ghauri, A.A.K., 1983b. Evidence of active faulting in Chilas District, northern Pakistan. *Geological Bulletin, University of Peshawar* 16, 185-186.

About 10km northeast from the town of Jalipur, a zone of breccia, 5-10km thick, is located along the Karakorum Highway. The breccia is found in Holocene fan-gravels developed at the foot of the Nanga Parbat massif. It is present at several locations along the road up to Raikot bridge, and also north of the confluence of the Indus and Astor River. Slickensides are developed in this breccia zone. Most of these appear to plunge along the dip of fault surfaces on which they are found. The trace of the fault is delineated by a line of hot springs, some right on the road and some on the river side. The ones located along the road can be easily spotted by the rising steam. The hot springs south of Raikot bridge are closely spaced and have a definite linear arrangement.

L/47. Lawrence, R.D. & Ghauri, A.A.K., 1984. Tectonics of the western Indus suture in Pakistan. EOS 65, p.1094.

The Indus suture extends from southern Tibet to northwestern Pakistan. This is a brief account of the tectonics of the western part of the suture in Pakistan. The suture is associated by mélanges at places. In Ladakh, the Indus suture bifurcates. A minor northern suture, the MKT, records a backarc basin north of the Kohistan andesitic arc. The major suture is south of the arc. It is made up of a complex set of terrains and structures. Ultramafic rocks initially emplaced by obduction, imbricated into subduction zones, and basal to the arc complex can be distinguished. At Dargai, A klippe of obducted material is intricately infolded into metasediments. In Swat, obducted material contains emerald mineralization in ophiolite metamorphosed to talc-carbonate. Subduction complex with blueschist, serpentinite, piemontite schist, and phyllite is preserved at Shangla. From Dargai to Shangla, the southern marginal fault of the suture zone is older than the northern fault mid-Cenozoic metamorphism of the northern margin of the Indian subcontinent occurred under the overriding Kohistan arc. Three units of metasediments are tentatively recognized: twice metamorphosed crystalline schists of probable Precambrian age, once metamorphosed shelf sediments of probable Paleozoic age, and one metamorphosed possible Indus flysch equivalent. The crystalline schists are intruded by augen gneisses, and both are unconformably overlain by the metamorphosed shelf sediments. The entire complex rides south on the Himalayan sole thrust as a tectonic flake. At Jijal, peridotite and garnet granulite are basal Kohistan arc complex; other elements are completely overridden. East of Chilas, the suture complex is cut by the active Rakhiot fault which trends north-south. Plio-Pleistocene Jalipur fluvial sandstones are preserved along the fault. Talus cones, alluvial fans, and glacial sediments are cut by the Rakhiot fault. It brings the psammitic gneisses of the Nanga Parbat-Haramosh complex to the surface. It extends north-south from Sassi to Chilas and probably continues to the Hazara-Kashmir syntaxis. We interpret it as a displacement transfer structure offsetting the Himalayan sole thrust. The MCT terminates against this fault. The Indus suture reappears east of the Nanga Parbat-Haramosh massif in the relatively well known Ladakh area. Previous workers have interpreted the suture zone to loop around the Nanga Parbat-Haramosh loop; we find that it is interrupted and displaced by the loop. The Nanga Parbat-Haramosh massif is not an ancient basement high of the Indian rock, but rather an active Himalayan structure that records the offset on the Himalayan sole thrust.

L/48. Lawrence, R.D., Kazmer, C. & Tahirkhelli, R.A.K., 1983. The Main Mantle Thrust; A complex zone, northern Pakistan. Geological Society of America, Abstracts with Program 15, p.624.

The Main Mantle Thrust, northern Pakistan, brings the Kohistan andesitic arc terrain against the Indo-Pakistani subcontinent and links the Indus suture zone (east) with the paired ultramafic complexes of Waziristan/Zhob/Las Bela and Altimur/Ras Koh (west). It is composed of melange, blueschist, and ultramafic rocks between major bounding faults. Ultramafic rock of three sources is present: that (1) obducted onto the leading, rifted margin of the Indo-Pakistani subcontinent, south side of the Neotethys, in latest Cretaceous/Paleocene, (2) emplaced within the subduction margin of the Kohistan arc, north side of the Neotethys, during Late Cretaceous, and (3) formed as the base of the late Jurassic Cretaceous, 7-8 km thick, Kohistan arc slab. Examples: (1) Dargai klippe and Swat Emerald Mine talc-carbonate slab, (2) Shangla Pass blueschist and Jawan Pass area, (3) Jijal Complex. Types (1) and (2) brought in contact during middle Eocene (?) suturing. Type (3) thrust over suture later during continuing collision. Resultant MMT complex is on top of Precambrian medium-grade metasediments (Salkhala?) with no intervening shelf or deep marine sediments. West of Nanga Parbat Haramosh massif MMT complex is replaced by a single active fault that brings a Tertiary migmatized and metamorphosed slab (High Himalayan slab?) over the Kohistan area.

L/49. Lawrence, R.D., Kazmi, A.H. & Snee, L.W., 1989. Geological setting of the emerald deposits. In: Kazmi, A.H. & Snee, L.W., (eds.), Emeralds of Pakistan: Geology, Gemology and Genesis, 13-38. Van Nostrand Reinhold, New York.

In Pakistan emeralds are found in fascinating surrounding. The spectacularly rugged Himalayan ranges (photo. 2.1) capped by the lofty snow-capped peaks of Nanga Parbat (8128m), Rakaposhi (7790 m) and Haramosh (7406 m) are dissected by awe-inspiring canyon of the Indus River which reaches over 6100 meters of relief in places. Farther south the verdant, picturesque Swat valley between pine-clad mountains give way to the barren, hilly and hostile terrain of the Malakand, Mohmand and Bajaur agencies. Though today the emerald occurrences are spread over a fairly extensive belt, their presence was not known until 1958 when the first emerald deposit was discovered at the northern edge of the city of Mingora in Swat (Kazmi, 1983). Since then, a number of deposits or showings of emeralds have been located in Mohmand Agency at Nawe Dand, Gandao (actually green beryl), Pranghar, Bucha, and Khanori; in the Bajaur Agency at Aman Kot and Maimola; in Swat District at Charbagh, Makhad and Gujarkili and in the Gilgit Agency at Khaltaro (fig. 2.1).

Detailed geological prospecting of the Mingora mines (Kazmi, 1983; Kazmi and others, 1984. 1986), has shown that they contain at least three distinct types of emerald deposit which differ in quality. Thus, Pakistan emeralds offer a wide range of color and quality, with the best ones coming from Gujarkili and Mingora mines (Kazmi and others. this volume).

Exquisite as these emeralds are as gems; their geological setting is also wonderful: they are the products of collision between the Indian and Asian continental crustal plates. This history has been briefly described in the previous paper (Kazmi, this volume). The present study indicates that all the emerald deposits and showing in Pakistan except the Khaltaro occurrence are located exclusively in the metamorphosed ophiolitic melange of the suture zone. Although the Khaltaro emerald occurrence is within the Nanga Parbat gneiss, it also is found in close proximity to the suture zone. The geological setting of these deposits is briefly described.

L/50. Lawrence, R.D. & Shroder, J.F., 1984. Active fault northwest of Nanga Parbat. Abstracts, First Geological Congress, Lahore, 50-51.

The Rakhiot fault is a newly identified active fault along the western margin of the Nanga Parbat-Haramosh massif. This active fault offsets the suture zone (MMT) and produces a gap in the trace of the suture. It is an oblique fault with a combination of reverse and right-lateral slip. Active fault features include crystalline basement overriding Quaternary sediments, fault scarps in fan gravels, lines of hot springs, sheared glacial till, offset glacial terraces, and slickensides in fan gravels. The scarp of the famous 1841 landslide is along the trace of the Rakhiot fault. The landslide was triggered an earthquake, presumably associated with the fault, in December 1840 or January 1841, and it dammed the Indus into a lake up to 300 m deep that broke out in June to overwhelm the Sikh army downstream at Attock. The still fresh scar of the landslide is located on the east side of the Indus south of the mouth of the Astor River. The to on the west side of the Indus preserves pressure ridges from the high-velocity movement. The rockslide diamicton is a chaotic mixture of pulverized rock fragments in a friable sandy matrix; the larger clasts are dominantly light colored gneisses. This diamicton is quite distinct from adjacent older semi-consolidated tills and the consolidated Jalipur diamicton that it overlies. The association of massive landslides with active reverse faults is well known and suggests possible future hazard in the area.

L/51. Lawrence, R.D. & Shroder, J.F., 1985. Tectonic geomorphology between Thakot and Mansehra, Northern Pakistan. Geological Bulletin, University of Peshawar 18, 153-161.

Geomorphic features between Thakot and Mansehra include, 1) bedrock terraces and an associated knickpoint on Nandihar Khwar, an Indus tributary, 2) deeply weathered residual soils on a relict upland surface called the Chhattar plain, 3) an escarpment developed at the edge of headward erosion into this upland surface, and 4) an incised intermontane sedimentary basin north of Mansehra. Together these features provide new data to be used in reconstructing the history of recent uplift of the Himalaya in Pakistan. They reflect a period of relative tectonic stability during tropical soil development on a surface of rolling hills between about 25 and 5 m.y. ago followed by uplift and erosion of that surface. These residual soils may be an important sediment source for the young intermontane basins developed in association with foreland thrust fault motion during the last 5 my.

L/59. Le Bas, M.J., Mian, I. & Rex, D.C., 1987. Age and nature of carbonatite emplacement in north Pakistan. Geologische Rundschau 76, 317-323.

The N Pakistan carbonatites of Loe Shilman, Silai Patti and those within the Ambela complex were formerly considered as comprising one alkaline igneous province associated with a Peshawar rift valley. New data show that these alkaline rocks occur in two distinct periods, Carboniferous and Tertiary, and are not related to any Tertiary rift faulting. K-Ar dates determined on biotites from the Loe Shilman and Silai Patti carbonatites reveal that the carbonatites were emplaced at 31 ± 2 Ma, and along thrust planes, not rift faults. Subsequent movement of the thrusts reset the argon contents in some biotites to indicate a deformation age of 24 ± 2 Ma for the carbonatites at

both localities. The Koga carbonatite in the Ambela complex occurs as a plug associated with nepheline syenites and ijolites, and Rb-Sr isotope determinations on the silicate rocks give dates of approximately 297-315 Ma. The study implies that there were thrust movements associated with the Indian – Asian plate collision more than 31 Ma ago, which is much earlier than the 20 Ma date previously advocated for the initiation of thrusting.

L/61. Le Fort, P., 1975. Himalaya: the collided range. Present knowledge of the continental arc. American Journal of Science 275A, 1-44.

From a presentation of the geological and geophysical characteristics of the Himalayas, the author tries to draw the main features of mountain building. After a common Precambrian story, the Higher and Lesser Himalayas separate in two basins, the northern one on a continental thinned margin, the southern one intracratonic under shallow marine and continental influences. The beginning of this distinct evolution may be traced in both domains by a widespread spilite keratophyre episode. Caledonian and Hercynian periods are only marked by epeirogenic movements and limited volcanism. The four phases of deformation and the three intervenient phases of metamorphism (the third being a retrogression) all belong to the Tertiary orogeny.

The orogeny is composed of distinct cycles. The first ends with collision of the Indian and China plates at the beginning of the Tertiary; it leads to the formation of the Trans Himalaya range and probably develops the first phase of folding and metamorphism in the Himalayas. The second cycle (Miocene) is thoroughly intracontinental with a very large scale subduction along the Main Central Thrust; such movements provide a simple and elegant explanation of the inverted metamorphism observed all along the Himalayas, together with particular tectonic features.

The amplitude of the intracontinental subduction seems to be limited in time; it brings a high rate of erosion whose products are partly accumulated in the foredeep of the range. When movement resumes, after 10 m.y., it takes place along a weaker, more southerly line. The fossilized movements of the Himalayas are now in action along the Main Border Thrust.

Key words: Collision, continental arc, Himalaya.

L/62. Le Fort, P., 1989. The Himalayan orogenic segment. In: Sengor, A.M.C. (eds) Tectonic evolution of the Tethyan Region. Kluwer Academic Publishers, Dordrech, 286-289.

Four major plutonic belts are related to the Meso-Cenozoic orogenic evolution of the Himalaya-Trans Himalaya-Karakoram realm: the Trans Himalaya belt and its satellite Kohistan arc, the Karakoram batholith, the High Himalaya belt and the North Himalaya belt. A fifth one results from the lower Palaeozoic epirogenic events: the 'Lesser Himalaya' belt. The tectonic settings of their production and emplacement are successively reviewed. Among the first four, two results from oceanic subduction along an Andean margin locally branching into an island arc and two result from intracontinental subduction after closure of the oceanic realm. Both Andean belts are made up of very large quantities of highly diversified granitoids produced more or less continuously during 70 Ma at least, whereas the intracontinental ones are limited to a small volume of very uniform anatectic granite produced during a 10-15 Ma period. The production and emplacement in the Andean belts is partly controlled by the obliquity of the convergence between India and Eurasia. The emplacement of the intracontinental belts is even more dependent on the regional tectonic setting. These contrasting belts are case studies probing the depths and mechanisms of their production and giving adequate models for older geodynamic frames.

L/63. Le Fort, P., 1996. Evolution of the Himalaya. In: Yin, A. & Harrison, M. (eds.), The Tectonic Evolution of Asia. Cambridge University Press, 95-109.

The collage of the three of the Himalaya (the Sub-Himalaya, the Lesser Himalaya, and the High Himalaya) has resulted from a long evolution starting at 50 Ma with the closure of the Tethys ocean and the collision of the Indian and Tibetan continental masses. This evolution can be divided into five periods: a prelude, three main acts, and a postlude. The prelude corresponded to the Andean-type evolution of the northern margin of Tethys during the closure of the ocean; it produced the Transhimalaya and Karakoram ranges, with abundant plutonism and volcanism. The first act was the collision of the northward drifting Indian plate with the accreted continental Eurasia. It was a progressive suturing that can be dated to around 55-50 Ma, on the basis of a survey of the Indian Ocean, the paleomagnetism of the continental masses, and stratigraphic and magmatic observations. It was accompanied by the obduction of a few ophiolitic nappes and the production of very limited eclogites in the northwestern Himalaya. The Alpine period, act 2, was characterized by the development of a large system of nappes overriding the present High Himalaya, with series more than 10-km thick issuing from the suture basin. That period induced the eo-Himalayan metamorphism best represented in the northwestern part of the range. Act 3, the Himalayan period, resulted in a doubly thickened Indian crust along the Main Central Thrust (MCT). Penetrative stretching lineation and S-C-type fabric characterize the deformation of this 5-10-km-thick zone. Gravity collapse, with kilometric folds and normal faulting, with some dextral shear component, was partly contemporaneous with the MCT. Metamorphism inverted below the MCT, and leucogranite magmatism resulted from this thrusting of hot crystalline gneisses over the cooler Lesser Himalayan formations. The protracted convergence between Indian and Asia has resulted in "hyper-convergence", a southward sequence of younging thrusts, the MCT being replaced by the Main Boundary Thrust, itself replaced by the presently active Main Frontal Thrust. This tectonic evolution is also recorded in the sedimentation. The present situation of the postlude is not different from the preceding period, but benefits from actual observations and measurements of such mechanisms as seismicity, uplift, and erosion. With erosion and uplift rates mainly around a millimeter per year, the Himalaya has remained a prominent range since at least 17 Ma, dominating the evolution of most Asia.

Key words: Orogeny, Himalaya.

L/64. Le Fort, P. & Cronin, V.S., 1988. Granites in the tectonic evolution of the Himalaya, Karakoram and southern Tibet. *Philosophical Transaction, Royal Society of London* 326, 281-299.

Four major plutonic belts are related to the Meso-Cainozoic orogenic evolution of the Himalaya-Transhimalaya-Karakoram realm: the Transhimalaya belt and its satellite Kohistan arc, the Karakoram batholith, the High Himalaya belt and the North Himalaya belt. A fifth one results from the lower Palaeozoic epirogenic events: the 'Lesser Himalaya' belt. The tectonic settings of their production and emplacement are successively reviewed. Among the first four, two result from oceanic subduction along an Andean margin locally branching into an island arc and two result from intracontinental subduction after closure of the oceanic realm. Both Andean belts are made up of very large quantities of highly diversified granitoids produced more or less continuously during 70 Ma at least, whereas the intracontinental ones are limited to a small volume of very uniform anatectic granite produced during a 10-15 Ma period. The production and emplacement in the Andean belts is partly controlled by the obliquity of the convergence between India and Eurasia. The emplacement of the intracontinental belts is even more dependent on the regional tectonic setting. These contrasting belts are case studies probing the depths and mechanisms of their production and giving adequate models for older geodynamic frames.

L/65. Le Fort, P., Debon, F., Pecher, A., Sonet, J. & Vidal, P., 1986. The 500 Ma magmatic event in Alpine southern Asia a thermal episode at Gondwana scale. In: Le Fort, P., Colechen, M. & Montenat, C. (Eds.), *Evolution des Domaines Orogeniques d' Asia Meridionale*. Science de la Terre, Memoir 47, 191-209.

Cordierite-bearing granitic plutons of about 500 Ma emplacement age occur in lesser Himalaya, including the Mansehra granite (consult the following account). Similar rocks of this age in Australia may be a continuity of these. The geodynamic implications of the Gondwana granitoids is discussed.

Key words: Granitic magmatism, Lesser Himalaya, Gondwana.

L/66. Le Fort, P., Debon, F. & Sonet, J., 1980. The 'Lesser Himalayan' cordierite granite belt typology and age of the pluton of Mansehra (Pakistan). Geological Bulletin, University of Peshawar 13, 51-62.

The Manserah pluton is a very typical example of the discontinuous belt of two mica-cordierite granite of the 'Lesser Himalaya'. It is aluminous, quartz rich but feldspar and sodium deficient, and igneous 'microgranular' inclusions are frequent. Severely deformed to the North, the Manserah pluton has been metamorphosed and gneissified during the Himalayan orogeny. Rb-Sr whole rock isotopic data give a well-defined seven point isochron with a Cambrian age of 516 ± 16 m. y. The high initial ratio of 0.7189 ± 6 implies derivation from a source containing a major and very old crustal contribution. The geodynamic framework for the genesis of this huge belt of similar plutons could be that of a simple thinning of a Precambrian shield or that of a late Pan African orogeny.

L/67. Le Fort, P., Debon, F. & Sonet, J., 1983. The Lower Palaeozoic "Lesser Himalayan Granitic Belt": Emphasis on the Simchar Pluton of Central Nepal. In: Shams, F.A. (ed.) Granites of Himalayas, Karakorum and Hindu Kush. Institute of Geology, Punjab University, Lahore, 217-255.

Simchar pluton is the western-most of the six main granitic bodies emplaced in the Precambrian formations of the Kathmandu nappe South of Kathmandu. Made up of a dominant porphyritic, two mica, sometimes cordierite bearing granite, it is associated with a two mica leucocratic granite. Both form a very characteristic and typical quartz rich aluminous association. Considered by most authors as Cenozoic, it has been deformed and metamorphosed during the Himalayan orogeny by the main phase of deformation.

A Rb - Sr study on whole rock samples gives an isochron age close to the Cambro-Ordovician boundary with a rather high Sr initial ratio. The petrographical, structural, geochemical and chronological characteristics of the Simchar Pluton are quite similar to the other plutons of the Kathmandu nappe, including the Palung one, as to the fifteen or so "Lesser Himalayan" plutons that stretch for 1600 km. There is a remarkable coherence within the "Lesser Himalayan" belt. Moreover the authors have found similar rocks of similar age in the Central Mountains of Afghanistan, the Tibetan Slab of Nepal (Formation III) and Lhagoi Kangri (North Himalayan) belt of Tibet. This very large scale phenomenon seems to be independent from any true orogenesis.

L/69. Le Fort, P. & Gaetani, M., 1998a. Geological map of western central Karakorum, North Pakistan, Hindu Raj, Ghamubar, and Darkot areas at 1:250,000 scale. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 108-109.

The authors have produced a new geological map at 1:250,000 scale of the mountainous region of NW Pakistan comprising the Hindu Raj and Ghamubar ranges, and the Darkot area in between. The map includes the Karakorum central granitoid belt, in the region where it is divided into two branches, and the slightly metamorphic Darkot sedimentary group.

The region of the present map covers three main units: two crystalline masses separated by a sedimentary unit: the northern crystalline masses, the Hindu Raj' unit, is mainly made up of plutonic rocks varying from diorite to granite in composition, the granite being in the center, flanked to the north and south by the mafic plutonic rocks. In general, the Chikar meta-sedimentary formations and migmatitic gneisses occur in the northern part; intruded by the

Ishkarwaz pre-Ordovician granitoid, they represent the basement of Karakorum; the middle sedimentary unit, the Darkot unit, is composed of low-grade meta-sedimentary formations, including arenites, slates, and limestones in which Upper Paleozoic bryozoans and brachiopods have been found [1]. We have also found Triassic megalodonts, and possible Cretaceous rudists;

the southern crystalline mass, the Ghamubar unit, is composed of plutonic rocks also varying from diorite to granite in composition, and intruding into a large northern stripe of Aghost gneisses and migmatites.

To the north and north-east, the area is separated by a series of folds, thrusts, and lineaments from the East Hindu Kush, in which outcrops a large Jurassic porphyritic granite outcrops. To the south, the Nialthi meta-sedimentary formation, at least Permian in age, is overlain by the Lower Cretaceous detritic and partly volcanic formations of the Yasin group. Within the Nialthi fm have discovered a separate strip of conglomerate: the Hundur formation. One of the salient feature is the presence throughout the map of extended pinched strips of sedimentary rocks (Reshun and Hundur conglomerates, Dobargar sedimentary horizons) that underline the lenticular shape of the crystalline masses. The large-scale tectonics can be divided into three main phases: a longitudinal stretching with boudinage of the batholith, a left-lateral strike-slip that has doubled the batholith and is probably responsible for the pinched structure of sedimentary formations, and a north-south extension fast enough to produce a layer of pseudotachylite (see Le Fort & Villa, this volume) on the southern side of the 5 to 10 km wide Darkot graben.

Key words: Mapping, Karakoram.

L/70. Le Fort, P. & Gaetani, M., 1998b. Introduction to the geological map of western central Karakoram, north Pakistan Hindu Raj, Ghamubar, and Darkot areas 1:250,000 scale. *Geologica* 3, 1-67 (French version, p.69-93).

These notes introduce a new geological map at 1:250000 scale of the mountainous region of NW Pakistan comprising the Hindu Raj and Ghamubar Ranges and the Darkot area in between. The map includes the Karakoram central granitoid belt, in the region where it is divided into two branches and the slightly metamorphic Darkot group. The two crystalline massifs of the Hindu Raj and Ghamubar are mainly composed of dioritic to granitic plutons, often in tectonic contact, that seem to pertain to Cretaceous time. In addition, on the northern side of the Hindu Raj massif, outcrops of Ishkarwaz pre-Ordovician granitoid, overlain by lower Ordovician sedimentary series. All these granitoids are intrusive to metasedimentary formations of varied metamorphic grade, from epi-metamorphic to magmatic, that represent the basement of the Karakoram range.

The sedimentary series of the Darkot group: at least permo-Triassic in age, have been preserved in a 5-10 Km wide graben, filled by the sedimentary cover series of the Darkot group between the two crystalline ranges. The map also includes the Jurassic plutonic complex of Shushar, intrusive into the Wakhan slates of the Hindu Kush.

The large scaled tectonics can be divided into three main phases: a longitudinal stretching, a left-lateral strike slip that has doubled the major batholithic belt of granitoid, and north south extension enough to produce a layer of pseudotachylite on the southern side of the graben.

L/71. Le Fort, P., Guillot, S. & Pêcher, A., 1997a. HP metamorphic belt along the Indus suture zone of NW Himalaya: new discoveries and significance. *Comptes Rendus del' Academie des Sciences, Paris* 325, 773-778.

Key words: Metamorphism, Indus Suture, Himalaya.

L/72. Le Fort, P., Guillot, S. & Pêcher, A., 1997b. Discovery of Retrogressed Eclogites in the Indus Suture, East of Nanga Parbat-Haramosh massif (Northern Pakistan) the HP Belt of NW Himalaya. Abstract volume, 12th Himalaya-Karakoram-Tibet International Workshop, Rome, Italy, 57-58.

The eastern contact between the Nanga Parbat Haramosh Massif and the Ladakh island arc is a north-south to NNE-SSW boundary known as the Indus Suture or the Main Mantle Thrust. It is a complex ductile shear zone with right-lateral strike-slip more recently reworked by pervasive brittle faulting. Along this contact, close from the confluence between the Stak and the Indus valleys, we have found a series of metric to decametric lenticular bodies of

serpentinized peridotites accompanied by smaller boudins of garnet bearing pyroxenites and amphibolites. These lenses only form a few percents of the 2-km thick contact zone. They belong to the Arc material.

The original paragenesis of the metabasic rocks is clearly retrogressed; diopside clinopyroxene (Jd10) appears as symplectitic association with Na-plagioclase (Ab85), the globularization of the symplectites is typical of the destabilization of omphacites during decompression. Mg-rich garnet is surrounded by amphibole + plagioclase + biotite corona. Most samples remain fresh and are devoid of alteration and weathering. The occurrence of pyroxene inclusions in garnet and the reconstruction from the symplectites of the initial pyroxene gives a 30 to 40 mol.% jadeite. It allows us to evaluate the eclogitic conditions at a minimal pressure of 13 ± 1 kbar and $610 \pm 30^\circ\text{C}$, typical of low- to intermediate-temperature eclogites. The retrogressed assemblage gives a minimal pressure of 8 ± 1 kbar at $610 \pm 30^\circ\text{C}$.

We have tried to find similar occurrences along the Astor section across the eastern Himalaya-Arc contact, some 30-km south of the retrogressed eclogites, but only found high-pressure granulite facies assemblage in Himalayan gneissic material, a few hundred meters from the contact. The rocks are characterized by garnet + diopside clinopyroxene (Jd5-15) + plagioclase (Ab75) $\pm$ rutile primary paragenese. The retrogression is marked by the development of poekilitic ferroan pargasitic amphiboles. P-T conditions of the granulitic stage are evaluated at 10 ± 1 kbar and $700 \pm 50^\circ\text{C}$ whereas the retrogression is characterized by a pressure and temperature drop (6 ± 1 kbar and $570 \pm 50^\circ\text{C}$). Thus, this assemblage very much resembles the HP-granulite facies occurrence of the higher Stak Valley (Pognante et al., 1993), some 20 km north of the new eclogitic occurrence. This suggests that, on the eastern side of Nanga Parbat, the Indian continental crust has been juxtaposed to the present Arc material after an eclogitic metamorphic period, and that they experienced together only the second part of the exhumation process at relatively high-temperature.

The new occurrence of eclogites is located between those reported at the Northwestern margin of the Himalaya (Kaghan Valley, Pognante & Spencer, 1991), 120 km more to the SW, the blueschists of Ladakh (Pashkyum, Shergol, Urtsi, Puga, see Honegger et al., 1989), 130 to 300 km more to the SE, and the eclogites reported in the eastern Ladakh, 400 km more to the ESE (Tso Morari, Guillot et al., 1995). The present eclogitic metamorphism, as the blueschist metamorphism from Ladakh has imprinted oceanic material from the suture, not crustal material of the northern Himalayan margin as in the Kaghan and Tso Morari occurrences. It suggests the existence of a 600-km long HP-LT belt in the northwestern part of the Himalaya probably related to subduction process.

L/73. Le Fort, P., Lemennicier, Y., Lambardo, B., Pecher, A., Pertusati, P., Pognante, U. & Rolfo, F., 1994. Geological Map of Himalaya-Karakoram Junction in Chogo Lungma to Turmik Area (Baltistan, Northern Pakistan). *Journal of Nepal Geological Society* 10. Abstract Volume, 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu, Nepal, 81-83.

The circa 800 km² of the map mostly covers the upper Chogo Lungma glacier system flowing into the Basha river, and the Turmik valley, all on the right (northern) bank of the Indus. Previously mapped schematically by Zanettin (1964) and Desio et al. (1985), it has been surveyed by three of our expeditions (1991-1993), it concerns three major units: the High- Himalayan Nanga Parbat - Haramosh crystallines, the Ladakh terrain possibly made up of a back-arc basin, and the Karakoram. These units are thrust on each other along two major fault systems: the Main Karakorum Thrust (MKT) between Karakorum and Ladakh and the Indus Tsangpo Suture (ITS) between Ladakh and Himalaya. The ITS, described as a normal fault in lower Stak (Verplanck, 1986) with a dextral component at Stak La (Pognante et al., 1993) swirls around the Nanga Parbat - Haramosh promontory, whilst the north-dipping more brittle MKT follows a quasi planar trajectory across the entire territory. In addition a leuco-trondhjemitic pod intrudes the ITS west of Remendok.

High-Himalaya: The High Himalaya crystallines consist of kyanite grade paragneiss slightly migmatized (part of the Shengus gneiss of Macin 1986), intruded by a mass of granitic orthogneiss resembling the 500 Ma "Lesser Himalaya" granites. Mafic dykes cutting through the gneisses retain a garnet granulite paragenesis (650-700°C and 8 to 13 kbar, Pognante et al., 1993).

Ladakh: The unit comprises: (1) the Ladakh volcanic arc intruded by numerous plutons and dykes to the SW and SE, and (2) the Greenstone complex or Turmik melange to the NE. The volcanic arc (1) is limited on the map to a band of amphibolites (Askore Fm of Desio) E of Stak La and S of Chogo Lungma glacier, and a granodioritic intrusion at the Turmik-Indus confluence; it is separated at Dasu by a mass of serpentinites from (2). The Greenstone complex is a volcano-sedimentary sequence with numerous limestone horizons and a tectonic melange of meta-volcanics and -sediments. The major lms horizon (Pakora lms) has yielded post-Valanginian rudists (Le Fort et al.,

1992) and separates a southern band of tuffaceous schists from a northern bank richer in mafic material including serpentinite lenses. The complex has been strongly deformed and metamorphosed in an epidote greenschist facies. It is intruded by a granodiorite to gabbro pluton ("Tisar tonalite" of Desio, 1963) in the Shigar valley.

Karakorum: It is the most complex unit. The back bone of the mapped zone is a dome of granitic orthogneisses (Mangol Bluk dome) with an offset migmatitic core (Arandu), and an intrusive contact into the surrounding metasediments. The orthogneisses are thoroughly infolded with the Basha paragneisses bearing kyanite and sillimanite (690 C and 10 kb, Allen & Chamberlain, 1991). Isoclinal folds have been deformed by the doming. On both sides, the folded alternations of marbles, schists, quartzites and amphibolites stretch WNW-ESE, narrowing towards W. They include a few orthogneissic bands (Bolocho, Mooraine gl.) and are intruded by the Karakoram batholith (Solu granite, up Dabadas). Most of the metasediments are in the amphibolite facies with staurolite $\pm$ kyanite and andalusite. The southern limestone (Chutrung lms) follows more or less the contact with Ladakh. A unique syenitic pod (Hemasil syenite) intrudes the metasediments to the SE. In 40 km from E to W, the entire structure thins down to 1/3, as it moulds itself on the Himalayan spur.

L/74. Le Fort, P., Lemennicier, Y., Lombardo, B., Pecher, A., Pertusati, P., Pognante, U. & Rolfo, F., 1995. Preliminary geological map and description of the Himalaya-Karakorum junction in Chogo Lungma to Turmik area (Baltistan, Northern Pakistan). *Journal of Nepal Geological Society* 11, 17-38.

Some 800 km² of the area lying between the Haramosh Spur of the Southern Karakorum Complex, centered on the Chongo Lungma glacier system, is presented on a preliminary geological map, after three expeditions. It includes three major units from SW to NE: the High Himalayan Nanga Parbat-Haramosh Crystalline (HHC), the Ladakh Paleo Island Arc, and the Karakorum Metamorphic Complex intruded by granitoids. The three units are thrust to the south. The High-Himalayan ortho- and para-gneisses are metamorphosed to granulite facies and migmatized. The Ladakh Arc is made up of two groups of formation, the Askore Amphibolite to the SW and the Greenstone Complex to the NE, separated by a screen of serpentinitized ultramafics. It is intruded by numerous granitoids including a leuco-trondhjemite body cutting the horizons that have yielded post-Valanginian fossils. The Karakorum Metamorphic Complex includes orthogneiss domes of granitoids intruded into the surrounding metasedimentary formations. A syenitic dome of granitoid at Hemasil is apparently syntectonic. Two phases of deformation are observed in Karakorum and Ladakh and seem to correspond, but with different grades of metamorphism. The late doming structures are characteristic of the Karakorum. The Himalaya-Karakorum contact varies from south to north, from normal fault to a strike-slip shear zone, and finally a thrust fault. The original Ladakh-Karakorum contact (Shyok Suture) is folded and reactivated by late brittle thrusting, possibly the latest large-scale deformation of the region. The closure of the Ladakh-Karakorum back-arc basin followed by the collision of India is mostly overprinted by the recent structures.

L/75. Le Fort, P., Michard, A., Sonet, J. & Zimmermann, J.L., 1983. Petrography, geochemistry and geochronology of some samples from Karakorum axial batholith (northern Pakistan). In: Shams, F.A. (ed.), *Granites of Himalayas, Karakorum and Hindu Kush*. Punjab University, Lahore, 377-387.

Granitoid samples from the Hunza Valley have been studied and analyzed. They include dominant type of biotite - hornblende granodiorites and minor two-mica adamellites. The granodiorites are relatively rich in dark minerals, but feldspar and quartz poor; their trend is typically calc-alkaline with subordinate subalkaline affinity. The granodiorite is always gneissic and very fresh; actually it is a metagranodiorite resulting from the high grade regional metamorphism of a previously emplaced plutonic rock. Three different methods of isotopic geochemistry have been undertaken on some of the samples. The oldest age is obtained by U-Pb on zircons with a lower discordant intersection at 95 ± 8 m.y. Four K-Ar amphiboles gather around 46 m.y. and three K-Ar biotites around 26 M.Y. Younger Rb-Sr and K-Ar mica ages form two groups: around 15 m.y. and around 6 m.y.

The initial Sr ratio appears to be high. The dispersion of ages may reflect the complex history of the Karakorum, mainly: Upper Cretaceous batholithic emplacement. Eocene regional metamorphism at the time of the Indo-Eurasian

collision, Miocene rebound of the Himalaya orogeny. Similarities with the eastern Hindu Kush and the Central Mountains of Afghanistan may help to restore the Cretaceous and subsequent geodynamics.

Key words: Petrography, geochemistry, geochronology, Karakorum axial batholith.

L/76. Le Fort, P. & Pecher, A., 1995. The Scar of the Shyok Suture between Kohistan-Ladakh and Karakoram from Hunza to Baltistan (Pakistan). Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

There is a marked lineament, underlined by discontinuous pods of serpentinized ultramafics that can be followed from the left bank of the Shigar valley in Baltistan to the Hunza valley near Chalt along some 160 km (figure). Our fieldwork from 1991 to 1994 has enabled to follow and map this lineament linking the northern boundary of Ladakh with that of Kohistan. Typically to the north of this line, a formation of polygenic sedimentary conglomerate occurs, whereas to the south volcanic tuffs and breccias are abundant. The three formations belong to the northern suture zone of Pudsey (1986).

The serpentinite lenticular bodies have been observed at the following localities:

just E of Chalt along the Karakorum highway (KKH), an outcrop mapped by Pudsey (1986), cutting the crest on the right bank of the Pisan glacier (Askoro pass) providing boulders on the right lateral moraine of the Minapin glacier, issued from the region of the pass leading to Bualtar valley, between the Sumayar and the Diran peaks, as big boulders on the left bank of the Chogo Lungma glacier, as pebbles in the river bed of Burimis (a right bank tributary of the Chogo Lungma), as boulders in the river cone of Brag Zago (a left bank tributary of the Turmik), forming a 40 m thick lenticular band crossing the Pakore valley, north of the summer huts of Pakore, as two pods described and mapped by Hanson (1989) on the north-eastern slopes of the Shigar.

The polygenic sedimentary conglomerate contains mainly ill-rounded pebbles of recrystallised quartz-arenite and limestone, reaching up to 50 cm in diameter. It is poorly sorted and the matrix is made up of limy sandstone. Volcanic contribution seems to increase progressively towards the south, as shown on the left bank of the Minapin glacier. The outcrops include, from E to W:

outcrops of the Mayon valley (Pudsey, 1986), a thick band of massive outcrops crossing the Minapin glacier around its lower bend, a large formation forming massive peaks on both sides of the Miar glacier, cliffs on the northern side of the pass between the Chogo and Barpu basins, feeding the upper moraines of both glaciers, outcrops of the Spantik base camp, a series of outcrops on the left (northern) bank of the Turmik valley, in particular, 100 m thick north of the summer huts of Pakore, screes on the left bank up to Tisar.

The southern conglomerates, tuffs and volcanic breccias belong to the Greenstone complex of Tahirkheli & Jan (1979), Rakaposhi volcanic complex (Tahirkheli, 1982), or Turmik formation of Desio et al. (1985) (cf Le Fort et al., in press; Rolfo et al., this volume). They are made up of varied mixtures of volcano-detrital rocks, with a constant imprint of mafic volcanism, almost impossible to map in detail. At the foot of the northern crest of the Diran a formation of quartz arenites show beautiful sedimentary features of prodelta distributary channel deposit (graded bedding, climbing ripples, according to G. Allen personal communication); it forms blocks in the moraines of the Minapin glacier.

Change in thicknesses is particularly conspicuous for the northern conglomerate that varies from a few meters, and may even lack in places, to more than a kilometre on the left bank of the Miar glacier. All three formations are deformed and metamorphosed. The deformation of the conglomerates on both sides of the lineament is heterogeneous, mainly of flattening plus constriction type (cigar-like shaped). The metamorphism is of low grade greenschist facies with typical chlorite, biotite, epidote, and acicular amphibole (see also Rolfo et al., this volume).

The lineament is almost vertical and rectilinear through the entire zone, oblivious of any Nanga Parbat-Haramosh Himalayan indenter. The slight bulge to the south that it shows in the eastern portion looks like moulding around the two gneissic domes of Mangolbluk and Dassu (cf Le Fort et al., in press; Lemennicier et al., this volume).

As already emphasized by Hanson (1989), the lineament cuts across tectonic and metamorphic structures. Its age has to be fairly young, most likely contemporaneous of the end of the doming structuration known to be less than 7 Ma (Smith, 1993; Villa personal comm.). The lineament cannot represent the original suture between Karakorum and Ladakh-Kohistan arc, bracketed between 102 and 85 Ma (Pettersen & Windley, 1985), but only the trace of a recent reactivation.

Key words: Ultramafics, structure, Shyok Suture, Kohistan, Ladakh, Karakoram, Baltistan.

L/77. Le Fort, P. & Pecher, A., 1998. A new map of Hunza to Baltistan at 1:150,000 scale, northern Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 112-113.

The authors are finalizing a new geological map at 1: 150,000 scale of the mountainous region joining Hunza and Baltistan. The map includes the central granitoid belt and the southern metasedimentary complex of the Karakorum range, volcano-sedimentary and igneous formations of the Kohistan and Ladakh island-arc units, and the northern tip of the gneissic Himalayan spur. Some of the salient features evidenced during mapping include:

Lithology: The very continuous marble horizons of the Karakorum metamorphic complex (KMC), some of them of Permian age (see Rolland et al., this volume). The existence of long stripes of orthogneissified granitoid in Karakorum. The reconnaissance of terrigenous formations in south-western KMC. The continuity of the Kohistan to Ladakh formations, limestone horizons in particular, some of them dated as Cretaceous. The existence of ultramafic lineament that separate the island-arc in two domains.

Tectonics: The large isoclinal folding of the Karakorum metamorphic complex (KMC), underlined by very continuous marble horizons. The folding of the Karakorum granites in the isoclinal folds. The presence of a *mélange* zone along the MKT, north of it (Karakorum side) to the west, south of it (Ladakh side) to the east. Folding of the boundaries between the three units, MKT and MMT. Likelihood that some traditionally described formations may actually belong to the neighbouring unit (e.g.: amphibolites in the Himalayan unit). The pervasive doming structure in a band, east of the Raikot fault, cutting across Himalaya-Ladakh and South-Karakorum. The northern tip of the Raikot fault, presently the most active fault, corresponding to the north-western edge of the NPHM dome.

Key words: Structure, mapping, Hunza, Baltistan.

L/78. Le Fort, P., Pognante, U. & Benna, P., 1992. The Himalaya-Karakoram contact: eastern termination of the Nanga Parbat spur (Pakistan). Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, p.48.

The contact of the Nanga Parbat High-Himalayan crystallines (HHC) with the surrounding low-grade metamorphic rocks has been studied during a geological expedition in the Turmik valley (NW of Skardu in Pakistan). On the HHC side, para- and ortho-gneisses show rather homogeneous high-pressure amphibolite facies assemblages (see companion abstract, Pognante et al., this vol.). The metamorphic foliation, strongly underlined by the banding of the gneisses, dips some 45° east and lies parallel to the contact in the upper Stake and Turmik valleys.

The surrounding rocks belong to the Greenstone complex of Tahirkheli & Jan (1979) and Hanson (1986). It is made up of a *mélange* of greenschists, amphibolites, conglomerates and marbles, all more or less lenticular, strongly deformed and metamorphosed in an epidote greenschist facies. The size of the lenticular bodies varies from several meters to a few kilometers in thickness. In the northern tributary valley of Pakora on the way to the Gonto-La, we have found fine grained black muddy limestone containing deformed recrystallized white shells of rudists. At least three different shapes of rudists are present, the age being most likely post-Valanginian, possibly Barremian-Aptian ? (J.P. Masse pers. comm.).

The Greenstone complex comprises tuffaceous schists, banded amphibolites, volcanic breccias and conglomerates, and at least one large occurrence of a body of gabbro. In addition, several screens of serpentinized ultramafics are distributed in the Turmik *mélange*, the major one underlining its southern boundary with a plutonic member of the Ladakh batholith, at the lower end of the valley (Dasu). Going up the Turmik valley, the foliation rotates from a northern to an eastern dip. In the upper reaches of the valley, the foliation is strongly refolded by a crenulation that has accompanied, under greenschist metamorphic conditions, the differential rise of the HHC gneisses.

L/80. Le Fort, P., Tongiorgi, M. & Gaetani, M., 1994. Discovery of crystalline basement and Early Ordovician marine transgression in the Karakoram mountain range. *Geology* 22, 941-944.

A granite pluton intruding low-grade quartzites and migmatites lies north of the Karakorum axial batholith of Cretaceous to Miocene age. The pluton is covered by transgressive litharenite and slate that contain a fairly rich assemblage of acritarchs of Arenigian age (Early Ordovician), belonging to the Peri-Gondwana biogeographic province. This is the first time that crystalline basement has been found in Karakorum and acritarchs in central Asia. These discoveries add new evidence that the Karakorum microplate, together with the Helmand block of central Afghanistan and the Lhasa block of Tibet, belongs to a Cimmerian domain at the northern fringe of Gondwana.

Key words: Ordovician, marine transgression, granite pluton, Karakoram.

L/81. Le Fort, P. & Villa, I., 1998. Pseudotachylites at crustal scale in Karakorum: the Thui pseudotachylite, northern Pakistan. *Geological Bulletin, University of Peshawar* 31 (Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop), 114-115.

The Karakorum mountain belt is typically divided into three main units: a northern sedimentary belt (NSB) and a southern metamorphic complex (KMC) separated by a central granitoid batholith (CGB) often referred to as the Axial batholith. In the western part of the Karakorum Mountain, two crystalline belts occur: a northern Hindu Raj belt, that includes Darkot pass and Garmush crystalline masses, and a southern Ghamubar belt, that are separated by the Darkot unit of mildly metamorphosed sedimentary series (see Le Fort & Villa, this volume).

In 1996, during the course of our regional reconnaissance and mapping of north-western Karakorum, with Maurizio Gaetani, we have discovered that the northern side of the Ghamubar belt is profusely invaded by a band of pseudotachylite. From north to south, the generally north-dipping section comprises:

the 4 to 7 km wide Darkot unit that had yielded Permian fossils and where we have retrieved Triassic megalodonts, and possible Cretaceous rudists (Gaetani, pers. comm., 1996); a tightly folded and metamorphosed contact zone, about a 100 m thick, mainly made up of black silicic schists at the top and quartzites at the base; the km-thick zone of Aghost banded gneisses, mostly granitic, but also containing very dark biotite and/or amphibole gneisses, as well as several group of layers of marble, presenting tight isoclinal folds usually north-verging. The Thui pseudotachylite fringes the northern boundary of this Aghost formation; a several km thick and massive zone mainly composed of biotite-garnet-sillimanite gneisses interlayered with granitic gneisses and partly migmatized. To the south, this zone is intruded by the Ramach granodiorite and the Ghamubar porphyritic granite (Ghamubar plutonic unit).

We have followed the Thui pseudotachylite for more than 40 km East-West, between Gazin glacier (Yarkhun valley), and summer settlement of Ghamubar (Darkot valley) at the eastern foot of the Ghamubar pass. More to the east, the pseudotachylite seems to pass to ultramylonitic bands within the Aghost gneiss. Vertically, it extends for nearly 3 km. The best set of outcrops is located in the upper Kerun Bar valley where the pseudotachylite forms most of the southern slope, and has a total thickness probably exceeding 10 m.

In the field, the rock appears as centimeter- to millimeter-thick black streaks anastomosing within the Aghost gneiss, disregarding the orientation of the metamorphic foliation. The disposition of the veinlets reminds of the hydraulic fracturation. The intruding dark veins have a glassy appearance, a conchoidal fracturation, and contain many cataclastic disrupted remains of the enclosing rock. Under the microscope, the veins have an isotropic texture. In the "basal shales" of the overlying Darkot group, the pseudotachylite develops a few meters thick "contact metamorphism" with micas and, occasionally, garnet. It is very little deformed: on a unique outcrop, we found it to be folded at 50 cm-scale. For the moment, ³⁹Ar/⁴⁰Ar dating by stepwise heating shows the predominance of inherited clasts from an older protolith. This apparently largest so far discovered pseudotachylite, is related to the fast collapse of the sedimentary cover along the top of the southern crystalline mass. One of the latest tectonic movement of the region, it has produced the Darkot graben.

L/82. Leghari, A.L., Khan, I.H., Khan, F. & Wazir, A.K., 1986. Occurrence of sulphide mineralization in Nomal area (Toposheet 42 L/8), Gilgit District, Pakistan. *Geological Survey of Pakistan, Information Release* 268.

Massive sulphide mineralization zone have been found in volcanics and metasediment arc rocks (Greenstone Complex) of Lower Cretaceous age in Nomal area about 25 km north of Gilgit (toposheet No.42 L/8). The mineralization is exposed in an area of 7.5 sq.km approximately. This sulphide zone is recognized as highly weathered and altered product of original rocks being pale, brownish, reddish and black in colour in the upper portion of the outcrop. During geological mapping of the area, 29 samples were collected and chemically analysed.

Majority of samples show very encouraging anomalies of massive sulphide mineralization. The metallic content of analysed samples (Table 1) shows that out of 29 samples, all samples contain Fe (averaging 4.17%), 27 samples with Mn (944 ppm), 25 samples have Cu, (353 ppm), 22 samples average in Zn (108 ppm), 6 samples with Pb (550 ppm), 2 samples show content of Au (as 0.65 and 1.03 ppm), two samples have Ag (one with 69 ppm content and other with traces) and finally 9 samples show traces of Mo. Two samples collected from Naltar Gah, northwest of Nomal where volcanics are exposed contain Mn (as 848 and 986 ppm) and Cu (as 7900 and 350 ppm), (Table-1). This report is based on field investigations and chemical analyses, and will be followed by a more comprehensive account of field work and laboratory studies which may prove the area promising for further study of sulphide mineralization.

Key words: Sulphide, mineralization, Nommal, Gilgit.

L/83. Leghari, M.B., 1990-91. The geology, stratigraphy, sedimentation and micro-paleontology of Jabri area District Haripur Hazara (NWFP), Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 106p.

The project area is located in district Haripur (N.W.F.P). It covers about 60 sq. km. It is the part of topographic sheet No.43 G/1 published by Survey of Pakistan at the scale of 1: 50000. Geological map at the scale 1:12500 of Jabri, Akhora, Faqir Muhammad, Lassan and Dunna Naural area is presented along with complete record of Pre-Cambrian to Eocene rock units especially, Hazara Formation, Samana Suk Formation, Chichali formation, Lumshiwal Sandstone, Kawagarh Limestone, Margala Hill Limestone, Chorgali Formation, exposed in the area. On the basis of field observations and petrographic studies the depositional environments of rock units have been interpreted. The formations exhibit varying fauna and lithology and microfacies from bottom to top.

Basal unit i.e. Hazara Formation which is predominantly slates and Samana Suk Formation which is mainly oolitic Limestone and shows shallow marine environment. The Chichali Formation which is dominantly Black slates with Iron Pyrite nodules, is the result of anaerobic conditions (lagoon environments) Glauconitic and ferrogenous Sandstone of Lumshiwal Formation shows open marine shelf environment. Kawagarh Formation possess mainly, fine grained micritic Limestone, which show deep sea environment.

Hangu Formation having laterite Bauxite, limonite, quartzite, red clays, Oolitic Haematitic sandstone and Carbonaceous shales which represent facies change and shows that the area was eroded during that time of deposition and marks unconformity between Cretaceous to lower Paleocene which is the result of regression of the sea for long period. Lockhart Limestone is mainly nodular, Limestone, medium to fine grained with bituminous smell having shales and marl at various places which shows shallow marine environment.

Patala Formation having Khaki shales with fossiliferous Limestone and marl which shows that the environment is shallow marine (Circa littoral sub zone).

Margala Hill Limestone is fossiliferous, nodular Limestone, which also shows shallow marine depositional environment. Chorgali Formation consists of Limestone flaggy marly having abundance of fossils of larger sized forams. It shows shelf environment. The thin section slides from Jurassic to Eocene rock units have been studied. Petrographically Samana Suk Formation (Jurassic) Lockhart Limestone (Paleocene) and Margala Hill Limestone (Eocene) have been studied in detail.

Samana Suk Formation is normally wack to pack stone, according to Dunham's classification, fossiliferous to packed biomicrite, according to Folk's classifications, Lockhart Limestone is normal to wackstone according to Dunham's classification and biomicrite according to Folk's classification. Margala hill Limestone biomicrite, biosparite and spary biomicrite according to Folk (1962) according to Dunham (1962) it is dominantly wackstone, grain stone and pack stone. The measured stratigraphic section of the rock units from Pre-Cambrian to Eocene is presented in Lithology. No. 5 (Pocket). Tectonically the area is highly disturbed, being involved in Himalayan Orogeny. Geological sub surface structures are described with the help of cross section, Almost all the structures follow the general trend NE-SW. From the cross section line along AB shows that intensive deformation in the area. Some important folds are Dunna Naural anticline, Dotara anticline and syncline, Dubran anticline, Langrial syncline. The project area is highly faulted, the major faults are Karral Haro thrust fault, Langrial Thrust fault,

Kohala Lasan fault, Jabri fault, Dubran fault. The Economic potential of Limestone of various rock units, laterite and aggregate have been discussed.

L/85. Lemennicier, Y., Le Fort, P., Lambardo, B., Pecher, A. & Rolfo, F., 1995. Tectonometamorphic evolution of the central Karakoram (Baltistan-Northern Pakistan). Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich), Switzerland.

The tectonometamorphic history of the Karakorum has already been considered by several workers, e.g., Bertrand et al (88), Allen & Chamberlain (91), Searle & Turrill (91), but timing and interpretation of this evolution are still discussed. We present here new structural and metamorphic data from the Chogo Lungma glacier area and Basha valley, at the northeastern side of the Nanga Parbat - Haramosh spur.

A multi-stage structural evolution has been observed, including a first cryptic tectonometamorphic event (not visible at field scale but deduced from the mineral fabric and chemical zoning of minerals), followed by two main syn-metamorphic episodes plus a late folding event.

The first event (we may call it D0, the first event recognized in the field being referred to as D1), is defined by a metamorphic cleavage within garnet porphyroblasts, underlined by quartz and opaque inclusions, and only visible in the innermost part of garnet. This cleavage is oblique on the main foliation, which at turn can be overprinted by the later garnet rims.

The main tectonometamorphic event (D1) is characterized by south vergent 61 isoclinal folds (Fig.1-a) at all scales (plurimillimetric to plurihctometric), associated with a metamorphic axial-plane cleavage Si. The axial planes of those folds always strike around N110°E, with a dip of 60° to 70° northward. The plunges of the fold axis are dispersed in the average axial plane, and are usually steep (pitches from 70°NW to 60°SE). It indicates that the folds were probably formed in response to a high flattening rate of deformation, with vertical extrusion of the pinched material. The predominantly flattening regime of deformation is also emphasized by the dispersion of boudin axes in the flattening plane, the presence of circular flattened enclaves, as well as the scarcity of coherent shear criteria. A medium pressure / medium to high temperature peak metamorphism (Mi) with Grt-Bt-Mu-Ky paragenesis corresponds to D1 (620 to 730°C and 7.5 to 11 Kbar; Fig. 2).

The D2 tectonometamorphic event corresponds to the development of several conical dome structures, in which D1 isoclinal folds are refolded. The dome structures, drawn by the main metamorphic cleavage inherited from D1, have N110°E to N140°E elongations. The S₂ cleavage is scarcely individualized as it usually corresponds to a reworking of Si. For this reason, it is often difficult to interpret metamorphic fabrics. In some areas, late evolution of the D₂ doming deformation is marked by a crenulation. Petrologically, D₂ is characterized by shearing and boudinage of M1 minerals, and by development of sillimanite. Thus, M2 corresponds to a retrograde evolution in the sillimanite field, with slight changes in temperature, but with a pressure decrease (from more than 7.5 Kbar down to 4 Kbar; Fig.2).

The interpretation of the dome structures can also be debated. The diapiric model, which may be now suitable to explain Archean domes (Choukroune et al, 1994), appears to be very much dependent of the rheology of the crustal component involved. The Metamorphic Core Complex model, associated with extensional mechanisms (Brun & Van Den Driessche, 94), fits rather well with the observed regional pattern, and could apply to the Panmah dome described by Bertrand et. al. (1988) north of Korophon. However, in the Chogo Lungma area, we have no evidence of extensional ductile fabrics or of normal faulting. For Ramsay (1987), doming can be due to heterogeneous shortening. Such heterogeneous strain is easily obtained around an indenter, such as the Nanga Parbat - Haramosh spur.

The D3 event corresponds to large undulations and open folds, as, e.g., the Spantik fold, which affect the D2 crenulation. Actually, D3 seems to be the continuation of D2. The complex tectonometamorphic evolution described here has also been observed by previous workers, but different interpretations have been proposed:

-For Bertrand et al. (1988), the evolution is a two-step's evolution, with (i) the main metamorphic episode related to the D1 isoclinal folds, predating the emplacement of the Mango Gusor granite, dated at 37 ± 0.8 Ma (U-Pb datation on zircon, Parrish & Tirrul, 1989), and (ii) a distinct Miocene metamorphism and deformation, with open folds and doming;

-For Allen and Chamberlain (1991), the whole tectonometamorphic evolution predates the Mango Gusor granite emplacement. They consider that the main metamorphic imprint was acquired earlier than the main deformation, and for them, the observed metamorphic pattern is mainly due to the stacking of two nappes, separated by a thrust.

In the Basha and Chogo Lungma area, the metamorphism is clearly synchronous with the deformation: kyanite grows in the S1 foliation plane and the sillimanite development corresponds to the doming deformation. This evolution can also be seen in the garnets associated with sillimanite, in which transects indicate a retromorphosis of the rim. Considering the timing of the tectonometamorphic events, for the doming phase (D2), preliminary $^{40}\text{Ar}/^{39}\text{Ar}$ results on amphibole and biotite (I. Villa, personal communication) give very young ages (<10 Ma), in good accordance with the Miocene ages proposed by Bertrand et al. (1988) for their second metamorphic and tectonic event. We have no good constraints for the D1 age. If we consider the interpretation of the previous authors, it could predate the Mango Gusor granite, and be related to the main continental collision. However, the pattern of the metamorphic PT path (Fig.2) corresponds to rapid exhumations' rates which do not fit quite well with a long gap of time between M1 and M2. The different phases could be part of a continuum of deformation.

We have not been able to define clearly the western prolongation of the Gama Sokha Lumbu thrust described by Bertrand et al (1988). However we have mapped orthogneiss sheets intercalated in the metasedimentary formations, north of Chogo Lungma glacier. They could indicate nappe stacking, but we have not found shear criteria at their contacts. They could also be interpreted as laccolitic intrusions of granites into the sedimentary pile, previous to the main D1 isoclinal folding and metamorphism. The occurrence of retromorphosed chistolitic andalusite (relics of contact metamorphism?) could validate this second hypothesis.

Altogether, the tectonometamorphic evolution of central Karakoram remains difficult to set into a global geodynamic frame. The recent age of the D2 event implies that most of the observed tectonometamorphic evolution is fairly young. The early evolution of this portion of crust may still be blurred by this more recent activity. If this is true, central Karakoram offers the possibility of being a young collision range.

Key words: Tectonometamorphism, Karakoram.

L/86. Lemmenicier, Y., Le Fort, P., Lombardo, B., Pêcher, A. & Rolfo, F., 1996. Tectonometamorphic evolution of the central Karakoram (Baltistan, northern Pakistan). *Tectonophysics* 260, 119-143.

New structural and metamorphic data from the Chogo Lungma glacier area and Basha valley enlighten the polyphased tectonometamorphic evolution of the Metamorphic Complex of Karakorum. A pre- to early D1 event is defined by a metamorphic cleavage in the core of some zoned garnet and staurolite porphyroblasts. The main tectonometamorphic event (D1) is characterized by N110°E south-vergent isoclinal folds associated with a metamorphic axial-plane cleavage formed in a predominantly flattening regime of deformation. It corresponds to a Grt-Bt-Mu-Ky peak metamorphism (M1: 620–730°C and 7.5–11 kbar). The D2 tectonometamorphic event corresponds to the development of several conical domes elongated striking N110°E to N140°E. The S2 cleavage is seldom individualized as it usually corresponds to a reworking of S1. In some areas, late evolution of D2 doming deformation is marked by a crenulation. Petrologically, D2 is characterized by shearing and boudinage of M1 minerals and by development of sillimanite. It corresponds to a decompressional evolution (7.5 down to 4 kbar) with only slight changes in temperature. A late event corresponds to large undulations and open folds which affect the D2 crenulation. We propose here a model of vertical plus dextral extrusion of the middle crust to explain the dome structures in Karakorum. The steep pattern of the metamorphic *P-T* path implies rapid exhumation rates and suggests that the different phases could be part of a continuum of deformation. Preliminary results by $^{40}\text{Ar}/^{39}\text{Ar}$ method give young cooling ages (<10 Ma) for the D2 event (Villa et al., 1996, this issue). Thus, most of the observed tectonometamorphic evolution in central Karakorum could be fairly young.

L/87. Lemennicier, Y., Le Fort, P., Pecher, A., Lapierre, H. & Rolfo, F., 1996. The Hemasil Syenitic Dome: An example of Miocene Syn-Orogenic Alkaline Magmatism, Karakoram-N

Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 85-86.

The Hemasil syenite is a small pluton intrusive in the continental formations of the Karakoram metamorphic complex near its southern contact with the Ladakh-Kohistan island arc formations. The syenite is emplaced in late Miocene times (Villa et al., in press) as a dome-shape pluton during the last tectonometamorphic event affecting the area in a compressive + transcurrent context associated with high denudation rates (Lemennicier et al. in press). It is a leucocratic rock with a fK-P1-B±Am±Sph main paragenesis and rare feldspathoids (sodalite). It is ferri-ferous and extremely potassic (7.0 to 10.6 wt% K₂O), with K₂O/Na₂O ratios from 1.15 to 5.24. La/Lu ratios are high (60.0 to 117.2). However, it shows a strong heterogeneity in trace elements composition with two main populations: population 1 enriched in MREE, Ba, Sr, V and slightly depleted in U, Th, Hf, Zr; population 2 normal in MREE, slightly enriched in HREE, enriched in U, Th, Hf, Zr, and strongly depleted in Ba. The same heterogeneity is observed in isotopic data recalculated at t=10 Ma (Fig. 2): population 1 has eSr = -2.3 and 3Nd = +4.3, whereas population 2 has positive eSr (+8.1 +/- 14.7) and slightly lower eNd (+3.0 to + 3.6). There is no isotopic correlation between the two populations. The variation cannot be explained by simple fractionation processes nor by alteration phenomena (very fresh rocks), but is more probably reflecting source heterogeneities or contamination processes. Whole rock isotopic ratios suggest a slightly depleted mantle source, mainly for population 1, but slightly enriched in strontium for population 2. However, trace elements indicate an obvious contamination, but different for each population. In addition, the trace element composition resembles that of the lower crust, except for incompatible elements. Lower crust can thus represent the (or a) contaminant. Actually, the Hemasil syenite, though it is emplaced in a continental collision chain, would result from partial melting of a mantle source contaminated, during its ascent, by a limited addition of lower crust material.

L/88. Lemennicier, Y., Villa, I.M., Le Fort, P., Pecher, A. & Briner, A., 1997. New ⁴⁰Ar/³⁹Ar age constraint on the metamorphic evolution of Karakoram metamorphic complex in Braldu and Chogo Lungma Areas, NW Pakistan. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 171-172.

The Karakorum Metamorphic Complex (KMC), the northern margin of the Cretaceous Neotethys, is composed of amphibolite facies gneiss (ortho- and para-) domes and metasedimentary formations. Its tectono-metamorphic evolution includes a first phase of south vergent isoclinal folding of unknown age and a second phase of doming considered as Tortonian (see Le Fort et al., 1995; Lemennicier et al., 1996; Villa et al., 1996).

Ten new samples from the KMC have been analyzed by ⁴⁰Ar/³⁹Ar stepwise heating: 4 amphiboles from the Basha-Chogo Lungma area and 6 micas from the Braldu valley on the Dassu dome, east of the Basha valley.

All amphiboles have been separated from orthogneisses, viz. mafic dykes or layers. The first amphibole (Moraine gl), collected far from the dome area in the isoclinally folded metasedimentary formations, is recrystallized. It gives a little-disturbed age spectrum around 55-60 Ma. The three other amphiboles come from the Mangol Block dome sector and give well-resolved mixed-phase degassing, with the younger amphibole generation ≤20 Ma and the older one >120 Ma for two samples.

From five granitic orthogneiss samples of the Braldu valley we dated five biotites and one muscovite. The biotites yield ages between 4 and 8 Ma, although they have been collected in similar structural position within the dome. The muscovite shows a clear mixed-generation spectrum with a young generation around 7 Ma and an old generation certainly >35 Ma.

Interpretation

The amphibole from the metasedimentary formations is sufficiently far from the dome area to be not affected by their thermal effect. Its age could be interpreted as the age of the amphibolite-facies isoclinal folding, and be related to the India-Asia continental collision for the western part of the Himalayan orogenesis. However, the span of some 45 Ma between folding and doming questions the continuum of metamorphism between the two phases (as had originally been proposed by Lemennicier et al., 1996).

The young amphibole generation of the three samples from the dome is compatible with our identification of a -10 Ma doming event in that area (Villa et al., 1996), and of a partial overgrowth of the amphibole, without rejuvenation of the old cores. The old amphibole generation suggests a minimum Jurassic age for the protolith of the KMC.

The ages of the micas from the Dassu dome confirm the already published data (~5 Ma: Searle & Tirrul; 1991; Smith, 1993). They show that the Miocene evolution of the Dassu dome and Basha valley domes is similar, and emphasize the 10 Ma event. The data scatter between 4 and 8 Ma for the biotites is difficult to interpret. Numerous (up to 10 Vol %) pegmatitic dykes cutting the foliation are present in this area, and they possibly have an influence on the age of the orthogneiss biotites. The mixed-generation muscovite gives informations similar to the amphiboles from the Basha domes.

These new data seem to point to a Paleocene metamorphism linked to south vergent isoclinal folding, but this age needs to be confirmed by a larger sampling in areas not affected by the doming. The second tectonometamorphic event results in neoformation of micas and (incompletely resolved) amphibole overgrowth between 10 and 4 Ma. Thus, the development of the KMC crust is not just a simple high-grade metamorphism followed by “episodic uplift”, but a more complex geological evolution comprised of a Mio-Pliocene shearing causing recrystallization of micas and amphiboles under amphibolite grade conditions.

L/89. Li, J., Derbyshire, E. & Shuyina, X., 1984. Glacial and paraglacial sediments of the Hunza valley, North West Karakoram, Pakistan - A preliminary analysis: In: Miller, K.J. (ed.), *The International Karakoram Project 2*, 496-535. Cambridge University Press.

The tills of the upper Hunza region include both lodgement and meltout types. Particle size analysis shows them to be relatively coarse-grained and somewhat positively skewed. There is evidence of modification of the particle size distribution by melt water eluviation, especially in the case of the Ghulkin and Pasu glacier deposits by the role of bedrock lithology and glacier size is also discernible. Tills currently being deposited are predominantly of meltout type: these have diffuse fabrics, rather granular matrixes and contain evidence of eluviation and collapse. Re-deposition of the abundant coarse supraglacial debris by sliding under gravity is common. The thickest exposures of compact and sheared lodgement till, on the other hand, are of Pleistocene age, especially those of the main valley (t2), diffuence col (t3) and expanded foot (t4) stages. There is no evidence of direct deposition of till by viscous flow either during or since the Pleistocene although the abundant debris flows do contain glacial material. It appears likely that the present combination of high-activity glacial regimes and arid to semi-arid valley floor climatic conditions have prevailed since at least the beginning of the late Pleistocene. The distribution of the dense, jointed lodgement tills of Pleistocene age is consistent with their deposition in generally free-draining environment beneath thick glaciers. The genetic classification of tills based on field relationships is generally confirmed by laboratory-derived data on particle size, particle shape, stone orientation and fabric.

L/90. Lillie, R.J., 1991. Evolution of gravity anomalies across collisional mountain belts: clues to the amount of continental convergence and underthrusting. *Tectonics*, 10 (4), 672-687.

A series of density models illustrates the gross form of free air and Bouguer gravity anomalies anticipated during ocean basin closure and consequent development of collisional orogens. When compared to gravity anomalies observed across some mountain belts, the hypothetical anomalies provide a clue to the degree of under thrusting of crust associated with one lithospheric plate beneath crust of the opposing plate margin. The results of the study suggest very early stage collision in the Ouachita Mountains of Arkansas and the Sulaiman Range of Pakistan, with thin transitional or oceanic crust still intact on the lower plate. In contrast, the Himalaya of Pakistan represent a much more advanced stage of collision, where continental crust may have underthrust the mountains for 600 km.

Key words: Collision belts, orogeny, geophysics, Suleiman Range, Pakistan.

L/91. Lillie, R.J., 1996. Foreland Fold-and-Thrust Belts of the Western Himalaya: diversity due to differing stages of continental collision. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 87-88.

The active foreland fold-and-thrust belts of western India and Pakistan show a variety of deformational styles that relate to the type of crust beneath the decollement. Studies incorporation surface, drill hole and seismic reflection profiles reveal differences in thickness of strata, lithology, and overthrust wedges taper; the differences relate to varying degrees of underthrusting of the Indian continental margin.

In India and northern Pakistan, there have been several hundred km of convergence since collision, so that the full-thickness craton India constitutes the underthrusting plate in the Sub-Himalaya (Duroy et al., 1989). The pre-collisional (Mesozoic and older) strata associated with the craton are only about 1 km thick; the buoyancy of the thick craton limits the thickness of post-collisional molasse to only 5 km. In the Sulaiman Range to the southwest, convergence since collision has been minor, so that the Mesozoic passive margin of India constitutes the lower plate. Seismic reflection profiles show that the undeformed sedimentary strata in front of the Sulaiman Range are 10 km thick (Humayon et al., 1991); cross-section balancing suggests that the deformed sedimentary package in the Sulaiman interior may be considerably thicker (Jadoon et al., 1994). These thicknesses are possible because the sediments rest upon thin crust of the continent-to-oceanic transition; the thick sediments are compensated by shallow mantle of the Mesozoic passive margin.

The nature of the crust of the Indian Plate influences the thickness and composition of overlying strata, thereby affecting the critical taper angle (basement + topographic slope) necessary for overthrusting (Davis and Lillie, 1994). The thin sedimentary package that overlies the Indian craton generally deforms in a brittle regime. Beneath the Sub-Himalaya of India there is strong coupling between sediments and basement, so that a broad critical taper angle ($>5^\circ$) is observed. An exception occurs in Pakistan, where evaporites of the Salt Range Formation behave ductily; the necessary critical taper angle is narrow ($\approx 1^\circ$; Jaume and Lillie, 1988). Beneath the central Salt Range and Potwar Plateau, seismic reflection profiles (Lillie et al., 1987) reveals that the basement slope alone is sufficient to provide critical taper; not topography slope is required, so that the region is translated southward with little internal deformation. In the eastern Potwar Plateau the basement slope is less than 1° , so that distributed deformation builds the topography necessary for critical taper (Pennock et al., 1989). In the Sulaiman region, carbonates of the Mesozoic passive margin may be buried so deeply that they are ductile, producing a narrow critical taper angle.

Along virtually all the deformation front of the Sub-Himalaya, only very young molasse is exposed. The notable exception occurs where the entire sedimentary section (Eocambrian to Recent) is brought to the surface along the Salt Range Thrust. Reflection profiles reveal that ramping occurs where the salt decollement is offset by a basement normal fault (Baker et al., 1988). The normal fault, within the underthrusting craton, was apparently caused by flexure of the Indian Plate as it was loaded by weight of the Himalaya. The modern expression of the flexural bulge is the Delhi-Sargodha Ridge, revealed by Precambrian outcrop in the Kirana Hills of Pakistan.

L/98. Lindsay, E.H., 1997. A new eumyarionine cricetid from Pakistan. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, 57.

Miocene deposits in four areas of Pakistan (Potwar Plateau, Trans-Indus area, Sulaiman foothills, and Balochistan) have produced a rich and diverse record of cricetid rodents that spans an interval of about 12.5 my (20 to 7.5 Ma). This interval apparently spans the “cricetid vacuums” of Europe (about 18-20 Ma) and North America (about 17-19 Ma); the Pakistan record fills a critical gap the history of Palearctic cricetid rodents and enriches our understanding of their evolution. A new species of Eumyarioninae cricetid, *Eumyarion kowalskii*, n.sp. is reported from the Sulaiman foothills of Pakistan. *E. kowalskii* probably gave rise to *Prokatzisamys* and the rest of the Rhizomyidae. In addition to Eumyarion, the Eucricetodontinae cricetids are represented in Pakistan by two species of *Primus*; the Democricetodontinae are represented by three species of *Spanocricetodon* and eight species of *Democricetodon*. The Megacricetodontinae are represented in Pakistan by four species of *Megacricetodon* and two species of *Puiyabemys*. The Myocricetodontinae are represented in Pakistan by two species of *Myocricetodon* and three species of *Dakkamyoides*. The Dendromurinae are represented by one species of *Potwarmus*, one species of *Paradakkamys* and two species of *Dakkamys*. The Miocene record of these six informal groups of cricetid rodents in Pakistan represents an important chapter in the history of muroid rodents.

The Cenozoic history of land mammals is marked by brief periods of intercontinental dispersal, termed dispersal events. One of these dispersal events includes the horse *Equus*, that evolved in North America, dispersed to the Old World in the Pliocene, and became a prominent member of Old World Pleistocene communities. *Equus* was derived from a species of the single-toed horse *Pliohippus*, known only from North America³. Timing for the Pliocene

dispersal of *Equus* into Europe was questioned⁴ following resolution for the appearance of *Equus* into the Siwalik sequence of Pakistan⁵. It seems that there were at least three major dispersal events of large mammals during the Pliocene (at 1.9, 2.6 and 3.7 Myr). We now report new data that limit the time of *Equus*' dispersal and into Europe to the 2.6 Myr dispersal event.

L/108. Lomdardo, B. & Rolfo, F., 2000. Two contrasting eclogite types in the Himalayas: implications for the Himalayan orogeny. Journal of Geodynamics 30 (1-2), 37-60.

The metamorphic evolution of granulitized eclogites recently discovered in the Eastern Himalaya compared to that of the eclogites of the Northwestern Himalaya (upper Kaghan Nappe and Tso Morari Dome) suggests the possibility of a Himalaya-wide eclogitic metamorphism of Early Tertiary age. Eclogites from the Northwestern Himalaya record peak metamorphic temperature of 580-600 °C at metamorphic pressures in excess of 23-24 kbar. They have

glaucophane as a retrograde phase and followed a nearly isothermal decompression path into the field of epidote amphibolite facies. In contrast, the Eastern Himalaya eclogites have a strong granulite-facies overprint at metamorphic temperatures of about 750 °C and pressures of 7-10 kbars, and followed a clockwise decompression path strongly convex toward high metamorphic temperatures. The main difference between the crystalline nappes of the Northwestern Himalaya and those of the East Himalaya appears to lie in the different P-T path they followed during exhumation. In particular the Northwestern Himalaya crystalline nappes lack the Miocene high temperature and low pressure overprinting which is characteristic of the Eastern Himalaya, where thermal relaxation of the thickened continental crust erased almost completely the mineralogical record of the early stage of continental collision.

Key words: Metamorphic evolution, eclogites, Kaghan valley, Himalaya.

L/109. Lombardo, B., Rolfo, F. & Compagnon, R., 1998. Glaucophane and barroisite eclogites from the High Himalayan Crystallines of the Kaghan valley, Pakistan Himalaya. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 116-118.

This report presents preliminary results of a petrographical and mineralogical study of the eclogite samples from the High Himalayan Crystallines (HHC) of the upper Kaghan valley in which Pognante discovered the presence of glaucophane.

The eclogites described here were collected by U. Pognante in 1991 just south of Babusar Pass, close to the summer settlement of Gittidas. They belong to the same suite as the garnet-omphacite-phengite-quartz-Futile eclogites dated as Eocene. The Gittidas eclogites show differences in mineralogy which reflect compositional differences in the protolith and were apparently equilibrated in different stages of the metamorphic history. In addition to omphacite, garnet and accessory rutile, most samples contain a significant amount of quartz (up to 15% vol.). The peak assemblage may also include kyanite, zoisite and ankerite or phengite. Poikiloblasts of blue-green or blue amphibole are conspicuous in thin section. In Fe-rich eclogite the amphibole is glaucophane, with high Al^{iv} (up to 0.2 atoms p.f.u.) and Ca in M4 (up to 0.4 atoms p.f.u.), whereas in more magnesian varieties it is barroisite with high Na in M4 (up to 0.7 atoms p.f.u.). Paragonite may be present either as part of the peak assemblage or as a retrogression phase after kyanite. A reddish epidote of allanite composition was found in the glaucophane eclogite.

Garnet is only slightly zoned in the glaucophane eclogite but displays strong prograde zoning in more magnesian varieties, with Fe decreasing and Mg increasing from core to rim. The iron-rich core is usually crowded with minerals of the peak assemblage, but locally inclusions of green and blue-green amphibole were also found. In foliated eclogites the garnet inclusions often define an internal foliation, commonly discordant to the main external foliation. In some garnet crystals, retrograde biotite appears to develop from the Mg-rich rim inwards, producing an atoll-like structure. Omphacite is frequently crowded with very small rutile needles, suggesting replacement of a former Ti-bearing igneous (?) pyroxene.

During retrogression garnet develops a thin corona of green amphibole, omphacite is replaced by a symplectite of albite + amphibole and phengite by a symplectite of biotite + feldspar.

The Gittidas eclogites are associated with a metasedimentary sequence of paragneiss with the high-pressure assemblage garnet-K-white mica-plagioclase-kyanite-staurolite-zoisite and accessory rutile, with retrograde margarite and biotite. Garnet is zoned, with Fe-rich cores and Mg-rich rims, its chemical composition and zoning being comparable with those found in the barroisite eclogites. This suggests that the quartzofeldspathic country rocks probably suffered the same high-pressure metamorphism as the eclogites did.

Equilibration conditions in the Gittidas barroisite eclogites have been estimated at T=600±30°C and P > 13 kbar from Fe/Mg partition in garnet-omphacite and garnet amphibole pairs, and from the jadeite content of omphacite (X_{jd} UP to 0.42). This estimate is close to temperature conditions estimated for the eclogites and high pressure metapelites of the North Himalayan Tso-Morari Dome (580±60°C and 550±50°C, respectively). However, the Tso Morari metapelites have jadeitic pyroxene, and hence this unit is believed to have equilibrated at metamorphic pressures significantly higher than the Kaghan HHC.

At the regional scale, metamorphic peak temperature recorded by both the Kaghan and Tso Morari eclogites during the Eocene high pressure event appear to be significantly different from those recorded by metabasaltic and metadoleritic garnet granulites in the HHC of the northeastern Nanga Parbat-Haramosh Massif, where geothermobarometry of the peak assemblage clinopyroxene-plagioclase-garnet-quartz-rutile suggests temperatures around 700'-800°C and pressures around 12-14 kbar for a younger (Miocene?) high pressure metamorphism affecting the High Himalayan Crystallines of the North Western Syntaxis.

L/110. Lombardo, B., Rolfo, F. & Compagnoni, R., 2000. Glaucophane and barroisite eclogites from the Upper Kaghan nappe: implications for the metamorphic history of the NW Himalaya. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 411-430.

This paper presents the results of a petrographical and mineral chemical study of glaucophane- and barroisite-bearing eclogites from the Upper Kaghan nappe in the Higher Himalayan Crystalline of the Pakistan Himalaya, and discusses the implication of the P-T path recorded in such rocks for the tectonic and metamorphic history of the NW Himalaya. The eclogites described here come from a previously undescribed outcrop at Gittidas, but belong to the same suite as the garnet-omphacite-phengite-quartz-rutile eclogites previously described elsewhere in the Upper Kaghan nappe. The metamorphic peak assemblage is garnet-omphacite-rutile-quartz in glaucophane eclogite and garnet-omphacite-zoisite-rutile $\pm$ kyanite $\pm$ phengite $\pm$ ankerite in barroisite eclogite. Most samples contain a significant amount of amphibole, white mica and quartz. White mica may be present either as part of the peak assemblage (phengite) or as a retrogressive phase after kyanite (paragonite). Amphibole is later than the metamorphic peak assemblage and is barroisite in most samples, but in relatively Fe-rich eclogite it is glaucophane with significant Na in the A site, Ca in the M4 site and tetrahedral Al. Garnet displays strong prograde zoning in the barroisite eclogites, with Mg increasing and Fe decreasing from core to rim. The iron-rich core is crowded with mineral inclusion of the peak assemblage, but inclusion of earlier paragonite, green and blue-green amphibole was also found. Peak metamorphic conditions in the barroisite eclogites have been estimated at $T=610 \pm 30^\circ\text{C}$ and $P=24 \pm 2$ kbar from Fe/Mg partition in garnet-omphacite pairs, and from the garnet-omphacite-phengite barometer. These values are close to the equilibration conditions estimated for the eclogites of the NORTH Himalayan Tso-Moriri Dome. Strong similarities between metamorphic evolution of the Upper Kaghan nappe and metamorphic evolution of the eclogite-bearing units in the Neelum Valley just to the east of the Kaghan Valley indicate that the eclogite extent, which was subjected to high pressure metamorphism in middle Eocene times. A comparison of the metamorphic evolution recorded in the eclogites of the NW Himalaya with that of the granulitized eclogites recently discovered in the E Himalaya suggests the possibility of a Himalaya-wide eclogitic metamorphism of pre-Miocene age. Therefore, the main difference between the Higher Himalayan Crystalline nappes of the NW Himalaya and those of the E Himalaya appears to lie less in the early part of their metamorphic evolution than in the different P-T paths they followed during exhumation.

L/112. Luff, I.W., Rex, D.C., Guise, P.G. & Windley, B.F., 1985. K-Ar and Ar-Ar dating of the Kohistan arc sequence, Northern Pakistan. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

The geological evolution of Kohistan is characterized by two stages of crustal accretion punctuated by a major tectono-metamorphic event. The initial island arc stage of Kohistan is represented by a sequence of dominantly meta-igneous rocks, which as a result of deformation and uplift provide a virtually complete section through the island arc. The arc sequence comprises, from north to south, the Aptian-Albian Yasin Group of upper-arc sediments, underlain by the island arc Chalt Volcanic series. The middle and lower crustal levels of the arc are represented by the mainly meta-volcanic Kamila Amphibolites, which are intruded by the Chilas Complex, an enormous mafic/ultramafic body which probably formed near the base of the arc. Metamorphic grade increases from greenschist in the north to granulite in the Chilas Complex. K-Ar dates from metamorphic mineral phases (mainly

hornblende) range from 7 to 340 Ma. Ar-Ar studies have shown that the oldest dates are due to excess Ar, with Ar-Ar patterns being generally U-shaped with minima in the range 70 to 80 Ma. The oldest reliable ages for pre-tectonic metamorphic rocks or post-tectonic intrusives are around 95 Ma, suggesting that the major deformational event took place shortly before this time.

Post-tectonic rocks in Kohistan are mainly represented by the Kohistan Batholith, a major I-type cordilleran plutonic suite forming the westwards continuation of intrusives in Ladakh and Tibet. The batholith has been dated using samples from three main areas: the northern margin gives ages in the range 32-95 Ma; the Karakoram Highway section southeast of Gilgit gives ages in the range 17-39 Ma, while at the southern margin of the batholith the 58 Ma Kalam andesitic Volcanics both overlie and are intruded by batholith rocks ranging in age from 40 to 94 Ma. In addition, an extensive post-tectonic dyke suite in the Hunza River section north of Gilgit gives Ar-Ar ages in the region 70-80 Ma. Young ages, down to 7 Ma obtained from rocks in the Indus Valley Section probably reflect recent uplift centered on the Nanga Parbat massif, as documented by Zeitler using fission track methods.

The major deformation event affecting the original island arc sequence in Kohistan must have taken place after the deposition of the Yasin Group sediments but before the oldest undeformed plutonics of the batholith at 95 Ma. This event is correlated with the formation of the Northern Suture and implies that the Kohistan Arc originally formed near the southern margin of the Asian Continent and was generated above a northwards-directed subduction zone. Continued northwards subduction following the initial collision with the Asian Continent led to the development of the Kohistan Batholith at an Andean-type margin. Major magmatism ceased around 40 Ma, close to the age of final collision with the Indian Continent, though the youngest intrusive rocks were emplaced close to 30 Ma.

L/113. Loucks, R.R., Ashraf, M., Awan, M.A., Khan, M.S. & Miller, D.J., 1992. Subdivisions of the Kamila amphibolite belt in southern Kohistan island arc complex, Pakistan. *Kashmir Journal of Geology* 10, 147-152.

Previously known Kamila Amphibolite Belt has been studied further now in details and found to consist of three principal subdivisions. These are Dasu, Kayal and Patan complexes underplated successively. They are composite of several mafic-ultramafic cumulate intrusions that vary in degree of metamorphic hydration and deformation. The Dasu Complex Indus Valley consist of extremely deformed, polymetamorphosed, epidote-garnet amphibolite banded gneisses. These record metamorphic P-T conditions averaging 5.5-6.5 kb and 520-580°C. The Kayal Complex consists chiefly of garnet-epidote amphibolites with strong foliation but only rare gneissic segregation banding with igneous hornblende and layering. Metamorphic assemblages record P-T conditions of about 7 kb and 620°C near base. The Patan Complex is massive to modally layered and locally crossbedded gabbro-norite at base to hornblende-gabbro-norite and diorite in the upper part with magmatic-epidote tonalite adjacent to its roof. Mineral geobarometry yields a pressure of 7.5 kb near roof. The stacking thus formed by a process whereby a thick crust of continent-like thickness and composition developed by repeated episodes of igneous intrusion along Moho.

Key words: Ultramafics, metamorphisms, Kamila amphibolites, Kohistan island arc.

L/114. Loucks, R.R., Miller, D.J., Ashraf, M., Awan, M.A. & Khan, M.S., 1990. The Jijal complex: Layered mafic-ultramafic arc accumulates from the crust-mantle boundary Pakistani Himalayas. *EOS*, 71, p 664.

The mafic to ultramafic rocks of the Jijal complex are cumulates that have formed under high pressure granulite facies conditions. These rocks crystallized from magma at the crust-mantle boundary.

L/115. Loucks, R.R., Miller, D.J., Ashraf, M., Awan, M.A. & Khan, M.S., 1992-93. Principal subdivisions of the southern amphibolite belt in southern Kohistan. *Regional Postgraduate Training Course in Plate Tectonics*, Punjab University, 37-38.

We have mapped the principal lithologic units and structural features of southern Kohistan along a succession of north-south traverses in the valleys of the Panjgora River (Dir), Swat River, Indus River (Besham northward), and another north and south from Chilas. Each traverse extends from the Main Mantle thrust northward to the southern

part of the Kohistan batholith. We have found that the region previously referred to as the "Southern Amphibolite Belt" or "Kamila Amphibolites" is in fact a composite of several mafic - ultramafic cumulate intrusions that vary in degree of metamorphic hydration and deformation, and can be correlated east-west from one traverse to another to develop a consistent "stratigraphy" of layered cumulate complexes in the lower crust of the Kohistan arc. From the deepest level upward, the four principal cumulate intrusions are the Jijal Complex which is overlain by the Patan Complex that is in turn overlain by the Kayal-Chilas Complex, which is overlain by the Dasu Complex. The contact of the Jijal Complex with the Patan Complex is everywhere a thrust fault contact. The contact Of the Patan Complex with the Kayal-Chilas Complex is an igneous intrusive contact where exposed in the village of Khwazakhela in Swat and along the Karakoram Highway (KKH) 9 km north of Patan village. The roof of the Kayal-Chilas Complex intrudes the gneissic Dasu Complex in upper Swat 18 km north of Bahrain, and along the Karakoram Highway 31 km north of Patan, and in Kiner Gah 5 km north of Chilas town.

L/125. Lyman, B.S., 1872. The topography of the Punjab oil region. American Philosophical Society Transactions, New Series 15, 1-14.

The Punjab oil region is in the corner between Cashmere and Cabul, and wholly between north latitude 32° 31', and 33° 47', and east longitude (from Greenwich) 71° 18', and 73° 5'; a nearly square space about a hundred miles long east and west by ninety miles wide, north and south.

Just inside the northeast corner of this square is Rawul Pindee, the largest town of the region, with about twenty thousand inhabitants; just inside the southwest corner is Pind Dadun Khan, a town of about twelve thousand inhabitants; and just inside the southwest corner is the ancient uninhabited ruin of a walled town, now called Kafir Kot. Just within the northwest edge of the region, and less than twenty miles from its eastern edge, stands the little village of Shah kee Dheree, on the site of the ancient capital Taxila, where the king Taxiles hospitably entertained Alexander the Great. The small town of Attok, where Alexander crossed the Indus into India, is only ten miles north of the middle of the northern edge of the square. The famous Muneekyala Tope, built by king Kanishka, about the Christian Era, to mark the spot where Booddha in compassion gave his own flesh to satisfy the hunger of a starving tiger, stands a little outside the square, fifteen miles southeast of Rawul Pindee.

The river Indus enters the square about the middle of the northern edge, and leaves it at the southwest corner. The Jhelum River (the "fabulosus Hydaspes" of the ancients), one of the five rivers that gives its name to the Punjab, flows across the southeast corner, past Pind Dadun Khan, southwesterly towards the Indus. The centre of the region is drained by the Sohan, which rises near Rawul Pindee, and flows west southwest to the Indus.

The region lies, then, mostly between the Indus and Jhelum, in what is called the Sind Sagur Doab (two rivers), and it is mainly in the mountainous or hilly part (Kohistan) of the Doab.

Although the landslides have a history decades long, the land slide problem has more recently assumed heightened significance in relation to rapidly occurring economic and social change such as the introduction of wage labour and seasonal outmigration.

M/4. Madin, I.P., Lawrence, R.D. & Rehman, S., 1984. Neotectonics of the western Haramosh Range. *EOS* 65, p.1094.

The structure bounding the western Haramosh range has been mapped as part of the MMT, the suture between Indian and Asia. Recent mapping indicates that this structure is an active E dipping fault zone separating "Indian" metasediments of the Haramosh range from diorites and amphibolites of the Kohistan island arc. Displacement on the fault is reverse slip, with some right lateral strike slip. The bedrock trace of the fault is marked by gouge and mylonite zones, drag folds, intense hydrothermal alteration and active hot springs. The width of the fault zone and associated mylonite zones implies displacement on the order of kilometers.

Neotectonic activity is indicated by deformation of Wisconsin age till and glaciofluvial deposits and recent talus slopes. Laminated fluvial sands beneath Wisconsin age basal till are tilted 20 to 40 degrees. A scarp in Wisconsin till has a vertical displacement of 122 meters. Assuming till deposition ceased 8,000 to 12,000 years ago, this scarp represents an uplift rate of 1.0-1.5cm/yr, comparable to regional uplift rates for the area calculated by Zeitler (1982) on the basis of fission track annealing dates.

Key words: Haramosh, neotectonics, Western Himalaya.

M/5. Madin, I.P., Lawrence, R.D. & Rehman, S., 1989. The Northwestern Nanga Parbat-Haramosh massif: evidence for crustal uplift at the north-western corner of the Indian craton. In: Malinconico, L.L. & Lillie, R.J. (Eds.), *Tectonics of the Western Himalaya*. Geological Society of America Special Papers 232, 169-182.

The Nanga Parbat-Haramosh (NPHM) massif is a unique structural and topographic high in the northwestern corner of the Himalayan convergence zone. Previously, the NPHM was thought to be bounded by the Main Mantle Thrust (MMT), a fault along which the Kohistan-Ladakh island arc was obducted onto the northern margin of India. This study presents field evidence that the recently active dextral reverse Raikot fault truncates the MMT and forms the western boundary of the NPHM.

The Raikot fault separates medium-grade, Mesozoic to middle Cenozoic mafic metasedimentary and intrusive rocks of the Kohistan Island arc (Kohistan Sequence) from high-grade Proterozoic metasedimentary rocks (Nanga Parbat Group) and orthogneisses of the Indian craton. The Kohistan Sequence rocks have experienced one tight to isoclinal folding event, probably associated with obduction of the island arc, and a second folding event associated with movement on the Raikot fault. The Nanga Parbat Group rocks were transposed by an early (possibly Proterozoic) isoclinal folding event and have subsequently been folded around east-trending axes in the early Cenozoic by the obduction of Kohistan, then around north-trending axes in late Cenozoic time in association with the uplift of the

NPHM and initiation of the Raikot fault. The Raikot fault consists of both mylonite zones and numerous major and minor faults. Slickensides and mylonitic lineations both indicate dextral reverse slip. The Raikot fault and associated folds appear to have accommodated as much as 15 to 25 km of uplift during late Cenozoic time. The localization of the uplift and the involvement of the Moho suggest that the Raikot fault follows a major crustal structure, possibly a pre-collision Indian plate boundary. If this is the case, rotational underthrusting of greater India along the MMT would require dextral slip along the Raikot fault. It is proposed that the Raikot fault is a terminal tear fault on the MCT.

M/8. Maheo, G., Rolland, Y., Guillot, S. & Pecher, A., 2001. Metamorphic and magmatic evidence for slab breakoff process below NW Himalaya. *Journal of Asian Earth Sciences* 19, 43-44.

In the southern Karakorum, NW-SE metamorphic zonation coeval with nappe stacking between 90 and 37 Ma is crosscut by a recent (20-5 Ma) E-W thermal anomaly, underlined by migmatitic domes North of the MKT suture zone. These domes evolved in two stages. Mid-crustal granulitic rocks were first heated from below 600°C to above 750°C during a slight pressure drop, from 0.7 to 0.5 GPa. This heating triggered muscovite and biotite dehydration melting. The retrogressive PT path crosscut the relaxed geotherm of a tectonically thickened crust. Further, geochronological data suggest rapid cooling and rapid exhumation rate ($>5 \text{ mm y}^{-1}$) since 6 Ma, and structural analysis show that the observed retrogressed P-T-t path can be explained by rapid exhumation during fold amplifications of previously molten midcrustal levels in a N-S shortening context. The main question raised by this evolution is: how to explain the formation of HT granulites in the India-Asia convergent context? These granulites are temporally and spatially associated with granulites and lamprophyres. On the northern edge of the domes area, the 20 Ma Baltoro batholith and associated lamprophyres as well as Hunza dykes show initial ϵNd (-13 to -6) and $87\text{Sr}/86\text{Sr}$ (0.705-0.725) intermediate between crustal and mantle isotopic end members (Searle et al., 1992; Crawford and Searle, 1993). South of the Baltoro batholith, close to the Dassu Dome, the 9-10 Ma Hemasil syenite and associated lamprophyres have much higher initial ϵNd (3.0-4.4) and lower initial $87\text{Sr}/86\text{Sr}$ (0.704-0.705) (Lemennicier, 1996), suggesting increased contribution of a mantellic source. Similar geochemical characteristics have been found in Neogene (23-12 Ma) volcanic rocks of S-Tibet, close to the Indus suture zone. The selective enrichments in LREE vs. HREE and in LILE vs. HFSE and intermediate mantle-crust isotopic signatures have been explained to result from melting of a metasomatized lithospheric mantle with little crustal contamination (Turner et al., 1996; Miller et al., 1999). The increased mantellic affinity of Hemasil syenite compared to Tibetan volcanics could be interpreted as a result of the melting of metasomatized asthenosphere below Karakorum, in the mantle wedge above subducting Indian lithosphere. Such magmatism and associated metamorphism with a specific location suggest heat advection through mantellic magmas intrusions. In S-Karakorum this narrow E-W striking zone of thermal anomaly is underlined by a strong negative gravity (bouguer) anomaly, which can be due to a hot body underplate below the crust. In the India-Asia convergent context, we propose that this tectono-metamorphic and magmatic evolution is due to slab breakoff of the Indian continental lithosphere starting at circa 20-25 Ma. Moreover, magmatic evolution is consistent with melting of a deeper mantellic source (from lithosphere to asthenosphere), related to a downward propagation of the slab gap.

M/10. Mahmood, A., 1985-87. Geology of Dunga Gali-Barian Area, District Abbottabad. M.Sc. Thesis, Punjab University, Lahore, 105p.

This report incorporates a comprehensive geological study of nearly 25 sq. km. area between Dunga Gali and Barian on the Murree-Abbottabad road. The study includes the preparation of a geological map on the scale 1:7040. Stratigraphically the rock units range from Upper Jurassic to Eocene and represent the sequence of the Hazara Province of the Kohat-Potwar Basin. It is primarily a limestone-shale sequence reflecting a stable shelf facies. Structurally, the area shows the development of a few synclinoria and anticlinoria, within which a generally tight parallel to similar asymmetric to overturn style of folding predominates. A number of dip-slip-strike faults, both of the normal and reverse type are present. A petrographic study of all rock units, based on fairly representative field sampling, is also present.

Key words: Geology, Abbottabad, Hazara.

M/11. Mahmood, A. & Ahmad, S.A., 1986. Petrography and geology of the Jogabunj-Sadiqa banda area, Dir District, Pakistan. *Acta Mineralogica Pakistanica* 2, 93-99.

A geological map covering about 66 square miles of the Jogabunj-Sadiqa banda area on the scale of 1:0.789 miles is presented. The area is mainly composed of metasedimentary complexes; the units are amphibolite, granodiorite, pegmatite and hornblende. The amphibolite are the oldest rocks. After their formation, an acidic magma intruded the amphibolites, resulting in the formation of granodiorite: the contact between them is sharp. Dykes are present both in granodiorite and amphibolite, showing the late residual composition of the granodioritic magma; quartz-feldspathic and pegmatite veins are present in the whole area. Garnet-bearing quartzofeldspathic rocks are intrusive. Modal analyses and petrography of 32 selected samples are presented and mineralogical statistical variation diagrams are plotted. The petrogenesis of the amphibolite and granodiorite is briefly discussed.

Key words: Petrography, amphibolites, granodiorite, Dir.

M/12. Mahmood, A., Ahmad, S.A. & Dawood, H., 1985. Geology of Warai-Jogabung area, District Dir Trans Himalayan island arc, Pakistan. *Acta Mineralogica Pakistanica* 1, 83-89.

A geological map covering about 45 miles² of Warai-Jogabung area of Dir district from toposheet 43 A/4 is presented. The area contains amphibolites, diorite and granite with small patches of quartzofeldspathic veins, pegmatites and hornblendites. The amphibolites are the oldest rock units formed from calcareous quartzite. Diorite late on intruded as patches veins and dykes of granitic material. Petrology of granitic rocks is presented in detail. Modal analyses and petrography of 24 selected samples are given.

Key words: Petrology, petrography, amphibolites, Dir, Himalaya.

M/14. Mahmood, F., 1985-87. Geotechnical studies of landslides with special emphasis on slope stability along Karakoram Highway (from Batgram to Thakot, District Mansehra). M.Sc. Thesis, Punjab University, Lahore, 95p.

The Project area is related to Hazara and Kohistan region of North West Frontier Province. Topographically the area is occupied by rugged rocks consisting of high peaks and alluvial deposits. The predominant, rock types are granite, granite gneiss, schists and various other minor bodies as dykes and sills. All the structural features coincide excellently to give NE trend that indicates NW-SE direction of tectonic forces.

The main objective of "Geotechnical Studies" is to analyse the scope of stability of rocks along roadside. For this purpose, various modes of failure, i.e. plane failure, wedge failure, toppling failure, rock fall, and circular failure etc. were observed. Theoretical models based on the actual readings (data) presented in the forthcoming chapters are intended to provide rational basis for the design of rock slope. It should however, be made clear that successful design of slope depends not only on the choice of correct theoretical model but also upon a number of other considerations which cannot be conveniently quantified.

A map has been provided which classifies the road segments as stable, unstable and potentially unstable. Stable segments are those which geometrically do not manifest any sign or chance of failure or show a high factor of safety i.e. 2.5 or 3. Unstable segments are those where small scale failures are kept on taking place with every successive rainfall. Similarly, potentially unstable segments are those which are stable in actual practice but the ratio of their resisting forces to driving forces is less than one.

Study of various roads alignment was made to emphasize on the effects of sliding. Different modes of failure were encountered, and their factors of safety were calculated. Finally, it was decided whether dangerous road or not and an attempt has been made to give remedial measures.

A comprehensive study of Geology and structure of Dhamtaur area is presented along with special constraints on the sedimentology of Hangu Formation and Lockhart limestone of Early Paleocene. Large-scale (1:10000) Geological mapping of a small segment of the Lesser Himalaya in the Dhamtaur area is presented. The lithostratigraphic unit range from upper Paleocene to Precambrian, Hazara Formation being the oldest. Structurally the area comprises NW-SE trending major anticlinorium. The folds are tight to isoclinal and opposing southeast and northwest vergence on the two sides of the lower formation. Some anticline shows plunge to the southeast direction. Almost all faults have vergence parallel to the folds developed in the core on the two sides of the main anticlinorium. Most are reverse faults although some may be of the normal type. Faulting appears to be dip-slip to oblique slip and in general involves a maximum displacement of few hundred meters.

Hangu Formation from Bagnotar and Mohar, District Abbottabad and from Chahla Bandi, Azad Kashmir has been studied for microfacies, petrographic characteristics, and environment of deposition and diagenesis in relation to sedimentary basin.

The formation shows variable lithology. The section from Bagnotar is totally residual deposit, whereas the sections from Mohar and Chahla Bandi are predominantly composed of siliceous clastics with few beds of residual deposits. The three topmost beds of Chahla Bandi section composed of coal and Bauxitic clay.

The environment of deposition varies from continental, supratidal, upper shore phase and lower shore phase. The section of Lockhart limestone near Chahla Bandi is thin to medium bedded. The Lower contact of Lockhart is disconformable with Hangu Formation and upper contact of Lockhart Limestone with Patala Formation is sharp unconformable. This section is comprises of 14 microfacies and 5 facies ranging from mudstone, wackestone and packstone, have been defined on the basis of field observation and petrographic studies. The deposition of Lockhart Limestone took place in open marine shallow shelf conditions. Neomorphism of syndepositional micrite has taken place under various conditions during different phases of tectonic activity. Mechanical and chemical compaction are present in the forms of aligned fracture and vug.

This report comprises a complete geological study of nearly 320 sq. km; located between and around Balakot-Garhi Habibullah. In the project area micaceous quartzites, quartz mica schists, garnet mica schists, dolomite, limestone, Sandstones and slates are encountered. A stratigraphic sequence has been worked out. The rocks extend in age from Precambrian to Miocene. Structurally, the rock, are folded into a number of major structures. The area comprises of major structures like Balakot Anticline, Garhi Habibullah syncline, Muzaffarabad fault and Murree Fault. Minor structures of the project area has also been discussed in detail. Hazara Kashmir syntaxis has a great influence on the stratigraphy, structure, and tectonics of the investigated area. In the field of economic geology a number of deposits including clays, graphite, limestone, feldspar, granites and sandstone have been discussed. This report also includes a petrographic description of the rock units as well as numerous sketch section and photographs, illustrating the geology of the area.

Key words: Geology, structure, Kaghan, Mansehra.

M/20. Mahmood, S., Sattar, A. & Khan, I., 1985. The geology and structure of the central part of the Attock-Cherat Range, District Peshawar (N.W.F.P.), Pakistan. M.Sc. Thesis, department of Geology, University of Peshawar, 103p.

The area under investigation is a part of the Attock-Cherat Range which forms the southern boundary of the Peshawar Basin. The area is bound by upper Tarkhel village in the north, Khairabad-Nizampur road in the south, Inzari village in the east and Drangkhwar in the west. The relief of the area is moderate to high; the elevation range from 2500 to 3200 feet, the highest peak is 3200' feet high. The general trend of the Range is east-west which coincides with the strike of the rocks.

The area consists of three types of rocks i.e. the Precambrian Dakhner formation on the extreme north, the younger formations of tertiary sequence in the center and the rocks of Silurian-Devonian sequence forming the southern limits of the Attock-Cherat Range. An outcrop of Jurassic limestone is also observed.

Following lithological units are distinguished

1. Dakhner Formation	)	Precambrian
2. Darwazai Formation	)	
3. Hisartang Formation	)	
4. Inzari limestone	)	Silurian-Devonian
5. Jurassic limestone	)	Jurassic
6. Lockhart limestone	)	Paleocene

7. Patala Formation	)	Paleocene-Eocene
8. Murree Formation	)	Miocene
9. Quaternary Deposits	)	Recent

The area exhibits extremely complex structural features. One major thrust fault, running along the northern extremities of the area, traverse the area in the east-west direction. This thrust fault is known as the Cherat thrust. A gravity fault, which separates the Silurian-Devonian sequence from the tertiary rocks, run parallel to the Cherat thrust. Faults of smaller dimensions, which are oblique to the Cherat thrust, are also present in the area. Several Drag folds are present near the thrust which reflect the direction and sense of slip along the fault.

The Silurian-Devonian rocks are overturned in response to the thrusting from the north. Enough evidence is gathered supporting the overturning of the Attock-Cherat Range, its southern limb being eroded away by the Indus River and buried under the alluvium.

M/23. Mahmood, T., 1981-83. Geology and Petrology of Darel Valley (District Diamer). M.Sc. Thesis, Punjab University, Lahore, 54p.

This thesis presents a geological map of the 30 miles² of project area (DAREL) on scale 1 inch=1 mile. The project area (Darel) lies in Gilgit Agency district Diamer. The area is located in the centre of Kohistan. Area is disturbed tectonically, being involved in Himalayan Orogeny. The area is composed of igneous and metamorphic rocks. The main rock units in the area are Norite, Diorite, Amphibolites and Granodiorite. Mineralogical description and petrographic analysis of this rock are reported in detail. An attempt is made to interpret the petrogenesis of rock types. The thesis presents a detailed geological and petrologic investigation of the project area. Norite and amphibolites represent oceanic crust while diorite and granodiorite etc. represent plutonic equivalents of arc.

Key words: Petrology, petrography, Kohistan island arc, Himalaya.

M/24. Mahmood, T., 1986. Appraisal of two marble deposits from Northern areas, Pakistan. *Acta Mineralogica Pakistanica* 2, 161-162.

This is a short communication giving brief details of two marble deposits of northern areas. These are Khyber area, Gilgit district and Chutran area, Baltistan, to check the mineability of these marble deposits. Geochemical analyses of samples from these deposits are also given.

M/25. Mahmood, T., 1985-87. Geology and mapping of Dulai-Kohala area with special emphasis on engineering characteristics of soils. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 91p.

Nearly 175 square km area has been mapped from Dulai to Kohala on both sides of the river Jhelum. The aim is to study the engineering characteristics of soils in detail and to classify them for the civil projects.

The engineering characteristics of soil reveal that

(A=22.6 g-36.2 g)	(B=10 g-22.2 g)
(C=7.6 g-24.9 g)	(D=14.8 g-28.4 g)
(E=5.6 g-52.5 g)	(F=1.67 g-1.83 g)
(G= 62.7 -106.7) and	(H=14.9 lb/ft ³)

is found to be suitable for construction after compaction.

A- Liquid limit.

B- Plastic limit

C- Shrinkage limit

D- Moisture content

E- Swelling test

F- Compaction test

G- Soil hardness test

H- Field density by sand replacement method

M/26. Mahmood, T., 1986-88. Geology and Structure of Azizabad-Baragali Area, District Abbottabad. M.Sc. Thesis, Punjab University, Lahore, 166p.

Large-scale geological map at the scale 1:9434 of Azizabad-Baragali area is presented. A detailed description of the Precambrian to Eocene rock units specifically in the area of investigation has been recorded. On the basis of large number of sections measured and interpreted. A study of Kawagarh Formation indicates its deposition in deeper water above carbonate compaction depth. Subsurface structure has been described and illustrated in the form of a number of sections and stereograms. Most folds are open to tight asymmetric double plunging and trend NE-SW. A latter fainter NW-SW trending fold set is superimposed on the earlier NE-SW. The faults are dip-slip strike type some normal others reverse generally medium to high angle. Most structure verge to NW. The economic potential of various limestones, laterite and slate has been assessed and an analysis of Dor River aggregate carried out suggests that the Dor River bed gravels are unsuitable and even harmful for durable construction.

M/33. Majid, M., 1979. Petrology of diorites from the “Kohistan sequence”, Swat, Northern Pakistan. A genetic interpretation at plate scale. Geological Bulletin, University of Peshawar 11, 131-151.

Diorites and related rocks of calc-alkaline nature include by far the most dominant rocks of various composite plutons extensively distributed within the suture zone in the Kohistan Himalayas in northern Pakistan. The main Himalayan suture zone has been recently traced across Kohistan through the Districts of Hazara, Swat, Dir and Mohmand by Tahirkheli et al. (1979).

The development of the thick complex of various types of diorite, granodiorite, hypersthene gabbro and calc-alkaline volcanics (andesite-dacite-rhyolite) within the suture zone in Kohistan is unique because along the Tsang Po and Indus valley in the east, the suture zone is characterized by a belt of flysch and volcanics with some ophiolites

and “melanges” (Gansser, 1964, 1977) and to the west of Afghanistan it is marked by large “nappes” of typical ophiolitic rocks.

In a tectonic discussion of the Kohistan area it has been pointed out that igneous rocks within the “Kohistan Sequence” represent products of calc-alkaline activity, associated with the subduction of the floor of the former Tethyan Ocean under a marginal basin. The mineralogical and chemical constraints of the diorites and related rocks described in this paper from the Kalam area (between latitude 35°15' to 35°52' N and longitude 72°20' to 72°27'E) favor the possibility of their derivation as a result of the active consumption of the oceanic crust dragged beneath the marginal basin while the concentrations of major and trace elements within the studied suite are strictly against the process of partial melting of sialic crustal material due to the increased geothermal gradients. This point has been discussed further in this paper.

Key words: Petrology, diorites, plate tectonics, Kohistan, Swat.

M/34. Majid, M., Danishwar, S. & Hamidullah, S., 1991. Petrographic and chemical variations in the rift-related basic dykes of the Malka area (lower Swat), NWFP, Pakistan. Geological Bulletin, University of Peshawar 24, 1-23.

This paper deals with the petrography, mineral chemistry and rock chemistry of dolerite dykes of Malka (Lower Swat). These dykes intrude Late Palaeozoic Utlā granite and consist of variable amounts of plagioclase (An 53-59%), clinopyroxene (augite), ilmenite, hornblende, biotite, apatite. Altered varieties show amphibole (calcic), plagioclase (An 21-23), Fe-Ti Oxides, chlorite and epidote.

Clinopyroxene, amphibole (both primary & secondary) and plagioclase have been studied in detail. Chemical composition of these rocks exhibits transitional character between alkaline and sub-alkaline basaltic composition. Major oxides versus S. I. indicate evolved composition for these rocks. Whereas CMAS model of O' Hara (1968) show the fractionation control of plagioclase and clinopyroxene. Compositions of these dolerite dykes indicate their association with rifting of the northern margin of Indo-Pak plate.

M/36. Majid, M. & Paracha, F.A., 1980. Calc-alkaline magmatism at destructive plate margin in Kohistan, northern Pakistan. Geological Bulletin, University of Peshawar 13, 109-120.

Four episodes of calc-alkaline igneous activity have been identified in the crust of a fossil island arc, ‘the Kohistan Sequence’, in the Kalam area, Swat. The sequence which includes a thick complex of pyroxene granulite, amphibolite, various types of diorites along with metasediments and associated volcanics is 10-15 km thick and is presumed to have developed, as a result of subduction of the primary Tethyan oceanic crust beneath an arc during the suturing of Indo-Pakistan and Eurasia.

The calc-alkaline rocks within the sequence are divisible into two distinct associations. One of these, characterized by iron- and alkali-rich differentiation on variation diagrams, is volcanic, (the Utror volcanic), consisting of andesite, dacite, rhyodacite and rhyolite. The second association includes rocks varying from hornblende biotite diorite to pyroxene-biotite diorite. Analyses of these rocks, unlike the volcanics, display an iron- and alkali-poor and Mg-rich variation trend. Chemically these rocks have been distinguished into low-silica diorite, normal diorite, high-K diorite and granodiorite (Majid, 1979). The former two types contain less K₂O than the latter two.

Field evidences suggest that the volcanic phase follows plutonic activity within the province. Most of the first-order features of the studied suite are identical with the calc-alkaline rocks of the circum Pacific type. The petrochemical indices, which identify the Kohistan calc-alkaline rocks, reflect a pronounced episodicity in their evolution. The macro-episode of major significance defined in the proposed genetic scheme is synchronous with first major tectonic event, which is referred to as the subduction of the Tethyan ocean crust in the plate tectonic model of Kohistan.

M/37. Majid, M. & Shah, M.T., 1985. Mineralogy of the blueschist facies metagraywacke from the Shergarh Sar area, Allai Kohistan, N. Pakistan. Geological Bulletin, University of Peshawar 18, 41-52.

A new occurrence of the glaucophane bearing rock within the Indus suture zone is reported from the Shergarh Sar area in Allai Kohistan. Being composed mostly of quartz with small amount of white mica, glaucophane, chlorite and plagioclase etc. the rock is described as blueschist facies metagraywacke. Constituent minerals are analyzed with probe; and P-T conditions of metamorphism (about 7 kbars and 400-450°C) are calculated. Petrographic and chemical constraints of the constituent minerals oppose any retrogression or oscillatory transition in metamorphic conditions as noted in the blueschist rocks from Ladakh, and Shangla section of Swat.

Key words: Mineralogy, blueschist, Indus suture, Allai Kohistan.

M/38. Majid, M., Shah, M.T., Latif, A., Aurangzeb, & Kamal, M., 1981. Major elements abundance in the Kalam lavas. Geological Bulletin, University of Peshawar 14, 45-62.

Andesite and sialic eruptives of calc-alkaline affinity in the Kalam volcanic zone constitute the upper part of the 'Kohistan sequence' developed in the western branch of the Himalayan syntaxis between 71° E and 75° E. The sequence is interpreted as a complete cross section of a mature island arc formed by subduction during Mesozoic in the southern part of the Neotethys and obducted onto the Indian plate in Upper Cretaceous time. The Kohistan sequence includes a thick complex of amphibolites, hypersthene gabbros, pyroxene diorites, hornblende diorites, granodiorites, metasediments and volcanic rocks.

The potential usefulness of the geochemical parameters of the extrusive rocks from the Kalam area, Swat as tectonic fingerprints and genetic indicators is discussed in this paper. There is a close correspondence between the available petrochemical indices of genetic significance of the studied suite to the calc-alkaline volcanics in western and southwestern Pacific regions, which substantiates earlier workers designation of an Island arc environment in the Kohistan Himalaya during Mesozoic time.

M/39. Malik, A.R., 1987-88. Geotechnical study of slope stability problems along the Kohala-Muzaffarabad Road. M.Sc. Thesis, Punjab University, Lahore, 174p.

Two stratigraphic units i.e. Murree Formation (Miocene) and the Hazara Formation (Pre-Cambrian) exist along the Kohala-Muzaffarabad road. A major structural element (Jhelum Fault) extend full length of the area.

Kohala-Muzaffarabad road is an important link between Pakistan and Azad Kashmir. Unfortunately this strategic route is under constant threat due slope stability problems as a result of which huge landslides occur along this road from time to time. The present study is aimed at investigating and highlighting the causes of land sliding and proposing remedial measures. In order to achieve the above aims detailed geological mapping was carried out along the Kohala-Muzaffarabad road. Field measurements such as discontinuity survey, roughness profiles of joints, compressive strength and field density (Chapter VI) were determined. A large number of samples of soil and rocks were obtained and tests were carried out in laboratory (Chapter VI) for data to be used in the slope stability analysis. On the basis of prevailing conditions of lithology, structural and nature of discontinuities and materials, a broad classification of the area is made as:

Stable zones.

Potentially unstable zones

Unstable zones.

Field sketches of a number of landslides were prepared and the relevant data of each slide as far as discontinuity were collected so as to identify and analyse each slide accordingly.

An attempt has been made, in this study, to suggest economical and feasible remedies for preventing landslides.

M/40. Malik, I.A., 1967-68. Geological report on Kuhai-Chinar Area (Lower Swat). M.Sc. Thesis, Punjab University, Lahore, 73p.

Martin et.al. (1962) made a geological reconnaissance map of the Lower Swat-Indus Valley Region. The author worked in part of Lower Swat and did a detailed geological mapping (Fig.-I). The Ambela granitic complex of Martin et. al. includes both igneous and metamorphic rocks. The grade of metamorphism is however low.

The Field Report presents a gist of observations made during the field work as well as in the Laboratories. Field work is completed in about three months in two consecutive field sessions in 1967 and 1968. The laboratory work includes study of forty thin sections of different rock units, preparation of orientation diagrams from reading of joints and beddings, and optics of a mineral.

The object of this report is to give a comprehensive account of the geology of the area. This report includes the description of various rock units, with an emphasis on the petrogenesis. The long discussion has been summed a chronological sequence given in "Conclusions".

M/45. Malik, M.H., 1978. Some engineering geological properties of the sediments from two borrow areas at the Simly Dam-site Simly, Pakistan. Geological Bulletin, University of Punjab 15, 15-24.

The Simly dam-site on the Soan river near Rawalpindi is located at coordinates 33° 43' 45" N and 73° 20' 25" E. The various geological units present in the area belong to the Siwalik system. More than two million cubic yards of only silt and clay are required to be used in the construction of this dam. Two borrow areas namely Simly Plain and the Tamair deposits were therefore investigated for this purpose.

Undisturbed samples from both the borrow areas tested and an attempt is made to compare their engineering geological properties. The results are presented in the form of diagrams of the representative samples to make this paper brief.

M/47. Malik, M.H. & Farooq, S., 1992-93. Effect of tectonic disturbance on the stability of slopes along roads in mountainous regions. Regional Postgraduate Training Course in Plate Tectonics, Punjab University, p.30.

Slopes in mountain regions are vulnerable to structural disturbance in general. These changes in stability of slopes are related with the already existing structural elements as fractures in different lithologies along the Murree-Muzaffarabad Road and along the Karakorum Highway, reveal interesting relations with major structural features which are the results of movement of plates in the region. The proximity of major faults seems responsible for increased fracture frequency and instability of slopes along these roads. Statistical analysis of laboratory strength test data has been used for wedge failure in rock slopes. Surface roughness of joints and wall compressive strength along-with friction angle have also been used for analysis.

M/49. Malik, M.H. & Rashid, S., 1997b. Correlation of some engineering geological properties of the Murree Formation at lower Topa (Murree District), Pakistan. Geological Bulletin, University of Peshawar 30, 69-81.

Uniaxial Compressive Strength, Young's Modulus, Point Load Strength Index, Schmidt Rebound Hammer Number and Matrix (calcitic as well as clayey) are correlated for 90 samples (30 from each lithology of alternating sandstones, siltstones and claystones) to determine the effect of lithological boundaries and that of the cementing material. Correlation Coefficients of different combinations of Strength, Young's Modulus and Schmidt Hammer Rebound Number were determined. Similarly various combinations of mineral assemblages and matrix with clasts and lithological position of samples were tried and compared with strength. It is observed that strength is not only variable in each lithology but also changes with position of sample with reference to the upper or lower lithological boundaries. Laboratory tests on cores seem to be imperative for supplementing the field index tests on such detritus materials.

Graphite at Patlepani-Mohriwali area, District Muzaffarabad (A. K.) occurs in a skarn formed due to an intrusion of pegmatite in recrystallised limestone of Salkhala Series of Pre-Cambrian age. Skarn formed at the upper contact of pegmatite, devoid of graphite, is barren skarn, whereas, at lower contact is fully mineralised with graphite. Mineralised skarn show a well defined zonation pattern from pegmatite to amphibole-pyroxene-graphite skarn to pyroxene-amphibole-graphite skarn to plagioclase-garnet-graphite skarn.

Graphite has an average concentration of 12% and occurs in skarn as concordent lenses, disseminated flakes, bands and is formed in two phases; organic carbon present in original impure limestone was converted into amorphous to semi crystalline graphite during regional metamorphism of area. During the subsequent process of skarnification, this amorphous to semi-crystalline graphite was fully crystallized and being mobile migrated into low-pressure zones of skarn.

M/58. Malik, R.H., Schoupe, M., Fontan, D., Verkaeren, J., Martinotti, G., Ahmed, K.S. & Qureshi, S., 1996. Geology of the Neelum valley, District Muzaffarabad, Azad Kashmir, Pakistan. Geological Bulletin, University of Peshawar 29, 91-111.

The central and north-western parts of Neelum valley have been mapped, proposing a new lithostratigraphic division for the region. The area comprises two main tectonic units: the Lesser Himalayan Crystalline Unit (LHC) and the Higher Himalayan Crystalline (HLC), separated from each other by the Main Central Thrust (MCT). The two units are characterized by a similar stratigraphy and share a common low-grade metamorphic assemblage. They, however, differ in the intensity of the imprints of the Himalayan metamorphism. The lithostratigraphic units comprise, from base to top, Naril Group (Precambrian basement), the Kundalshahi Group (pre-Himalayan cover) and Surgun Group (an Upper Paleozoic to Mesozoic Himalayan metasedimentary cover comprising paragneisses, mica schists, marbles, amphibolites, calc-schists and impure quartzite). This lithostratigraphic sequence is intruded by a megacrystic granite, similar to that of Mansehra (Early Cambrian) and meta-doleritic dykes, correlated with the Permo-Carboniferous Panjal Trap volcanics. Geochemistry reveals an igneous granitic calc-alkaline origin for the Naril granulitic gneiss, whereas, the sediments of Kundalshahi Group are characterized by a high SiO₂ and highly variable trace element contents except REE. In the Surgun Group two types of marbles have been distinguished on the basis of high CaO and Low MgO. The amphibolites in the Surgun Group as well as of Himalayan cover share the same igneous protolith and are basaltic in composition. Geothermobarometric studies indicate polyphase metamorphic evolution for the lithological units of the Neelum valley in the Tertiary Himalayan event. The P-T-t path suggests a prograde metamorphic evolution up to Upper Cretaceous-Eocene times, followed by a retrograde path, essentially of decompressive type. The final part of the path being accompanied by a decrease in temperature. The LHC tectonic unit and a southern portion of the HHC unit followed a different P-T trajectory, under greenschist-facies conditions. The ⁴⁰Ar/³⁹Ar determinations on muscovite and biotite from these low-grade rocks yield middle Oligocene cooling ages. Four phases of deformation have been distinguished. Isoclinal overturned to recumbent folds represent the D1 and D2 phases; contemporaneous with the regional Himalayan metamorphism, during upper Cretaceous to Miocene. The MCT developed after D2 phase of deformation generating the LHC and HHC nappes and the reversed metamorphic zonation of Neelum valley. The D3 structures comprise of open large megascopic flexural slip buckle folds trending NE-SW. The D4 deformation affects the Hazara Kashmir syntaxis.

M/61. Malinconico, Jr. L.L., 1982. Structure of the Himalayan Suture Zone of Pakistan Interpreted from gravity and magnetic data. Unpublished Ph.D. dissertation, Dartmouth College Hanover, New Hampshire, 128p.

Two-dimensional analysis of gravity and magnetic data in northern Pakistan suggest that the Indian plate is being thrust under the Asian plate and that the major structures in this region dip towards the north.

In northern Pakistan the westward extension of the Indus Suture Zone bifurcates into two structural zones which surround a sequence of rocks interpreted as a wedge of island-arc terrain caught between the colliding Indian and Asian plates. The Main Mantle Thrust (MMT), the southern suture zone, represents the contact between the Indian plate to the south and the island-arc complex to the north. The Indian plate is composed of Paleozoic metasediments intruded by granites, while the southern portion of the island arc complex is composed primarily of mafic rocks.

These contrasting lithologies provide a strong density contrast for modeling of gravity data. The northern suture zone, the Main Karakoram Thrust (MKT), separates the island-arc from the Asian plate to the north. On the south side of the MKT are the meta-sedimentary, meta-volcanic rocks of the island-arc sequence while on the north side of the MKT are the meta-sedimentary rocks of the Asian plate. Thus there is not as strong apparent density contrast across the MKT as there is across the MMT. Close to 600 gravity and magnetic measurements were made along traverses that were approximately normal to the major structures in the area. The gravity data were reduced to terrain-corrected Bouguer values and were then analyzed using two-dimensional modeling techniques.

The results of the modeling suggest that both the MMT and the MKT dip toward the north. The MMT at angles of 35 to 45 degrees while the MKT dips at around 20 degrees. The island arc appears to be 8 to 19 km thick with its southern edge tilted upward and eroded back to expose the lower layers of the sequence. The amphibolite layer which outcrops along the southern margin of the arc must extend at depth along the entire width of the arc. Total field magnetic anomalies along the same traverses do not reflect major structural trends, but correlate instead with bodies of ultramafic rock which appear to be localized along the suture lines. An ultramafic klippe is observed 25 km south of the present outcrop of the MMT and suggests that the island-arc terrain once extended farther to the south.

The Main Boundary Thrust is the youngest structural feature studied. It is the zone of current crustal shortening along which Indian crystalline terrain is being thrust southwards over recent sediments along a plane which is modeled as dipping less than 15 degrees to the north. When the present attitudes and presumed ages of the MMT, MKT, and MBT are taken into account the generalization can be made that the older a suture zone is, the steeper its present dip. The suture margins of the island arc have been recently modified by recent uplift in the Nanga Parbat region. This has caused the suture zones in that area to steepen into near vertical attitudes. Modeling of gravity data a traverse that crosses the entire length of the suture zone in northern Pakistan suggests that the Indian plate be being thrust under the Asian plate. This thrusting is forcing sialic material to a maximum depth of 100 km.

A possible tectonic history for the area can be constructed. Approximately 40 my ago the Indian plate collided with an island arc that was growing due to the northward subduction of the Tethyan oceanic crust. The Collision caused the island-arc terrain to be obducted onto the Indian plate along a very shallow thrust (the MMT). While this was happening, the basin behind the arc began close. With the complete closing of the back-arc basin, the arc ran into the Asian plate and the Asian terrain was thrust over the arc (along the MKT). Continued northward migration of India steepened the MMT and MKT into their present attitudes, while crustal shortening was accommodated along shallow thrust (the MBT).

M/62. Malinconico, Jr. L.L., 1986. The structure of the Kohistan-Island Arc terrane in Northern Pakistan as inferred from gravity data. *Tectonophysics* 124, 297-307.

Modelling of gravity data taken across the Kohistan Island-Arc terrane in northern Pakistan can be used to constrain the shape and thickness of the Arc. Over 600 new gravity measurements were made across the Kohistan Island-Arc terrane in northern Pakistan. These data were taken along traverses normal to the structures bounding the Arc and were reduced to terrain-corrected Bouguer values. The reduced data were then modelled using standard two-dimensional modelling techniques. The southern margin of the Arc, the Main Mantle Thrust (MMT), dips to the north at approximately 45° and gradually flattens out at a depth of 7–9 km. The northern margin of the Arc, the Main Karakoram Thrust (MKT), also dips towards the north, but at a shallower initial angle (15°). From the models, the Arc terrane now appears to be around 7–9 km thick with the thicker sections occurring closer to the southern margin. The proposed model, in particular the angle of the MMT and the MKT, may have been significantly affected by the recent and rapid uplift that is occurring along the Nanga Parbat-Haramosh Massif.

M/63. Malinconico, Jr. L.L., 1989a. Crustal shortening in the west-Himalaya. *Geological Bulletin, University of Peshawar* 22, 55-64.

The main collision between the Indian and Asian lithospheric plates occurred during the late Eocene (40 million years ago) and continued closure at the rate of 5 cm/yr has resulted in approximately 2000 km of crustal shortening between the two plates (Molnar and Tapponnier, 1975; Molnar, 1984). In northern India it has been suggested that while some of the shortening is by underthrusting (Molnar and Tapponnier, 1975) much may be the result of diffuse

deformation in China (Tapponnier, 1982). However, in northern Pakistan the problem is complicated because there is no Tibetan plateau analog and no evidence of strike-slip structures that could have removed significant amounts of crustal material. In order to place tighter constraints on tectonic models for the Indian-Asian collision in the western Himalaya it is important to be able to estimate the amount of crustal shortening that has occurred. Current estimates of 500 to 700 km of convergence in northwestern Pakistan (Butler, 1986), are calculated from balanced cross section methods. This is significantly less than the 2000 km required by closure models based on paleomagnetic data (Powell, 1979; Molnar and Tapponnier, 1975; Molnar, 1984). An important step in estimating the amount of shortening that has occurred is to determine the volume of crust that remains in the orogen. The crustal models based upon observed gravity profiles presented in this paper suggest that there may be enough crustal volume to account for between 550-1100 km of shortening. This is still significantly less than the 2000 km of closure that has presumably occurred. The balance of the closure might be accounted for by erosion and/or defused deformation or it might suggest that less than 2000 km of closure has occurred in the northwestern Himalaya.

Key words: Structure, tectonics, collision, crustal shortening, Himalaya.

M/64. Malinconico, Jr. L.L., 1989b. Crustal thickness estimates of the Western Himalayas. In: Malinconico, L.L. & Lillie, R.J. (eds.), *Tectonics of the Western Himalayas*. Geological Society of America, Special Papers 232, 237-242.

The main collision between the Indian and Asian lithospheric plates occurred during late Eocene time (40 to 50 m.y. ago). Continued northward migration of the Indian plate since that time at the rate of 5 cm/yr has resulted in approximately 2,000 km of closure between the two plates. In northern India it has been suggested that, while perhaps 500 to 1,000 km of the closure can be accounted for by crustal shortening, underthrusting, and thickening, the balance (1,000 + km) may be accounted for by eastward motion along strike-slip faults in China. However, in northern Pakistan, the problem is complicated because there is no Tibetan plateau analog and no evidence of strike-slip structures that could have removed significant amounts of crustal material.

In order to place tighter constraints on tectonic models for the Indian-Asian collision in the western Himalaya, it is important to be able to estimate the amount of crustal shortening that has occurred. Current estimates of 500 to 700 km of crustal shortening in northwestern Pakistan are calculated from balanced cross-section methods.

An important step in estimating the amount of shortening that has occurred is to determine the volume of crust that remains in the orogen. The crustal model based on observed gravity profiles presented in this chapter suggest that there may be enough crustal volume in the western Himalaya to accounted for between 570 and 1,140 km of shortening. This is still significantly less than the 2,000 km of closure that has possibly occurred. The balance of the closure might be accounted for by erosion and/or diffuse deformation, or it might suggest that less than 2,000 km of closure has occurred in the northwestern Himalaya. The crustal models also suggest that the style of underthrusting in the northwestern Himalaya may be significantly different than that proposed for the Himalaya of northern India. Here the underthrusting seems to be occurring at a very steep angle when compared to the shallow underthrusting proposed for northern India.

M/68. Mallick, K.A. & Valiullah, M., 1972. Mineralogical study of the non-clay fraction, in the bauxite and the associated rocks of Azad Kashmir. *Acta Mineralogica – Petrographica*, Szeged XX/2, 271-286.

Bauxite and the associated rocks from seven different localities of Muzaffarabad and Kotli areas of Azad Kashmir have been investigated for their non-clay mineral correspondence. Rocks in contact with the bauxite are the fire clay at the base and Eocene shale at the top. The fire clay overlies the Muzaffarabad Formation of Permo-Carboniferous age. The bauxite and the fire clay correspond closely with each other in their mineralogical composition. No relationship could be found between the top of Muzaffarabad Formation and the bottom of the fire clay.

The study reveals similar provenance and cycle of deposition for the fire clay and the bauxite with some breaks and changes when the pisolites of the bauxite were being formed.

M/69. Maluski, J. & Matte, P., 1984. Ages of alpine tectonometamorphic events in the northwestern Himalaya (northern Pakistan) by ^{39}Ar - ^{40}Ar method. *Tectonics* 3, 1-18.

The main tectonometamorphic alpine events which occurred, in the western part of the western Himalayan migration at south of the main suture, in northern Pakistan, are dated by the $^{39}\text{Ar}/^{40}\text{Ar}$ method. These events are as follows: (1) the blueschist metamorphism (80 ± 5 Ma) present in tectonic/ophiolitic mélanges along the suture (this event occurred during an early subduction or obduction stage) (2) the alpine barrovian metamorphism (50-30 Ma) developed in the sedimentary cover and orthogneisses of the Indian Plate during the postcollisional northward underthrusting of this plate below Asia, leucogranites (23 Ma) resulting from the melting of the Indian crust during the climax of the alpine metamorphism.

M/70. Maluski, J. & Schaeffer, O.A., 1982. ^{39}Ar - ^{40}Ar laser probe dating of terrestrial rocks. *Earth and Planetary Science Letters* 59, 21-27.

We have shown that for metamorphosed granites, as well as for metamorphosed sediments, it is possible to obtain a reliable K-Ar age from a sample as small as 0.2 µg. Samples with ages as young as 40 m.y. are easily studied. There is no reason to believe that the method could not be used for samples considerably younger. The main application of the laser will probably be for cases where the same mineral species has been formed during two distinct metamorphic events in the same rock. In this case, it is difficult, if not impossible, to make a mineral separate suitable for a ^{39}Ar - ^{40}Ar study. We have shown that in the case of an old granite the biotite in one sample distinctly shows thermal events at 1600 m.y. while its primary cooling age is 2100 m.y. The thermal release study yields a good plateau age, roughly an average age of the two thermal events. Another interest of this method is demonstrated by argon dating of two different kinds of glaucophane, only one of these showing argon in excess.

Key words: Chronology, metamorphosed granite.

M/74. Marcoux, J. & Aymon, B., 1995. Late Permian to late Triassic evolution of the Northern Indian continental margin. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

During the late Permian, the north Indian margin is the seat of rifting processes. The rift geometry is characterized by a rim basin, a thick upper-plate volcanic extrusion on the shoulder (Panjal Trap) and a terrigenous intrarift shelf and slope. After the uppermost Permian break up the Northern part of India evolves as a passive margin.

Typical of the Permian rim basin is the Nammal Gorge section of the Salt Range. The lower part of the Wargal Formation (late Murgabian) consists of regressive shallow-water carbonate sequences. On the shoulder, the Kashmir area shows a great thickness (up to 1 km) of early, late Permian volcanic rocks: the Panjal Traps. At the Guryul Ravine-type section a marine, fossiliferous, mixed carbonate-terrigenous shelf (Zewan Formation) transgresses the Panjal Traps. On the rift side of the shoulder, in the Phuktal section, the open marine Kuling sandstones occur, transgressing on partly tilted blocks. The same lithologies characterize the whole Tethys Himalaya in India and in Tibet. Although absent in the central Himalaya, the Permian Traps, named the Abor volcanics, form large accumulations in the eastern part.

On the Zaskar traverse, the terrigenous Kuling shelf passes oceanward to the flyschoid Lutchungse basin in the Markha Valley area. The Permian exotic blocks consist of open-marine fossiliferous brecciated limestones (the Lamayuru block) or limestones with lava intercalations as in the Spongtag area. The same limestones have been found west of Raskas lake in southwest Tibet.

During the early and middle Triassic, the north Indian margin is characterized by a well-developed slope and a deep, wide, structural shelf. The distal and deeper part found in the Lamayuru and Yamdrock Tso areas consists of shaly and silty deposits with common marly intercalations, often representing turbidity currents. The deep shelf invariably characterized by nodular, condensed mudstone/wackstones of the Tamba Kurkur Formation, more shaly towards the top and cropping out in northwest Zaskar, Spiti, Kumaon, where it corresponds to the Kalapani Limestone, and Nepal. In Kashmir middle Triassic sediments, the inner-shelf, nodular limestones are richer in fine clastics, as in the Khreuh Formation. The Salt Range was mostly covered by shallow water carbonates, now dolomitized (Kingriali Formation).

In the late Triassic, the distal deeper-water sediments were found in Lamayuru, with large Dachstein-type olistoliths and in the Yamdrock Tso area with shaly and silty deposits with common, marly intercalations, often sedimented by turbidity currents. The most distal part is found in the exotics of the central Himalaya, the Kiogar Peaks, with typical shallow water Dachstein-type limestones. On the margin, the shallow shelf is characterized by fine well-sorted subarkoses and outcrops in northwest Zaskar, Spiti and Nepal. In Kumaon, the corresponding deposits are the Kuti shale. In Kashmir the inner-shelf limestones are very thick. The Salt Range area was emerged; but to the west, shallow-water limestones are present in the Samana Suk Range where the lower part of the Samana beds are middle to late Triassic in age. To the northwest the carbonate platform (Kashala Formation) is now metamorphosed to the greenschist facies.

Key words: Permian, Triassic, evolution, stratigraphy, Panjal Traps.

M/75. Marks, P. & Ahmad, A., 1962. The Giumal sandstone transgression in the Hazara mountains, West Pakistan. Geological Bulletin, Punjab University 2, 54-55.

During the field season of 1960 and 1961, parties of the Geology department, Punjab University, collected a large number of ammonites from the Giumal sandstone formation at various localities in the Hazara mountains. These faunas proved to be of different stages of the Lower to Middle Cretaceous. Previously, Spath, (1930) had already described such faunas from the same formation. The Giumal Sandstone Formation overlies in all localities the Spiti Shale Formation, which, in turn, disconformably overlies the Oolitic limestones of the Triassic (?) formation, whereas, however, the boundary between the Triassic (?) Formation and the Spiti Shale Formation is dated in all localities by an Upper Oxfordian Jurassic fauna, the faunae identified from the Giumal Sandstone Formation vary in different localities. The fauna in the eastern part of the area is Berriasian in age; that in the centre (localities 3 and 4) is Valaginian/Hauterivian; while that in the western part of the area is Middle to upper albian (Spath, 1930, 63-64). These later localities lie, generally, on the north-south line, which suggests that the change of the faunae takes place from east to west. As the thickness of the Giumal Sandstone Formation is rather small, varying from about 100 feet in the east to about 50 feet in the west, and the Formation only contains a single fauna in each locality, it follows that the Spiti Shale/Giumal Sandstone Formation boundary shows a marked time-shift from east to west.

M/78. Martin, N.R., 1962. Tectonic style in the Potwar, West Pakistan. Geological Bulletin, Punjab University 2, 39-50.

A brief description is given of detailed structural observations made on number of the faulted folds of the Potwar region of West Pakistan. An attempt is made to analyze the kinematics of these structures in terms of a number of phases, and to show the general style of the tectonics. The structural analysis of the region by some of the previous workers is discussed.

Key words: Structure, tectonics, Potwar.

M/79. Martin, N.R., Siddiqui, S.F.A. & King, B.H., 1962. A geological reconnaissance of the region between the Lower Swat and Indus rivers of Pakistan. Geological Bulletin, Punjab University 2, 1-13.

The present results of a rapid reconnaissance of the Lower Swat-Indus region are given. The map is based on the interpretation of aerial photographs and selected traverses, and on some detailed mapping in the Lower Swat area. Tentative suggestions are made for the correlation of the formations encountered, and the structure of the region. Stratigraphy and structure are accompanied by description of the granitic rocks and gneisses. The southern amphibolites belt of the Kohistan magmatic arc is named as the Upper Swat Hornblendic Group. The geological map also shows the lensoid serpentinized body of the Shangla-Alpurai area.

M/92. Marussi, A., 1978. Results of seismic sounding: gravity and crustal structure in the Kashmir Himalaya and the Karakorum – Hindu Kush region. Abstract International geodynamic conference, Kathmandu, March 26-29.

Generally speaking, geophysics fields show little correlation with geological fields in the region of the Pamir-Kun Lun-Karakoram-Himalaya-Hindu Kush syntaxis. The gravity field shows regular symmetric trends astride the Karakorum range, but west of the Chitral Line this trend is substituted by strong negative gravity anomalies. The zone of transition coincides with the area of the Hindu Kush intermediate earthquakes, is marked by the junction of the Chaman and Heart fault systems, and thus testifies deep seated phenomena. An even more striking lack of correlation is appearing if satellite gravity data are considered.

The deep seismic sounding operations performed in 1974 and 1975 between India, Italy, Pakistan and U.S.S.R. show a thickening of the crust under the Karakorum and a progressive deepening of the Moho discontinuity proceeding from the Indus platform towards North. The Nanga Parbat massif shows high velocity surface layers. A map of the lineaments of the systaxial zone has been drawn from Landsat imageries.

M/93. Marussi, A., 1980. Gravity, crustal tectonics and mantle structure in the central Asian syntaxis. *Geological Bulletin, University of Peshawar* 13, 23-27.

An attempt is made to interpret the gravity field in the zone of the Tien Shan-Hindu Kush-Kun Lun-Karakorum-Kashmir Himalaya syntaxis, considering the local features of the field generated by density anomalies in the lithosphere separated from the regional geoidal features generated by anomalous density distributions in the Mantle as obtained by satellite geodetic methods.

The local isostatic anomalies show a marked dichotomy astride of a line representing the prolongation of the Chaman Fault lineament. Remarkably, the nest of intermediate Hindu Kush earthquakes is to be found at the intersection between the same line with the Herat Fault lineament. Strong negative anomalies unrelated to either the topography or the geology prevail NW of such line, whereas SE of the line the field is characterized by stripes of alternating negative and positive anomalies all having the Himalayan trend.

Both the Himalayan and the Chaman Fault trends are to be recognized in the geoidal features of GEM 10. The Himalayan trend is here related to the upheaval of the geoid that accompanies all along the Alpine-Himalayan geosyncline, and the Chaman Fault trend to the geoidal downwarping that follows the northern continuation of the tensional zone of the Arabian Sea crossing the syntaxial zone and continuing in the Balkash-Baykal Rift Zone in Central Asia. A tentative hypothesis is made to interpret the relationship between mantle structure and the crustal tectonics by the mechanism of gravity sliding.

On the basis of gravity survey, it is shown that negative anomalies, over Karakorum and the Nanga Parbat – Haramosh orogens, are related to granite bodies while the positive anomalies are related to regional amphibolites, basic granulites and basalts. It is further shown that the Nanga Parbat – Haramosh tectonic event as a huge diapir is genetically related to the Karakorum axial batholith.

M/107. Mason, K., 1932. The Karumbar Glacier. *The Himalayan Journal* 4, 182-183.

About 2nd March 1930 the local chief in the Karumbar valley went to see if the route in this valley was clear for a tour that Mr. Todd proposed to undertake. He found that the glacier above Bort had advanced a very long way in the past year, but that it was still about a hundred paces from the far bank. On the 22nd March, however, one of his men reported that the glacier had closed up and blocked the entire valley. The chief, doubtful of the accuracy of this report, again went up the valley to investigate and found that the glacier had actually advanced a hundred paces in three weeks. Mr. Todd visited the glacier on 20th October and found it stretching right across the main valley with its snout hard pressed against the high steep cliff of the far bank. He estimated the height of the snout to be between 120 and 150 feet, and its breadth from 250 to 300 yards. The width of the valley at the block is about 400 yards wide. Some local Wakhis had succeeded in crossing the glacier to visit their fields upstream, but it must have been a perilous passage owing to the formidable barrier of ugly pinnacles and crevasses. The main river was flowing underneath the ice close to the snout and was quite clear. The muddy waters of the glacier itself were issuing from it some 200 feet above the snout. In recent years floods have been caused by the bursting of the Karumbar ice-dam on two occasions, in July 1893 and in June 1905. Mr. Todd gives the following information concerning the latter, thereby supplementing the notes he gave in his letter published in the *Himalayan Journal*, vol. ii, p. 174. In the autumn of 1904 the Karumbar glacier made an advance similar to that of last spring, and eventually closed against the cliff on the far side in November and December 1904. It was inspected in April 1905 and reported to be about 120 feet high at the snout. A lake formed behind the barrier in the winter and spring of 1904-5, which was reported by locals to be stretching for a full day's march upstream, a statement which was probably exaggerated, unless the march is considered a laborious and difficult one. On the night of 17-18th June the imprisoned waters forced a channel underneath the glacier, and the ice-bridge above the tunnel gradually caved in. The resulting flood reached Gilgit about 8 a.m. where it carried away the one-pier bridge. It will be interesting to note whether a similar flood occurs next year. If we take the block dates as the winters of 1891-2, 1904-5 and 1929-30, the intervals between the times of maximum advance are approximately 13 and 25 years. It would be interesting to know whether there was a minor block about 1917, which would give us a fairly regular periodicity of about 13 years. We are still groping for the laws that govern glacier-movement and we hope that the future movements of this glacier will be recorded annually by the authorities at Gilgit.

M/109. Masood, H., 1976. An evidence of Maestrichtian rocks in Hazara. Geological Bulletin, Punjab University 13, 111-112.

In his first reference to the geology of Hazara Verchere, 1866-67, gave a rough description of the geology of Hazara without giving any reference to the occurrence of the Upper Cretaceous rocks in the area. Waagen and Wynne, 1872, in their succession of rocks mentioned a bedded limestone, without fossils apparently, possibly of Cretaceous age. Middlemiss, 1896, included the above referred thin bedded limestone as part of Tertiary rocks, as lowest bed of the Nummulitic Series. Latif, 1962, recorded the presence of microfossils of Upper Cretaceous age in the rock units referred above. Latif, 1970, identified more than 30 species of microfossils and dated the rocks as Upper Coniacian to Campanian, Upper Cretaceous. He further identified the rocks as Chanali Limestone and separated it from the overlying Tertiary formations. The microfossil studies carried by Latif, 1970, were based on a study of five samples from Changlagali section. It was found to be necessary to advance the studies by measuring various sections in Hazara and studying the relevant samples. The investigations have shown the presence of twenty seven microfossils in addition to those of Latif, 1970. These microfossils are newly recorded from Hazara.

M/110. Masood, H., 1989a. Samana Suk Formation, depositional and diagenetic history. Kashmir Journal of Geology 6 & 7, 157-162.

Samana Suk Formation exhibits an excellent example of what is called as oolite shoal in the literature. Many such examples exist in the geological record and their studies carried out. In this study we tried to interpret the depositional and diagenetic environments of the Jurassic Samana Suk Formation from Hazara, Pakistan.

Several lithofacies are differentiated on the basis of the presence of oolites, fossils and terrigenous content. They include pure micrite to a sandy facies which is classified in the sandstone category.

The diagenetic environment include cementation of the grains with coarse crystalline, bladed calcite which represent an early cement, and equigranular calcite cement representing a later phase. Dolomitization in the phratic zone has replaced all the textures including intraclasts and cements. Replacement of the oolites by the dolomite crystals is another phenomenon observed in the Samana Suk Formation which happened in the later stage of the diagenetic history.

Key words: Stratigraphy, Jurassic, Samana Suk Formation, Hazara.

M/111. Masood, H., 1989b. Hardground surfaces in Samana Suk Limestone. Kashmir Journal of Geology 6 & 7, 185-on ward.

Hardgrounds are the surfaces of the beds which show evidence of hardening or lithification on the sea floor indicating syn-sedimentary cementation. Such hardgrounds have been recognized in Samana Suk Formation in different parts of Hazara where some work is being carried out on the depositional and diagenetic processes in this formation. The study of the hardground reveal that the formation have been deposited in intertidal environments with possible transgressions of sea and slow sedimentation where the sea floor was lithified before the overlying beds were deposited.

M/114. Mateen, A., Ahmed, A., Butt, K.A., Qureshi, A.A., Zaidi, H.A. & Chaudhry, M.N., 1997. Igneous phosphate (apatite) deposits associated with carbonatite of NW Pakistan: Mineralogical features and possibility of ore beneficiation. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

The apatite mineral - group is characteristic of carbonatite that commonly form apatite - carbonate ore bodies within the carbonatite complexes. Such igneous phosphate ores of commercial interest occur in the carbonatites of Sillai Patti, (Malakand) and Loe -Shilman (Khyber Agency) in N.W.E.P. Pakistan. We carried out detailed mineralogical study in order to assess the possibility and appropriate conditions for the beneficiation of the apatite - carbonate ores that can be developed as a source for the supply of raw material for phosphate fertilizer and chemical industry. Both the Sillai Patti and Shilman carbonatites are characterized by marked mineralogical and textural variations. Based on the variations genetic and mineral - petrographic features and their associated rocks, we have classified the ore-type as apatite - carbonate - silicate ore. The bulk mineral compositions of the two deposits were evaluated by several independent methods including, large number of thin-sections study, large-volume of bulk samples and chemical analysis of representative samples within the entire limits of the carbonatite. The overall apatite contents are about 5 to 8% and 4 to 6% for Sillai Patti and Shilman deposits respectively. The impurities consist of calcite and dolomite (about 80% of overall amount of carbonates - predominantly calcite), ferromagnesian silicates, iron oxide (mainly as magnetite) and other accessory heavy minerals including pyrochlore. A simple process flow - sheet is developed for the physical beneficiation which consists of crushing grinding and floating the apatite concentrates almost free from the gangue minerals. Experiments were conducted using apatite crushed ore 0.2 mm and deslimed on 0.045 mm. Relationships are discussed between quality of the apatite concentrate and the particle size and its intergrowth with coexisting minerals.

Key words: Phosphate, carbonatite, mineralogy, ore beneficiation.

M/116. Mateen, A., Baloch, I.H., Hussain, S.S. & Chaudhry, M.N., 1997. Mineralogical characteristics and industrial utilization of the Koga nepheline syenite deposit, Buner, Swat, Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 2p.

Nepheline syenite rocks are among few industrial raw materials that can be used directly in the industry without much pre-treatment or processing. These rocks find numerous commercial applications, primarily in the manufacture of glass and ceramic wares. Because of its excellent glass and ceramic properties the Koga nepheline syenite can be considered as a suitable matrix for vitrification of high - level radioactive waste. We carried out detailed mineralogical study of the Koga nepheline syenite deposit occurring in Buner. Swat. One of us (Baloch 1994) performed electron microprobe analysis to determine the compositional variations in the different mafic and felsic mineral constituents found in these rocks. The primary aims of this study were to determine the initial mineralogy and chemistry for which the success of mineral separation can be evaluated in the industrial beneficiation of nepheline syenite and to assess the suitability for the nepheline based wasteform. The feldspathoidal rocks comprise of foyaites, sodalite - cancrinite foyaites. feldspathoidal syenite, garnet- bearing nepheline syenite, pulaskites and alkaline syenites occurring as intrusions, plugs, dykes and pegmatitic bodies within the Koga alkaline igneous complex. The important felsic modal mineralogy consist of nepheline (5 to 42 % close to ideal Na:K ratio of 3:1), K- feldspar (20 to 70% as microcline Or95 to Or100), soda - feldspar (2 to 10% as almost pure albite Ab98 to Ab100), Cancrinite and sodalite (up to 12% and 15% respectively in same sections). The iron bearing mafic mineral phases comprise of sodic clinopyroxene (2 to 3% as aegirine), Fe- rich black mica (1 to 4% as biotite - phlogopite -

Annite), iron ore (up to 3% mainly as magnetite), garnet (up to 4% in some sections as andradite - mainly Mn - bearing melanite), sphene (up to 1%) and amphibole (rare). Apatite and zircon occur as accessory minerals. Mafic minerals texturally occur as aggregates, clots and intergrowth within the felsic major phases. For industrial utilization laboratory - scale feasibility study was carried to assess the merit of the Koga nepheline syenite deposit for the glass and ceramic industry and possible use in the vitrification of radioactive waste. A process flow- sheet based on magnetic separation of iron bearing mafic mineral phases is developed for the Koga deposit to meet the commercial product specification for the industry. Results of preliminary investigations for the utilization of the Koga nepheline syenites as ceramic matrix for vitrification plant for radioactive waste disposal are presented. A glass composed of 85% nepheline syenite and 15% lime offers the best compromise in respect of high resistance to attack by water of various Eh - pH conditions.

Key words: Mineralogy, Koga, Nepheline syenite, Buner.

M/119. Mateen, A., Chaudhry, M. N. & Tingu, C., 2000. Permo-Carboniferous Potassic-Rich Shoshonitic Alkaline Magmatism in the Koga-Bunerai area, Swat Himalaya, NW Pakistan. In: Abstract volume, 3rd South Asia Geological Congress (GEOSAS-III), Shams, F.A., Choudhry, M.N., Hassan, Mahmoodul, Kamran, M. & Rashid, S., (Eds.), Lahore (September 23-26, 2000), 5-6.

In this paper we document for the first time a distinct potassic-rich shoshonite alkaline magma series found within the Koga alkaline underand igneous complex in Buner area of Swat, NW Himalaya Pakistan. The dominant alkaline felsic plutons investigated were previously considered mostly syenitic, typically of sodic alkaline feldspathoidal syenite suites (Siddiqui et al. 1968). An entire spectrum of potassic alkaline subvolcanic rocks comprising felsic to mafic suites representing the Pangaeon Permo-Carboniferous alkaline magmatism ($^{40}\text{Ar}/^{39}\text{Ar}$ age = 290±3 Ma) been identified. The rocks of this association consist of intrusions of nepheline bearing K - rich microsyenites (well exposed near Koga village) and dykes and sills of micro-monzogabbros, monzodiorite and shoshonite lamprophyres belonging to trachybasalt-latite magma series. These are Ti shoshonitic magmatic suites, mafic to intermediate in composition slightly SiO₂- undersaturated (SiO₂ = 46.2 to 61.3Wt%) moderately alumina (Al₂O₃=12.1 to 18.5wt%) and potassium (K₂O=2.82 to 7.9) possibly representing potassic equivalents of sodic transitional rocks. elements chemistry shows enrichment in large ion lithophile elements (LILE) and light rare earth elements (LREE) relative to high field strength element (HFSE) and heavy REE with fractionated chondrite-normalized pattern (La/Yb = 9.32 to 24.4). Trace element composition and initial $^{143}\text{Nd}/^{144}\text{Nd}$ ratio (positive ~Nd: +2.3 to + 4.1) indicated metasomatized depleted lithospheric mantle source. (Mateen & Lan, unpublished work). The petrogenetic evolution of this magmatic series is interpreted in terms of late stage product of igneous activity similar possibly to Roman type potassic alkaline magmatism found away from mature volcanic arcs and/or observed along the east African Rift Valley System. The compositional variations in the magmatic series have been discussed in relation to the polybaric fractionation. Both the sodic and potassic alkaline rocks of the Koga igneous complex are discussed in relation to the spatial and temporal evolution of what is now the Himalayan orogen. This igneous activity associated with the Permo-Carboniferous, alkaline magmatism in the early stages of rifting of NE Gondwanaland.

Key words: Carbonatite, shoshonitic magmatism, Koga, Buner, Swat.

M/120. Mateen, A., Hussain, S.S., Chaudhry, M.N. & Dawood, H., 1995. Occurrence of carbonatites in higher Himalayan basement rocks of Pakistan. Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, 16-17.

In the northern Pakistan carbonatites and related alkaline igneous rocks occur both in the metamorphosed belt of Lesser Himalayas as well as the Higher Himalayan crystalline slab. The carbonatite occurrence just south of the Suture zone in the Higher Himalaya exposed in Malakand Agency (Sillai Patti), Bajaur agency (Turghar-bagh-Andarai) and Swat (Jambil) have distinctly unique geochemical environment and have no apparent relationship with the typical rift-related alkaline silicate-carbonatite complexes of Koga, Loe-Shilman in the Lesser Himalaya. The Silai Patti carbonatites are characterized by predominant dolomite-Anderite carbonate mineralogy with silicate-rich components of pyroxene, amphibole and biotite (>75% biotite and amphibole at places) and relatively higher REE and PO₄ (Apatite) content.

Key words: Carbonatite, Himalaya.

M/121. Mateen, A., Majid, C.A., Hussain, M.A. & Butt, K.A., 1994. Characterization of uraninite from rare metal granitic pegmatite, Bagrian, Mansehra, Pakistan. Pakistan Journal of Geology 2 & 3, 80-84.

Amorphous uraninite is described from an extremely fractionated rare earth bearing zoned complex granitic pegmatite exposed in Bagarian area, Mansehra District, NWFP Pakistan. X-Ray diffraction study suggests a complete amorphous uraninite state. X-ray diffraction pattern shows two broad bands around 317°A and 274°A, and a possible indication of very broad band around 12°A. Carefully devitrified at annealing temperature of 1350°C yielded X-ray diffraction pattern of crystalline uraninite with chemical phases in atomic proportions of UO₃ (97.15%), ThSiO₄ (1.51%) and ThO₂ (1.51%) and ThO: (1.1%).

M/123. Mateen, A., Qureshi, A.A. & Chaudhry, M.N., 2001. Petrological and geochemical characteristics of the Tertiary lamprophyre/ ultrapotassic rock from the Loe-Shilman carbonatite complex, Khyber Agency, N.W.F.P. Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.7.

Lamprophyritic dykes and minor magmatic intrusions of ultrapotassic rocks occur within the Loe-Shilman carbonatite complex, Khyber Agency, NWFP, Pakistan. The lamprophyre dykes yielded 40Ar-39Ar biotite plateau age of 32.8 ± 0.2 Ma and isochron age of 33.4 ± 0.6 Ma. Potassic-rich alkaline rock sequence includes carbonatitic lamprophyre, alkali lamprophyre, K-micromonzonites, K-syenites and pseudoleucite syenites. Petrographic and textural features clearly show that these rocks have a magmatic rather than metasomatic origin. Lamprophyre/ultrapotassic rocks are very heterogeneous in terms of grain size, mineralogy and modal proportions. Lamprophyres are composed essentially of amphibole, biotite, sphene ± K-feldspar ± calcite. Alkali feldspar dominates in the pseudoleucite syenites. All the rocks have strong incompatible element enrichment in multi-element spidergrams which lack Nb-Ta anomaly. The rare earth element (REE) patterns are steep with fractionation ratios of (La/Yb)_m range from 27 to 87 for lamprophyres and 16 to 38 for K-syenites and pseudoleucite syenites. The enrichment of LILE, Nb-Ta, Zr-Hf, LREE and high La/Yb ratios are consistent with a phlogopite-bearing garnet peridotite residual source. Association of lamprophyres and carbonatites in the collision zone NW Himalaya of

Pakistan demand their parental magmas derived from a heterogeneous sub-continental mantle. Lamprophyres/ultrapotassic rocks are suggested to be generated by partial melting in the mantle, modified by fractional crystallization, immiscibility and magma mixing at shallow levels. Their emplacement is related to the Tertiary extensional rifling environment.

This is an excellent geological river log, beginning at Kalam in Swat Kohistan and ending at Mastuj in Chitral. Traverse follows the course of the Ushu River up the Dadarili Pass. Then on, it follows the Ghizar River up to Gupis. This is followed by turning northwest along the course of the Yasin River to Nazbar. From then on, crossing the drainage divide, entry is made into upper reaches of the Yarkhun River for descent into Mastuj. The author used Brunton and pace method to prepare simple topographic and geological sketch maps at 1:35,000 to 1:50,000 scales for the entire route. In addition, field features were shown in a large number of neat hand sketches (totaling 75) and photographs (4). Descriptions of rocks, structures, and field relations of various rocks, especially of the granitic intrusions and their host rocks, are elaborated. A strong aspect of the paper is the description and sketches of the glaciers, moraines, glacial terraces, stream deposits, talus, etc. In the Swat-Gupis section, much of the traverse is through the granite batholith (now called the Kohistan Batholith), and the author has distinguished a succession of plutons and dykes. In the Naz Bar valley, he records the following succession of rocks:

Terrace Deposits	Pleistocene
Glacial Deposits	Pleistocene
Granite.	Tertiary
Yasin Group	Lower Cretaceous
Darkot Group	Permo-Carboniferous

The overall stratigraphic setup is given on page 84 of the paper in the following table.

Age	Eastern Hindu Kush	Upper Swāt
Pleistocene	8) Terrace deposits	8') Terrace deposits
Tertiary	7) Granite of Ghizar river	
EarlCretaceousy	6) Yasin group of Yasin 5) Green series of Ghizar valley	
	4) Granite of Shunji Gol	4') Granite in the vicinity of Kalām
Permian and Carboniferous	3) Darkot group of Darkot	? 3') Kalam group in the vicinity of Kalām
Unknown		2) Gneissose granite of Ushū Gol
Unknown		1) Gneiss of Unshū Gol

(Eds.), Geology of the Karakoram and Hindukush. Results of the Kyoto University Scientific Expedition to the Karakoram and Hindukush, 1955, Vol. VII, 89-92. Nippon Printing & Publishing Co., Ltd., Japan.

This is a summary of the geological studies performed by the Japanese Expeditions to the Eastern Hindukush and Western Karakoram during 1955, 1956 and 1957. The various groups of rocks have zonal arrangement and appear in some cases to be separated by faults. One of these faults runs from the south of Mastuj, through the north of Yasin, Pakhor in Ishkuman, Chalt and Chogolungma Glacier north of Haramosh. This may be the trace of the now called MKT or Shyok suture. They also describe other structures, including the extension of the NP dome and the syntaxial bend between the Hindu Kush and Karakoram.

Division of geological sequence in the Western Karakoram and the Eastern Hindu Kush

Division of the Area Age	Eastern Hindu Kush and Upper Swāt	Syntaxial area	Western Karakoram	No. of division
Unknown; probably Tertiary	Granite of Ghizar valley	Granite of Gupis and Gakuch	Pegmatite dyke near Dusso	(6)
Early Cretaceous		Yasin group of Yasin		(5)
	Green Series of Ghizar river	Green Series of Gupis and Gakuch	Green and black phyllite of Tormik and Chalt	(4)
Unknown	Granite of Shunji Gol	Granite of Karambar	Granite of Baltoro	(3)

This volume is the 7th of the series published since 1960. It comprises a Preface, Introduction, eight papers, References and a geological map of the western Karakoram and eastern Hindu Kush. Individual papers cover general geology, stratigraphy, paleontology, petrography, geochemistry, metamorphism geochronology, and are dealt with in appropriate places. The Introduction to the volume contains a brief history of geological investigations in the area.

M/136. Matthew, W.D., 1929. Critical observations upon Siwalik mammals. American Museum of Natural History, Bulletin 56, 437-560.

During the winter of 1926-27 I spent six weeks at the Indian Museum in Calcutta and two months at the British Museum (Natural History) in London making a critical re-examination of the type collections of the Siwalik Fauna preserved in those two institutions. The object of this study was to check up in the light of modern palaeontological evidence the classic researches and descriptions of Falconer and Cautley and of Lydekker, and the admirable later work of Pilgrim, as a basis for researches and description of the collections obtained for the American Museum by Mr. Barnum Brown in 1921-1923. The expenses of making this study were defrayed from funds provided by Mrs. Henry Clay Frick, as a part of her gifts to the American Museum for Siwalik collecting, preparation and research work.

To the President and Trustees of the American Museum I desire to express my high appreciation of the opportunity and privilege of making this research, involving release from Museum duties over a period of several months. I am likewise deeply indebted to the friendly aid of Director Pascoe, Superintendent Pilgrim and others of the staff of the Geological Survey of India, to Doctor Bather and Mr. A. T. Hopwood and other good friends at the British Museum, who placed the collections wholly at my disposal for study and comparison, provided every facility for examining the specimens and referring to the published literature and the museum records, and aided and enlightened me upon various obscure points.

The accompanying series of notes and criticisms are by no means to be regarded as final conclusions. They represent principally an attempt to verify, revise and supplement the type descriptions with the aid of subsequent palaeontological knowledge, to point out doubtful or erroneous identifications or conclusions as to the affinities of certain types, and to reconsider the correlation of the Siwalik faunas with those of Europe and America. The views here expressed upon the affinities of various Siwalik mammals, and especially upon the faunal correlation, will call for a further and more careful criticism when the monographic researches upon Mr. Brown's collections have been completed. They represent the present personal viewpoint of the author, and no attempt is made at this stage to bring them into conformity with the conclusions of Professor Osborn based upon his proboscidean researches, or those of Doctor Pilgrim based upon his extensive and detailed studies of the stratigraphy and faunas of the Siwalik region.

IAHS/AISH Publication*, 218, 289-296.

This paper reports on ablation research carried out on the Rakhiot Glacier, Punjab, Himalaya. Specifically, detailed measurements of ablation rates on debris covered and debris free surfaces allow specification of relationships between ablation and debris cover thickness. Direct ablation measurements indicate a sharp increase in ablation with debris cover thickness increasing from 0.0 to 10 mm followed by a decrease in ablation with debris cover thickness increasing beyond 10 mm. Field observations reveal a critical thickness of 30 mm indicating that at any greater debris thickness ablation is suppressed from that expected on debris-free ice. A comparison with previous research indicates similar hyperbolic trends in the relationship between debris cover thickness and ablation, however, the intensity of these trends differ with global location.

M/144. Mayewski, P.A. & Jeschke, P.A., 1979. Himalayan and Trans-Himalayan glacier fluctuations since AD 1812. *Arctic and Alpine Res.*, 11, 267–287.

Historical records of the fluctuations of glaciers in the Himalayas and Trans-Himalayas date back to the early 19th century. Local and regional syntheses of 112 of these fluctuation records are presented in this study. The local syntheses deal with fluctuations of glaciers in Kanchenjunga-Everest, Garwhal, Lahaul-Spiti, Kolahoi, Nanga Parbat, Karakoram (north and south sides), Rakaposhi- Haramosh, Batura Mustagh, and Khunjerab- Ghujerab. Regional syntheses deal with the composite record and the differentiation of records by glacier type (longitudinal versus transverse) and regional setting (Himalayan versus Trans-Himalayan). In a gross regional sense Himalayan and Trans-Himalayan glaciers have been in a general state of retreat since AD 1850. Filtering of the fluctuation records with respect to glacier type and regional setting reveals that the period AD 1870 to 1940 was characterized by alternations in the dominancy of retreat, advance, and standstill regimes.

Key words: Glaciers, Himalaya, Karakoram.

M/145. Mayewski, P.A., Pregent, G.P., Jeschke, P.A. & Ahmad, N., 1980. Himalayan and trans-Himalayan glacier fluctuations and the South Asian monsoon record. *Arctic and Alpine Res.*, 12, 171–182.

Termini fluctuations for glaciers in the Himalayas and Trans-Himalayas are examined for the period AD 1850 to 1960. This period can be characterized as one of general retreat. Differentiation by geographic subdivision, however, reveals that Himalayan glaciers (best exemplified in Lahaul-Spiti, Kolahoi, Nanga Parbat, and Garwhal) show consistent retreat throughout the period, while Trans-Himalayan glaciers (best exemplified on the north side of the Karakoram and in Batura Mustagh and Rakaposhi-Haramosh) deviate from this pattern by displaying a major period of advance from AD 1890 to 1910. Although no apparent relationship exists between the magnitude of termini advances and glacier lengths, termini retreat records are commonly characterized by short- to medium- length glaciers (< 30 km). Termini advances are, however, related to flow direction; advancing termini most commonly face east, southeast, northwest, and west. Glaciers characterized predominantly by retreat flow commonly, but not exclusively, east and south- east. Advances of Trans-Himalayan glaciers during the period AD 1890 to 1910 are

attributed to strengthened monsoon wind currents and to secular variations in Indian rainfall. Such changes in the general atmospheric circulation, implied by climatic data, produce subsequent increases of moisture influx to the Asian land mass.

M/147. McDougall, J.W., 1992. The Main Boundary Thrust and propagation of deformation into the foreland fold-thrust belt in northern Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, p.54.

In the western Himalaya, the Main Boundary thrust (MBT) is the floor thrust for imbricate slices incorporating Precambrian and Phanerozoic rocks in the hill ranges that are emplaced over Cenozoic strata of the northern Kohat and Potwar plateaus. In the western Kala Chitta Range, north of the MBT and south of the Attock-Cherat Range, steep thrusts (some S-dipping) do not ramp up directly from the decollement thrust at the base of the MBT allochthon. Shallow contraction is manifest as pronounced thickening and tight folding in Mesozoic strata in the upper third of the allochthon with preferred decoupling in Jurassic rocks, particularly in a belt 0-6 km north of the MBT and west of the Indus River.

The MBT is folded and exposed in a deep re-entrant of Eocene Kuldana Formation parallel to and 2-4 km north of the front fault between Mazari Tang and the Indus River. South of the MBT in the northern Kohat Plateau area of the foreland fold-thrust belt, tight folds in early to middle Tertiary rocks, including synorogenic deposits of the Murree Fm., indicate preferential decoupling at the base of the Tertiary section and in underlying Mesozoic strata. These nearly symmetrical lift-off or box folds include the Panoba anticline and related structures, which indicate out-of sequence thrusting along the MBT that deformed the northern Kohat Plateau over (against) the back limb of the M thrust sheet to the south.

Dip displacements are tens of kilometers for major thrusts on either side of the MBT, for example (from S to N), the M thrust of the northern Kohat Plateau (29-32 km), the MET (estimated >40 km), the Hissartang fault (~25 km), the Cherat fault (?>10 km), and the Khairabad fault (~25 km). South of the MET to the Surghar Range there has been about 50% shortening across the foreland fold-thrust belt on a system of blind thrusts overlying a nearly flat 8-10 km deep basement. Net horizontal shortening increases north of the MBT. The section exposed by thrusting changes markedly in the Attock-Cherat Range, 6-30 km north of the MBT, where Precambrian rocks are exposed and Mesozoic rocks are absent in thrust slices of the N-dipping Khairabad, Cherat, and Hissartang faults.

West of the Indus River, present day low-angle decollement thrusting from the top of the basement projects to the surface 40-70 km south of the MBT and is most recently active in the northern Kalabagh fault zone. Thrusting along the MBT in the Kala Chitta Range at 2.1-1.9 Ma was followed by ongoing shallow regional N-S compression and thickening of the foreland fold-thrust belt allochthon. The MBT allochthon was deformed prior to its low angle emplacement over the northern Kohat and Potwar plateaus, and folded and eroded during or after this emplacement. The MBT thrust front may participate in its own later deformation, but not as an emergent low angle thrust through the Quaternary.

M/149. McDougall, J.W., Hussain, A. & Yeats, R.S., 1993. The Main Boundary Thrust and the propagation of deformation into the foreland fold-and-thrust belt in Northern Pakistan near the Indus River. In: Treloar, P.J. & Searle, M.P. (Eds.), *Himalayan Tectonic*. Geological Society, London, Special Publication 74, 581-588.

The Main Boundary Thrust in northwestern Pakistan is a floor thrust along which a thrust system incorporating Precambrian and Phanerozoic rocks of the Kala Chitta and Attock-Cherat Ranges was emplaced over Cenozoic strata of the northern Kohat and Potwar Plateaus. The MBT and successive thrusts toward the foreland are interpreted as low angle to flat decollement thrusts at 8–10 km depths that bound thrust sheets with large lateral dimensions. Admissible cross sections indicate over 60 km of shortening along the largely pre-Palaeocene Khairabad, Cherat, and Hissartang thrusts within the MBT allochthon. In the toe of the MBT allochthon, contraction is manifest at the surface as tight folds in largely Mesozoic and lower Tertiary strata, decoupled in the upper third of the allochthon. Displacement of the MBT is estimated at over 40 km and south of the MBT, shortening is interpreted along blind thrusts accompanied by shallow (0–3 km deep) backthrusting. The MBT allochthon was deformed prior to its low angle displacement over the northern Kohat and Potwar Plateaus, and folded and eroded during or after its emplacement. The MBT thrust front may participate in its own later deformation, but not as an emergent low angle thrust through the Quaternary.

Key words: MBT, deformation, Foreland, Kalachitta, Attock-Cherat, Potwar.

M/150. McDougall, J.W. & Khan, S.H., 1990. Strike-slip faulting in a foreland fold-thrust belt: the Kalabagh fault and western Salt Range, Pakistan. *Tectonics* 9, 1061-1075.

The 120-km-long Kalabagh fault zone is formed by transpressive right-lateral strike-slip along the western Salt Range-Potwar Plateau allochthon in northern Pakistan. Lateral ramping from a decollement thrust along an Eocambrian evaporite layer produced NNW- to NW-trending folds and NE- to N-dipping thrust faults in a topographically emergent zone up to 10 km wide. Piercing points along the main Kalabagh fault indicate 12–14 km of middle to late Quaternary right-lateral offset. The older right-lateral Surghar fault displaced axes of frontal folds of the eastern Surghar Range by 4–5 km. Total displacement is reduced northward in the Kalabagh fault zone where north-dipping thrust faults splay to the west. Cumulative right-slip offset in the Kalabagh fault zone is comparable to displacement along the Salt Range frontal thrust, at a minimum average displacement rate of 7–10 mm/year near the Indus River since 2 Ma. In the basement, which dips 2–3° north along the Kalabagh fault, a NNW-trending discontinuous ridge beneath the lateral ramp is interpreted from residual gravity anomalies. The eastern flank of this basement ridge probably ramped allochthonous strata upward from a depth of over 5 km in the Kalabagh fault zone. Kalabagh faulting displaced and uplifted Holocene terrace deposits and shifted the course of the Indus River eastward. A high slip rate and associated seismicity indicate that the Kalabagh fault zone should be considered active and capable of earthquakes.

M/152. McGinnis, L.D., 1971. Gravity fields and tectonics in Hindu Kush. *Journal of Geophysical Research* 76(8), 1894-1904.

Gravity fields in Afghanistan are characterized by large, negative mean free-air anomalies in the eastern Hindu Kush and by essentially zero anomalies in the western Hindu Kush. Thus, the western Hindu Kush are in isostatic equilibrium, whereas the eastern Hindu Kush are associated with a large mass deficiency. A mechanism involving underthrusting of light continental crust into higher density mantle in the eastern Hindu Kush and Pamirs is consistent with regional seismicity and gravity fields. Positive free-air and Bouguer anomalies mark a belt of intrusives that occupy a region of northeast-striking fractures along the Chaman fault zone. This zone may represent the northwest border of the Indian subcontinental plate.

M/157. McMahon, C.A., 1887. The Gneissose-Granite of the Himalayas. *Geological magazine (Decade III)*, 4 (5), 212-220.

The cause, or causes, which result in the foliation of igneous rocks is a subject which at present occupies the attention of many geologists, and seems likely, in the near future, to lead to some discussion. In view of this, a short account of the foliated granite of the Himalayas may be of interest. It may be as well, however, to preface my remarks by saying that I believe that foliation may be produced in several distinct ways, and the explanation which I offer of the mode in which the foliation of the Himalayan granite has been brought about is only intended to apply to the case of that granite.

In the following pages I propose to give a brief summary only of some of the more important results worked out in detail in a series of papers published in the *Records of the Geological Survey of India*; and to add thereto a brief consideration of the question whether the foliation of the gneissose-granite of the Himalayas

Key words: Structure, Himalaya, granite, Gneisses.

M/158. McMahon, C.A., 1897. Notes on the age and structure of the gneissose-granite of the Himalaya with reference to Mr. Middlemiss's memoir on the Geology of Hazara. *Geological Magazine (decade IV)*, 304-313 and 345-355.

I am indebted to Mr. C. S. Middlemiss, Superintendent of the Geological Survey of India, for a copy of his Memoir on the Geology of Hazara and the Black Mountain recently published. Mr. Middlemiss has embodied in his Memoir the results of an unfinished survey by Mr. A. B. Wynne, late of the Geological Survey of India, and by linking these with his own more recent work, has given us an interesting and valuable Memoir on the Geology of the Himalayan district of Hazara.

M/159. McMahon, C.A., 1900. Notes on the Geology of Gilgit. Quarterly Journal Geological Society, London, 56, 337-369.

My son, Capt. A. H. McMahon, C.S.I., C.I.E., Y.G.S., Political Agent, Malakand, when stationed at Gilgit, made field-observations and collected rock-specimens for me in the course of numerous traverses through the Gilgit area. I have not had an opportunity of visiting the region covered by this paper; but I have seen much of the neighbouring Himalaya, and I have had the advantage of correspondence not only with my son, but also with Capt. J. R. Roberts, I.M.S., regarding the geology of Gilgit. I am greatly indebted to Capt. Roberts for much valuable information, for field-observations undertaken on my behalf, for careful drawings of sections, and for numerous additional specimens supplementing those sent by my son. I cannot overrate the obligations under which I am to him.

A sketch-map (see p. 344) has been prepared to accompany this paper, compiled mainly from the map of the Pamirs (1896) by H. Sharbau and the Right Hon. G. N.—now Lord—Curzon; and from the map of Astor and Gilgit (1883) by the Surveyor-General of India. The geology of the neighbouring parts of Kashmir has been described by Mr. R. Lydekker, Y.R.S., in vol. xxii (1883) of the Memoirs of the Geological Survey of India, and in papers published in the Records of the same Survey. The map published with the above-mentioned Memoir shows the geology of Kashmir as far as Astor, at which place this paper takes up the geology.

M/161. McMahon, C.A. & Huddletone, W.H., 1902. Fossils from the Hindu Khoosh. Geological Magazine 9, 49-57.

The Himalayas, with the help of that singular replica of the more mountainous region known as the Salt Range, have afforded to the paleontologist, in one place or another, a fairly good series of the several Paleozoic horizons.

1. The First Paleozoic Horizon. – The Lowest Cambrian, or Neobolus-Fauna, perhaps the lowest recognized fauna in the world, is to be found in the Salt Range in immediate succession to the Salt series. This fauna was discovered by Warth, and has been elucidated in the Paleontologia Indica at considerable length. In the volume for 1899 there is a plate of these fossils, which are described as consisting of simple forms like Neobolus, or rather complicated ones like Pseudotheca.

The Carboniferous overlap in the Salt Range, noticed by Waagen and confirmed by subsequent observers, has had the effect of shutting out the rest of the infra-Carboniferous horizons from that range, so that we there obtain nothing between the lowest Cambrian and the Carboniferous beds. On the other hand, I cannot find that the Neobolus-fauna has been recognized in the Himalayas proper.

2. The Second Paleozoic Horizon.- This must be sought in the Himalayas alone without the valuable confirmatory evidence supplied by the Salt Range in the case of the Carboniferous fauna.

A very valuable find of fossils belonging to this horizon, which in the main may be regarded as of Lower Silurian (Ordovician) age, was made by General Strachey some forty years ago in Niti. These were described and figured by Salter in a memoir printed for private circulation, to which H. F. Blanford contributed. To give an idea of the importance of this find, Salter enumerated some sixty species, as follows: - Crustacea 8 species, Annelida 2, Cephalopoda 8, Gasteropoda 11, Lamellibranchiata 3, Brachiopoda 21, Bryozoa 3, Amorphozoa 2, Zoophyta 2. Referring to the Brachiopoda only, Leptana, Strophomena, and Orthis are perhaps the best represented genera, and the fauna was regarded as most resembling Caradoc. Many of these fossils are in a fairly good state of preservation. The types are to be seen at the British (Natural History) Museum.

Shortly afterwards Stoliezka wrote a memoir on the Paleozoic formations in Spiti. Here he came across a fossiliferous horizon which he called the Bhabeh-series, but the fossils were badly preserved. In this recapitulation Steliezka described his Bhabeh-series as probably of Lower Silurian age, consisting of sandstones, slates, and quartzites, containing Orthis and other genera not specifically determinable.

Subsequently it is believed that important additions have been made to the collections from this horizon in the Himalayas, but at present these matters are in reserve. The following extract from Mr. R. D. Oldham's Manual, published in 1893, bears upon this point. It occurs as a footnote. "A large number of fossils from General Strachey's

collections were described by Messrs. Salter and Blanford in 1865, and the collections which were made by Griesbaeh, which are still in the course of description, will doubtless add to their number. Until this fauna has been worked out and its relations fully determined, there does not appear to be any benefit in printing a nominal list of the species that have been described.”

3. The Third Paleozoic Horizon. – Like the second horizon, this has no replica in the Salt Range. So far as anything is known about it, we are still indebted to Stoliezka. Referring to his experiences in Spiti, he thus speaks of the Muth-series: - “Above the true Silurian rocks there will be found a thickness of beds, of about 1,000 feet, distinguished by a different shade of a bluish colour; their age is left undecided. The fossils of this series occur in an arenaceous limestone, some of the beds being of a purer limestone of a dark colour. Specific determination is not easy owing to the bad state of preservation.”

Two species of *Cyathophyllum* were recognized, whilst the Brachiopoda were represented by *Strophomena* and two species of *Orthis*. In his summary Stoliezka regarded the Muth-series as of Upper Silurian age, and he correlated, as already stated by General McMahon, the middle or fossiliferous division of that series with the Blaina-limestone.

4. The Fourth Paleozoic Horizon.- This may be focused under the general term of the Kuling-series. The fine collection of Carboniferous fossils sent by Colonel Godwin-Austen from Kashmir engaged the attention of Davidson many years ago. A considerable number of these specimens may yet be seen in the Museum of the Geological Society. This very abundant and characteristic fauna is receiving samples attention from the writers in the *Paleontologia Indica*, supplemented as it is by the high fossiliferous Productiv limestones of the Salt Range.

M/171. Mehdi, S.E., 1982-84. Geotechnical studies of landslides along Karakoram Highway from Shetan Pari to Ali Abad. M.Sc. Thesis, Punjab University, Lahore, 122p.

This thesis is mainly composed of the study of about land sliding along Karakoram High Way from Shetan Pari to Aliabad. A brief description of other geological features are also included in the thesis. The geological map shows the different types of rocks present in the project area. Detailed study has been made in the project area to collect the data about discontinuities as joints, which plays the dominant role in case of sliding in hard rocks. This data has been plotted on equal-area stereonet to check the stability of the slopes. In case of sliding in soft material like alluvial fan, samples were collected and tested for detailed analysis. Finally on the basis of this analysis, the road is classified into stable, potentially unstable and unstable regions.

M/174. Mehmood, T., 1999-2000. Geological mapping, stratigraphy, petroleum geology and tectonics of Kohat sub-basin, N.W.F.P., Pakistan with special emphasis on structure and sedimentology of Shadi Khel-Gumbat area District Kohat N.W.F.P., Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 95p.

The study area lies in the Kohat sub-basin of upper Indus Basin which constitutes the western part of the Himalayan fold-and-thrust belt and is bounded by Surghar Range in the south. Regionally Kohat plateau is underlain by sedimentary rocks ranging in age from Pre-Cambrian to Pliocene. Oldest rocks are exposed in the north while most of the middle and southern portions are covered by rocks of Rawalpindi and Siwalik groups. Deposition of the

sediments was interrupted several times, however, the major one with in the exposed sequence is between the Eocene and Miocene. The rocks, exposed in the area, are locally highly folded and faulted due to orogenic movements related to Himalayan uplift.

The objective of the project was to study the structural style, stratigraphy, petrography of different rock units and to evaluate the hydrocarbon potential of the area. Within the exposed rock units, shales of the Chichali and Patala Formations are the potential source rocks. Limestone of the Samana suk, Lockhart and Shekhan Formations are the potential reservoir rocks. Potential cap rocks of the Kohat plateau are shale/clay of Datta, Patala, Kuldana and Kohat Formations. Bahadurkhel salt and Jatta Gypsum may prove very effective cap rocks, especially in the southern portion of the study area. Structural analysis of different rock units shows that there are two deformational events i.e. D1 and D2 which are related to F1 and F2 folding. F1 folds related to D1 are north vergent folds with NE-SW extension. F2 folds and structures are formed by northeast and southwest compression. D2 deformation phase change the fold axis and plunge of F1 fold. The F2 cross folds are mainly anticlines and synclines.

M/176. Meier, A. & Wahrenberger, C., 1991. The stratigraphy of the Higher Himalaya at upper Kaghan Valley, NE-Pakistan. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Auris, France, 59.

As a part of the Himalayan research programme of the ETH we has the opportunity to do the fieldwork for our diploma thesis in summer 1990 in Pakistan. During the fieldwork a stratigraphic profile of a total measured length of about 1400-m was taken. The effect of deformation on the original bed thickness has not yet been considered.

Three major lithological groups can be defined: a group of metagranitoid rocks overlain by metapelites form a “basement” overlain by a series of metamorphic calcpelites, which have been interpreted as cover to this basement (Greco et al., 1989).

The stratigraphically lowermost group is represented by a leucocratic-mesocratic garnetiferous two mica-gneiss. A banding with dark mica dominated schist layers takes place at 10-cm scale.

The transitional contact with a stratigraphically overlying group of micaschists takes place within about 2 m. No angular discordance was observed. These rocks are garnet-two micas gneisses characterized by porphyroblastic feldspar and an abundance of biotite. The aluminium rich nature of these rocks and the preservation of sedimentary structures show that the original material was pelitic to semipelitic sediment. The group also comprises occasional quartzitic layers and rare marbles. The contact to the uppermost group is also transitional over a distance of about 15 to 20 m. this group consists mostly of metamorphic calcpelites which vary from pure marbles to garnet-micaschists together with more psammitic layers. At the top of the profile stromatolitic layers are associated with structures indicating syndimentary extension. Amphibolites are present in all groups. These being interpreted associated with the Panjal Trap Basalts (Papritz and Rey, 1989). They are probably of both extrusive and intrusive origin.

Key words: Stratigraphy, Kaghan Valley, Himalaya.

M/177. Meier, A. & Wahrenberger, C., 1992. Metamorphism and tectonics in the higher Himalaya crystalline of upper Kaghan valley, NE Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 55.

Based on the field data from summer 1990 we summarize our observations and interpretations on the geology of Burawai-Jalkad Section in Upper Kaghan Valley as follows:

The rocks can be separated in three major stratigraphically successive groups: The lowermost group of metagranitoid rocks form a basement to a first cover of metapelites. These are overlain by a series of metamorphic calcpelites (second cover). The stratigraphic profile taken in the field confirms this succession, but must include at

smaller scale several duplications produced by the F1 folds. The geological map shows regional unconformities between all lithological groups.

Different metamorphic histories can be derived for basement and cover rocks. Second cover metapelites suggest two phases of metamorphism. A first phase (M1) being of staurolite-kyanite grade syn- to postkinematic to f1 and a second phase (M2) postkinematic to f2. Kyanite of the first phase is broken during f2 and re-crystallizes during M2. Peak metamorphic conditions are reached during M2 and are estimated to 600-650 °C and pressures between 6 and 9 kbars by petrographic grid. First cover rocks suggest a two-fold re-equilibration of an earlier metamorphic event. Euhedral clinopyroxene, which is later consumed by amphiboles, encloses symplectitic structures of diopsidic pyroxene with plagioclase. These symplectites as well as rutiles enclosed in titanite are preliminary regarded as indicators for a former eclogite facies event. Eclogites which formed under 650±50 °C and 13-18 kbars are reported further to the north by Pognante and Spencer (1991). These observations, as well as the presence of migmatized rocks, suggest a decompressional path with rising temperatures. The dissolution of white mica indicates the beginning of high temperature metamorphic overprint in the basement.

The structural data analysis leads to a ductile deformation of rocks documented by a polyphase folding history. Three different folding phases can be distinguished: A first phase (f1) produces tight to isoclinal folds with axial planes strongly deformed as a result of later folding phases. The well-developed penetrative schistosity, made up by oriented platy and acicular minerals, is the most dominant microstructural feature. Bedding and schistosity planes are subparallel and are folded together with schistosity-bedding intersection lineations (interpreted as first phase fold axes) by the second deformation event (f2). The second phase folds show an open fold type. The axial planes strike NE-SW and the fold axes are gently plunging to the southwest. A third folding phase (f3) deflects the older structures. The superpositions of the folding phases result in interference patterns. The crenulation of penetrative schistosity with constantly oriented fold axes plunging to southwest could document a further deformation event.

Key words: Metamorphism, tectonics, Himalaya, Kaghan valley.

M/178. Meier, W., Heintz, M., Kretzschmar, D., Niedtfeld, B., Wagner, E., Wagner, R., Dr. Gerhard Weiß, Beheng, K., Dr. Anno Diemer, Holtmann, G., Jaeger, W., Michaelis, W., Obrocki, U. & Wasel, P., 1976. Eine expedition ins Hohe Lungma-Gletscherbecken. Kolner Karakorum-Expedition 1976. Prufer, Kasendorf.

On August 8, the Cologne started with two jeeps and two tractors through the Shigar-Valley by the end of the jeep track to Jouna. At the mouth of the river in the Braldu Basha River at Youno or Jouna they rented carriers and marched along the Braldu in northern direction until Dassu had to the base camp withdraw. Only on August 24, a new trial could be started, because of fresh snow but managed only to Camp 1. Now turns at the mouth of the Hoh River Lungma the Braldu River to the east. But the Germans followed the Hoh Lungma-River and camped in Tapsa (3700 m). Here she first had with the inhabitants negotiate for the permission for entering the Hoh Lungma-area. After the agreement it went to Hoh Lungma Glacier where on the "Bärenwiese" in 4150 m Height on August 11, the base camp was. About the lower plateau of the glacier Tsilbu (4500 m) we went up to the upper plateau, where in 4700 m camp 1 has been built. On August 15, a barrage increased from three climbers on the top Tsilbu-Glaciers to South Hikmul pass on and established in 5390 m camp 2. After there was once a weather burglary and Cologne the weather was consistently bad and so they decided to retreat. Hillside, the Germans had split into two groups working completely separately. The second group was on August 12 by Tapsa the orographic right side the lower Sosbun glacier until about 4200 m height. The following day erected it their base camp on the upper Sosbun Glacier in 4440 height. After a rest day it continued on August 15 and was at the foot of Sosbun Brakk-west ridge stock 1 built in 4820 m height. In the following days, the climbers started the Climbing at West Ridge. In about 5000 m, they crossed a glacier, and laid on Gratfuß to a first material depot. Another depot was with rope Insurance (IV Degrees) created in 5250 m. Following were equipment and food up stock 1 made from base camp. On August 23, it was in complicated Ridge climbing above the second depot on. There had to a large intersection and an ice slope (V degree) to be overcome in 5350 m. Following was the explored route insured. Behind the intersection it went on 25 August. Next, the Cologne reached the actual rock body in 5400 m height. Smoothness Plates and mixed terrain (V-VI grade) were a real challenge. Of the highest point, which was achieved, was in about 5500 m altitude. Because of slumping Night rose the roped off a piece, but then had in 5300 m altitude a bivouac set up. Prolonged snowfall demoralisierte Cologne so much that they decided dismount.

The Parachinar quadrangle occupies approximately 3500 square miles along the western border of West Pakistan. The area consists mainly of sedimentary rocks that range in age from Jurassic to Pliocene. A total of 23 stratigraphic groups and formations, most of them having formally accepted names, have an aggregate stratigraphic thickness of more than 23,000 feet; more than 13000 feet is Late Tertiary in age. Sixteen stratigraphic sections provide much detailed information on the lithology and stratigraphic relations of the rock units. The work was correlated with that done in the Kohat quadrangle to the east and the Bannu quadrangle to the south. Of major stratigraphic importance is the juxtaposition of two distinct facies of Cretaceous rocks in the quadrangle, a shale facies on the west and a limestone facies on the east.

The Kohat quadrangle (Survey of Pakistan topographic sheet 38-O) consists of approximately 4,000 square miles. Sedimentary rocks in the area have a total stratigraphic thickness of more than 25,500 feet. The oldest rocks crop out in the northeastern and northwestern parts of the quadrangle, and are slate, slaty shale, and sandstone of Precambrian or early Paleozoic age. Jurassic, Cretaceous, Paleocene, Eocene, Miocene, and Pliocene sedimentary formations are found in the Kohat quadrangle. Pleistocene sedimentary rocks also may be present, but were not recognized.

The rock sequence of 21 formations, six of which are formally defined for the first time.

The Jurassic System consists mostly of limestone: two subdivisions have been recognized. The Lower half of the Cretaceous System is mostly marine sandstone, and the upper half is mostly marine limestone. The Paleocene Series, which includes three formations, consists mostly of carbonate rocks but also contains some sandstone and shale. Of the Eocene Series, only rocks of early Eocene age are present in the Kohat quadrangle, and they contain extensive deposits of gypsum, rock salt, marine limestone and shale. A relatively thin section of the Murree Formation of Miocene age unconformably overlies lower Eocene rocks. It, in turn, is overlain by more than 10,000 feet of strata.

Nanga Parbat lies on the western end of the Himalayan Mountain chain in NE Pakistan. This >8 km high peak, sculpted from Indian crust, is the site of rapid uplift, denudation, and young (<1 Ma) igneous and metamorphic activity. Substantial reworking of the crust occurs today, although the initial collision between India and Asia occurred ~55 my ago. While the Indian basement gneisses that make up the Nanga Parbat massif were clearly involved in a major collisional event, they exhibit virtually no evidence for early Himalayan metamorphism. As part of a multidisciplinary study to understand the active tectonic processes at Nanga Parbat we deployed a dense seismic array to characterize active seismicity at the massif (fault geometry and kinematics) and determine crustal structure beneath the mountain. Extremely rapid exhumation, the presence of hot springs, young intrusive rocks, and young metamorphism all suggest an anomalous thermal structure lies beneath Nanga Parbat.

Our 60 station array consists of 10 broadband and 50 short period three component stations deployed in a 60 x 60 km area surrounding the massif. Station spacing varies from 1 to 6 km, and station elevations range from 1.0 to 4.3 km. The array recorded local and regional seismicity for a 4 month period (May-September, 1996). Primary source regions are the Hindu Kush, the Karakoram, the Himalayan and Hazara arcs, and local seismicity beneath the massif itself. The Hindu Kush events which originate 200-300 km northwest of Nanga Parbat, and at 200-300 km depth serve as a beam source to illuminate the structure beneath the massif.

In a four month time window we recorded over 1500 associated events, a combination of teleseismic, regional, and local earthquakes. Our initial focus has been on locating events and analyzing waveforms. Ultimately, we'll use the Hindu Kush events and additional regional events from a range of azimuths combined with local events to produce a tomographic image of velocity and attenuation structure beneath the massif.

Our array recorded a high level of microseismicity at Nanga Parbat, between 3 and 8 small magnitude events per day. Seismicity is somewhat distributed along strike beneath the massif but exhibits a sharp drop off in intensity both west and east of the main summit. The sharp cut off in seismicity to the west corresponds to the mapped trace of the Raikot fault. This young active structure juxtaposes Indian Pre-Cambrian gneisses against mafic rocks of the Kohistan Island arc captured during the collision of Indian and Asia and provides a mechanism to expose Indian plate rocks from beneath Asia. The adjacent Kohistan terrane is virtually aseismic. The sharp cut off in seismicity to the east is bound by the region of highest topography. In fact, the highest intensity of distributed seismicity is associated with the region of highest topography. Local seismicity beneath Nanga Parbat is restricted to very shallow depths (< 8 km bsl) providing constraints on the transition from brittle to ductile deformation. Hypocenters projected to a NW-SE cross section outline a prominent bow or antiformal shape. The cutoff of seismicity with depth is shallowest beneath the summit (5-km bsl) and deepens to 8 km to the NW and SE. This observation is consistent with petrologic and thermochronologic data indicating very high geothermal gradients (~60-100o/km) at Nanga Parbat. At these rates, rocks pass through the 450o isotherm by ~7 km depth which approaches the ductile regime for quartzofeldspathic rocks, especially in the presence of fluids and high strain rates.

Most of the local events have clean impulsive signals allowing high quality focal mechanisms to be determined. While we recorded some thrust and some right-lateral strike-slip focal mechanisms, much of the observed seismicity is from a set of shallow normal faults striking roughly parallel to the main massif and dipping south to southeast, back toward the summit.

While many of the igneous, metamorphic, and petrologic observations at Nanga Parbat could be explained by a young intrusive body at depth, complicated but prominent S wave arrivals at stations throughout the array rule out the possibility of a substantial magma body beneath Nanga Parbat. This observation holds for both Hindu Kush events with a relatively vertical ray path beneath the massif sampling the entire crust and local events, which travel through the shallow crust. However, we do see local travel time delays and anomalous waveforms suggesting small scale heterogeneity possibly related to small partial melt zones. We also see a large variation in waveform coda associated with propagation path (not site affects). While we see many clean impulsive arrivals, others appear more harmonic, not unlike signatures associated with geothermal systems and volcanoes, suggestive of magmatic or fluid injection at shallow depths. These events are intriguing given the evidence for recent igneous activity focused at the core of the massif and evidence from fluid inclusions indicating a dry steam phase associated with a hydrothermal system below 3 km depth. Finally, on many of the local events we see evidence of shear wave splitting presumably due to anisotropy associated with the metamorphic or strain fabric of the rocks.

Key words: Seismicity, structure, Nanga Parbat, Himalaya.

M/190. Meltzer, A., Seeber, L., Sarker, G. & Armbruster, J., 1999. Seismic characterization of active metamorphism, Nanga Parbat, Pakistan Himalaya. *Terra Nostra* 99 Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 98-99.

Earthquakes recorded by a dense array of seismometers deployed around the Nanga Parbat massif in the Himalaya of Pakistan provide new insight into synorogenic metamorphism and deformational processes. Microseismicity distributed along strike beneath the massif exhibits a sharp drop-off to the east bound by the main summit massif. An abrupt cessation of seismicity with depth defines a shallow brittle-ductile transition at 5-8 km bsl. Low P and S wave velocity anomalies observed at the core of the massif extend to depth through the entire crust. At Nanga Parbat local seismicity and low seismic velocities are associated with the highest topography, youngest metamorphic and igneous ages, high geothermal gradients, and active crustal fluid flow suggesting a genetic link between these phenomena.

Most of the local events have clean impulsive signals allowing high-quality focal mechanisms to be determined. While we have recorded some thrust and some right-lateral strike-slip focal mechanisms, much of the observed seismicity is from a set of shallow normal faults striking roughly parallel to the main massif and dipping south to southeast, back toward the summit. These extensional focal mechanisms are not associated with low-angle crustal-scale faults typically associated with tectonic denudation in orogenic belts. Instead, they fall along planes that are relatively high angle, limited in lateral extent, and restricted to the shallow portions of the crust (upper 5-8 km). These normal faults are consistent with extension above the doubly vergent thrust system which bounds the massif.

Some extensional events may also record hydrofracturing associated with the release of overpressured fluids at depth. We see a cluster of events associated with the Tato hot springs. These events, when relocated using a cross-correlation technique, locate within $\pm 50\text{m}$ of each other defining a tightly constrained fault plane that may serve as a pathway for circulation of meteoric water to and from the surface. A 3-D joint inversion for hypocenter location, V_p , and V_s shows that the velocity structure beneath the Nanga Parbat massif is anomalously low, up to 10%, over lateral distances of 20-40 km (11). In the shallow crust ($<10\text{-km}$ depth) V_p ranges from 5.6-5.8 km/s and V_s from 3.3-3.5 km/s within the massif compared to velocities of $V_p=6.0\text{-}6.4\text{ km/s}$ and $V_s=3.5\text{-}3.6\text{ km/s}$ in adjacent regions. Analyzing arrivals at the stations deployed in valleys as subsets of small linear arrays yields similar velocity values confirming the robustness of these results. At greater depths (10-50 km) V_p ranges from 5.8-5.9 km/s and V_s from 3.5-3.6 km/s within the massif compared to velocities of $V_p=6.2\text{-}6.5\text{ km/s}$ and $V_s=3.6\text{-}3.8\text{ km/s}$ in the surrounding area. Both the P and S wave velocity anomalies are observed at the core of the massif and extend to depth through the entire crust. Low velocities imply hot rocks at depth in this region as the composition of the massif is monotonously homogeneous with respect to seismic wavelengths. The distribution of low velocities found at Nanga Parbat is consistent with the prediction of numerical models examining the evolution of the conductive geotherm during rapid advection of crustal rocks, which indicate that Nanga Parbat should resemble a “pillar of heat”. This result also suggests that the primary flow path of material into the massif is from depth rather than along a shallow detachment. Finally, our initial inversions yield slightly low V_p/V_s ratios at several areas within the massif, which may reflect the presence of super-critical fluids in small regions of limited extent. While many of the igneous, metamorphic, and structural observations at Nanga Parbat could be explained by a young intrusive body at depth, prominent but complicated S wave arrivals at stations throughout the array rule out the possibility of a substantial magma body beneath Nanga Parbat. This observation holds for both Hindu Kush events with a relatively vertical ray path beneath the massif sampling the entire crust and local events, which travel more obliquely through the shallow crust.

The seismic data recorded at Nanga Parbat supports a model of strain induced metamorphism. Focal mechanisms, travel time and waveform anomalies, low V_p and V_s , and low V_p/V_s ratios are consistent with the model in which rapid and dramatic exhumation leads to pervasive reworking of continental crust. Dehydrated Indian gneisses are transported from depth toward the surface. As this material is brought to the surface advection of isotherms results in low P and S wave velocities throughout the crust and elevates the position of the brittle-ductile transition causing it to bow, convex upward beneath the massif. As dry gneisses then pass into the lower strain zone beneath the summit, they are brought into communication with surface waters. Fluids may be released due to shear failure at elevated fluid pressure or due to local hydrofracturing providing the source of some of the microseismicity recorded at Nanga Parbat.

M/194. Mensink, H., Mertmann, D. & Ahmad, S., 1986. Stratigraphical dates on the Triassic rocks of Landu Nala, Surghar Range. Geological Bulletin, Punjab University 21, 104-119.

The stratigraphy and microfacies of some of the Triassic rocks of Landu Nala are described. Within the pisolitic horizon on top of the Mianwali formation a few species of conodonts namely *Gondolella timorensis*, *Neospathodus homeri* and *Ozardina tortilis* are recorded. Within the Kingriali succession some brachiopod species of *Spiriferinoides* and some pelecypods have also been identified. An Anisian and Carnian age is proposed on the basis of fossil contents.

M/195. Mensink, H., Mertmann, D., Ahmad, S. & Shams, F.A., 1984. Facies of Jurassic rocks in the Surghar Range, Pakistan. Abstracts, First Pakistan Geological Congress, Lahore, 63-64.

The Jurassic sediments of the Surghar and Salt Range show a variety of microfacies-types. It is possible to distinguish 12 different rock facies. Furthermore, the sections contain many discontinuities. Both are interpreted. The sedimentary history can be divided into 5 subsequent phases between the Upper-Trias and Neocom.

Microfacies-analysis of 60 thin sections based on 80 rock samples from two sections namely Nammal Gorge and Gulakhel belonging to the Kingriali-Formation is presented. Eleven types of microfacies have been differentiated and are described. Most of these are of dolosparitic nature, others are dolomicritic. Furthermore, calcitic onco-, oo- and bio-sparites are also encountered during the present investigation. Based on facies-analysis the rock sequence is subdivided into different facies units. Paleoenvironments are interpreted as shallow marine to intertidal.

M/206. Mertmann, D. & Ahmed, S., 2000. Foraminiferal assemblages in Permian carbonates of the Salt Range and Trans Indus Ranges, Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, 21-22.

The marine Permian sediments (Amb-, Wargal- and Chhidru Formations) of the Salt Range and the Trans Indus Ranges yield an abundant fauna of foraminifera. Main groups include Fusulinina, Miliolina and Rotaliina. The fauna occur as benthic organisms setting under open marine to lagoonal conditions in a warm Tethyan sea (P.J.R.G., 1985). The foraminifera show strong palaeobiogeographic relations to other Tethyan carbonate platforms situated in today's Iran, Afghanistan, China and Asia (Jenny-Deshusses 1983, Lys 1988).

Fusulinaceans (*Parafusulina* (*Monodiexodina*) *kattaensis* (Schwager) and *Codonofusiella laxa* Douglass) are rare in the Amb Formation due to strong clastic input and an agitated coastal water. In the lower Wargal Formation and association comprises *Neoschwagerina margaritae* DEPRAT, *Sphaerulina* sp., *Schubertella* sp., *Chusenella* sp. and *Reichelina* sp. Therefore, a Murghabian age is evident. The occurrence of the *Neoschwagerina*-association is related to a major marine transgression together with a warm surface current along the northern margin of Gondwana. In the upper part of the Wargal Formation and in the Chhidru Formation, *Nanlingella simplex* Sheng & Chang, *Reichelina* sp., *Nankinella* sp. and *Staffella* sp. indicate a Djulfian age. Small foraminifera include a variety of long ranging species from *Parathuramminidae*, *Earlandiidae*, *Nodosinellidae*, *Endothyridae*, *Lasiodiscidae*, *Hemigordipsidae* and *Fischeridae*. Others are more interesting *Globivalvulina vonderschmitti* REICHEL and *Dagmarita chanakchiensis* RIETLINGER indicate a Murghabian to Djulfian age. Both are present in the Wargal- and Chhidru Formation. *Globivalvulina mira* REITLINGER (Midian - Djulfian) occurs from the Upper Wargal onward. *Colaniella* ex grupo *lepidi* WANG and *Colaniella* ex grupo *minima* WANG are restricted to the Upper Wargal and the Chhidru Formation. Stratigraphically confined to the Midian to Dorashamian, older forms are described only from the Pamir and Caucasus. In the southern Peri-gondwanian areas they represent a Djulfian age, whereas the youngest forms are

known from China (Jenny-Deshusses et al., 1989). Within the Wargal Formation they are often distributed in a coral reef facies.

M/207. Mertmann, D. & Ahmed, S., 2000. Evolution of Tethyan carbonate platform during the Upper Permian (Salt Range, Surghar Rang), Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, 22-23.

During the Permian, a large carbonate platform developed on Gondwana continental crust in front of the Indian Shield. The platform was influenced both by sea-level fluctuations and by repeated intervals of hinterland uplift associated with an increase in clastic terrigenous input. Sedimentary environments were mainly of the following types; deltaic and siliciclastic shelf and carbonate platform with a variety of reef mounds, bioclastic shoals and tidal flats. The sequence can be divided into depositional sequences and the system tract philosophy can be applied. Third-order cycles are represented by at least 6 depositional sequences with internal shallowing- upward parasequences. Moreover, a superimposed cycle spans the whole Zaluch Group.

M/209. Mian, I., 1970a. The chromium-bearing minerals of the North West Frontier Province. Geological Bulletin, University of Peshawar 5, 131-134.

During the past few years, many interesting minerals have been reported from the N.W.F.P. Of these, the chromium-bearing minerals – emerald, mica, spinal and tourmaline – merit special attention because of the economic and / or academic importance. Gem quality emerald from Swat and Mohmand Agency is sold at high price and has attracted a lot of people during the past few years. All of the chromium-bearing minerals are closely associated with ultramafic rocks from which chromium was derived by various mechanisms. In this paper, the writer has tried to gather all the published data available on these occurrences, and has added some new information.

M/212. Mian, I., 1994. Sulphide occurrences in Shinkai area of North Waziristan Agency, FATA. Abstracts, Second SEGMIITE International Conference on the Export Oriented Development of Mineral Resources and Mineral Based Industries, Karachi, 33-34.

Waziristan area representing a typical ophiolite environment with a diagnostic sequence of ocean floor ultramafics, sheeted dykes and pillow lava with subordinate deep marine sediments. The ophiolite sequence is intruded by plutonic rock (Diorite and granodiorite).

Copper occurrences in brecciated pillow lavas of the ophiolite have been recorded in a North-west trending belt. Various gossans have been identified along 100-kms, as linear belt and confined to the west central part of Waziristan area. Major occurrences are confined in Shinkai and Degan-Paikhel area, North Waziristan Agency and Spinkamar area of South Waziristan Agency, total of 15 prospects of various area extent have been studied for sub-surface behaviour of copper and related sulphide in Shinkai and Degan Paikhel area.

Primary sulphide mainly (pyrite, chalcopyrite and bornite) are confined to the chloritized pillow breccia as stock work in the form of fractures, cavity fillings and fine disseminations. These sulphides are mostly associated with quartz, epidote, calcite and chlorite. The stock work zone is capped by a thin layer of secondary oxides including malachite, azurite, Limonite, iron limonite, jarosite, goethite and hematite. Geochemical studies of 92 bore hole samples of about 12,462 meters strata at 1 meter interval are conducted for copper and related sulphides.

Multidisciplinary geophysical survey has been conducted in the Degan Paikhel through Geological survey of Pakistan in 1988. Induced polarization survey has been initiated at Shinkai area. Total of 1411' profiles at 50 meters and 100 meters electrode spacing have been conducted. Based on bore hole geochemical studies, petrography, induced polarization (IP) studies and subsurface alteration, it is suggested that the sulphide mineralization is of volcano genic massive sulphide type (VMS); formed at or near the submarine spreading center and later on subjected to uplift and exposure during collision of Indian mass with the Eurasian continental block.

The Koga syenites are intruded and fenitized by at least two carbonatite intrusions having different Na/K ratios. The carbonatite with high Na/K ratio formed Na-fenites, while the low Na/K ratio produced K-fenites. Amongst the fenitic pyroxenes, Na-pyroxene shows a trend from actinolitic to diopsidic and/or hedenburgitic component in contrast to magmatic trend. The fenitic Na-amphibole occurs only in Na-fenitized rocks and shows a trend from magnesio-arfvedsonite to richterite, which is opposite to the magmatic subsolidus trend. The amphibole composition shows an increase in MgO ratio with increasing intensity of fenitization and suggests the crystallization of fenite amphibole under strong oxidation conditions.

Key words: Mineralogy, pyroxene, amphibole, Koga, Buner.

M/215. Mian, I. & Le Bas, M.J., 1986. Sodic amphibole in fenites from the Loe Shilman carbonatite complex, NW Pakistan. Mineralogical Magazine 50, 187-197.

The carbonatites at Loe Shilman, near Khyber in NW Pakistan, fenitize their country rocks to form a metasomatic zone c.100 m wide of alternate dark blue (mafic) and pale grey (felsic) banded fenites which grade into unfenitized bedded slates and phyllites. The Na-amphiboles in the banded fenites form a complete solid solution series between magnesio-arfvedsonite and magnesio-riebeckite which coexist with varying proportions of aegirine, albite, and K-feldspar, with or without phlogopite or biotite. The amphiboles show a gradual decrease in Na₂O, K₂O, Mg ratio [100Mg/(Mg + Fe^T + Mn)] and iron oxidation ratio, and an increase in total iron away from the carbonatite contact. The pleochroism correlates with the chemistry and distance from the carbonatite contact.

The Mg ratio decreases from 74 to 35 away from the carbonatite contact. The iron oxidation ratio [100Fe³⁺/(Fe³⁺ + Fe²⁺)] decreases in the magnesio-arfvedsonite for the first 30 metres from the carbonatite contact, and then increases in the magnesio-riebeckite from 40 to 60 metres from the carbonatite contact. K relative to Na decreases away from

the contact in the amphibole, and the decrease in K causes an increase in vacancy in the A site. The main variation in the chemistry in this solid solution series is due to $(K, Na)_A + (Mg, Fe^{2+})_c \rightleftharpoons \square + (Fe^{3+})_c$ substitution.

Key words: Mineralogy, amphibole, Loe Shilman.

M/216. Mian, I. & Le Bas, M.J., 1987. The biotite-phlogopite series in fenites from Loe Shilman carbonatite complex, NW Pakistan. *Mineralogical Magazine* 51, 397-408.

The Loe Shilman carbonatite sheet complex comprises an extensive amphibole sovite which is intruded by minor biotite sovite and amphibole ankeritic carbonatite. The carbonatites have fenitized the country rocks to form a metasomatic zone c. 100 m wide of alternating mafic and felsic mica-bearing banded fenites which grade into slates and phyllites. Phlogopite-rich micas occur nearest to the carbonatite contact. The biotites occur in K-feldspar + albite $\pm$ Na-amphibole $\pm$ aegirine and $\pm$ phengite fenites produced by the intrusion of the early amphibole sovite. Aegirine buffered the iron distribution and the biotites became more magnesian. Veins cross-cutting the fenites consist of biotite and/or Ba-bearing K-feldspar, and are interpreted to result from solutions emanating from the biotite sovite. The ankeritic carbonatite is responsible for the formation of phlogopite in the fenites in a c. 3 m wide zone adjacent to the carbonatite, and evidently are the result of fenitizing fluids rich in Mg. Chemical equations calculated to balance the reactions interpreted to have taken place in the fenites suggest that about 10% of the Al and Si in the protolith was mobilized and moved towards the carbonatites during fenitization, and that the fenitizing solutions were strongly alkaline and oxidizing.

Key words: Mineralogy, biotite, fenite, Loe Shilman, NWFP.

M/217. Mian, I. & Le Bas, M.J., 1988. Feldspar solid solution series in fenites from Loe Shilman carbonatite complex, NW Pakistan. *Geological Bulletin, University of Peshawar* 21, 71-83.

The carbonatite sheets at Loe Shilman in Khyber Agency, NW Pakistan, fenitize their country rocks to form a metasomatic zone, c. 100 metres wide, of alternate dark blue (mafic) and pale grey (felsic) banded fenites which grade into unfenitized slates and phyllites. The carbonatite sheets comprise a more extensive amphibole sovite which is intruded by biotite sovite in different parts of the complex. These sovites are in turn intruded by ankeritic carbonatite mainly along the southern contact with the country rocks.

Among the new minerals, formed as a result of three fenitizations (two sodic and one potassic), K-feldspar are formed as a result of contact thermal effect by the early amphibole sovite at the expense of phengite and argillaceous material. The more disordered K-feldspar, which were formed at high temperature ($\sim 7000^\circ\text{C}$), in the inner zones 3, 4 and 5 are now readjusted to maximum-microcline to intermediate-microcline. While in zone 2 the more disordered relict K-feldspar escaped readjustment, and therefore, produces reverse zonation in contrast to the temperature gradient. The effect of biotite sovite is restricted to the thin veins composed of K-feldspar (Ba=1.4 wt %) and biotite. The samples SM93 and SM84, amongst the banded fenites, have been also metasomatized by the biotite sovite.

Albite, which coexists with other metasomatic minerals, formed first by the early amphibole sovite, was presumably more disordered towards the carbonatite contact. It is now readjusted to its present lowest structural state by the ankeritic carbonatite. The presence of relict disordered intermediate low-albite now shows reverse zonation in contrast to the temperature gradient. Both the solid solution series are well correlated with distance from the carbonatite igneous contact.

Key words: Mineralogy, feldspar, fenite, Loe Shilman, Khyber Agency.

M/218. Mian, I. & Le Bas, M.J., 1990. The geochemistry of the zoned fenites at the Loe Shilman carbonatite complex, NW Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 26-27.

The carbonatite at Loe Shilman in Khyber Agency, NW Pakistan, fenitize the country rocks to form a metasomatic zone c. 100m wide of alternate dark blue (mafic) and pale grey (felsic) banded fenite which grade into unfenitized thin bedded laminites (slates and phyllites).

The banded fenites are syenitic in composition which show gradual increase in Na from 2 to 13.7 (calculated into a standard cell of 100 anions) while Si and Al decreases from 37 to 33.7 and 11.7 to 0.8 respectively from the outer zone 1 to the inner zone 5. K, Mg and FeT remain approximately constant in the outer four zones and range between

3.5-4.3, 1.9-3.0 and 2.5-3.5 respectively while K decreases sharply from 6.0 to 1.5 and Mg and FeT increase sharply from 5 or less to 9 and 11 respectively in the innermost zone in contact with the carbonatite. The decreases and increases correlate well with the distance from the carbonatite contact.

Trace elements La, Nb, Zr and Zn are approximately constant in the outer four zones but increase sharply in the inner zone. However, Rb, Ba, Cr, Ni, Ga, and Y decrease gradually from the least fenitized laminites towards the carbonatites and decrease sharply in the inner zone. Similarly, the total REE increases towards the carbonatites and the LREE to HREE ratio remains constant in the outer zones and increases in the innermost zone in contact with the ankeritic dolomite carbonatites. A negative Eu anomaly is present in the least fenitized rock and is gradually diluted in the inner zones (1-4) and almost disappears in the inner zone 5. These gradual increases and decrease in major, trace and RE elements are due to the metasomatism as result of Na-fenitization fluids (from the early amphibole sovite) soaking through the low permeability slates and phyllites. The latter biotite sovite has superimposed K-metasomatism over the Na-metasomatism. However, an even later ankeritic dolomite carbonatite is responsible for the sharp increase and decrease of major, trace and RE elements in the inner zone as a result of a second Na-fenitization, this time by fluids rich in Mg and Fe.

This is a generalized account of the Hunza valley in central Karakoram. It deals with various aspects of the geography of the area.

Key words: Exploration, expedition, Hunza, Karakoram.

M/220. Middlemiss, C.S., 1890. Preliminary note on the coal seam of the Dore ravine, Hazara. Geological Survey of India, Records 23(2), 267-269.

As this account does not have an abstract, the first few pages of the account are presented here as an introduction.

It is usual in the Memoirs of the Geological Survey to begin the description of a country with some remarks on the surface features, physical geography, etc. if I seem to be departing from a good old rule here, it is for the reason that all particulars, such as cannot be gathered from an inspection of the map, will more consistently find a place in the following chapters, when I come to describe in detail the geology of each of the zones, or strike areas, into which I shall find it expedient to divide up the country. This seems the more desirable inasmuch as the very varied aspects of the country are so indissolubly connected with the geological components of the zones that the former would be bare and meaningless if presented without their structural raisons centre.

I may remark, however, that Hazara is a strip of generally mountainous country, bounded on the south by the Rawalpindi plateau, on the north by the little-known mountainous country belonging to a number of warlike, independent hill clans, on the west by the Indus river, and on the east by Kashmir, with the Jhelum river below Domel as the line of demarcation.

Structurally, and therefore geologically, it connects the Rawalpindi and Jhelum districts (which embrace the Salt-Range) with the territory of Kashmir; all of which have been geologically described in considerable detail by former members of the Geological Survey of India (see list of authors and works in the Introduction).

The table which follows shows the stratigraphical elements or formations which take part in the Geological Record of Hazara, arranged chronologically:—

Table of formations in Hazara {in descending order}.

Historical Rocks.

VIII.—Murreebeds. . . Miocene .

VII.—Kuldana beds (passage). * ' I Tertiary ' .

VI.— Nummulitic series . Eocene

V.— Middle Cretaceous = Chalk Marl and U

Greensand = Cenomanian > Mesozoic
IV, — Jurassic•

III.— Triassic

II.— Inira-Triassic=Carboniferous or. Carbo. Paleozoic and pro-Permian(P) probably older.

I.— Slate series . Age unknown . . .)

Crystalline and Metamorphic Rocks.
b.^Tanol . . . Infra-Triassic in the main \

a. Crystalline schists. . Equivalentents of I and II f

v Palaeozoic or above in the main, or older.

x. Intrusive gneissose-granite. . . . A

y. Intrusive dyke rocks /

From the above table the youngest Tertiary, or Siwalik formation, Pliocene, is absent, as it does not occur in Hazara, although it is well developed towards the south in the Rawalpindi plateau. From the Murree beds to the Jurassics the Geological Record in Hazara is fairly complete, save that Upper Cretaceous rocks (if represented) are not marked by any fossil zone; and that the Jurassics, if lithological identity with other parts of India is disallowed as evidence, cannot be subdivided more closely into life-zones. With the Trias comes a small, though consistent, stratigraphical break. The evidence for any trustworthy subdivision of the Trias is wanting, or very doubtful. At the base of the Trias there is another stratigraphical break, and it seems certain that all representatives of the great Carboniferous, or Carbo-Permian epoch, so well developed in Kashmir and the Salt-Range, are either completely absent in Hazara or are represented by the unfossiliferous Infra-Trias limestone (but see p. 29).

With the so-called Infra-Trias we enter on unfossiliferous rocks of unknown age; but a comparative study of other Indian regions gives us a possible clue to the age of its lowest member (see p. 19 et seq.). Below the Infra-Trias is a great stratigraphical break with total unconformability upon the great azoic Slate series beneath. The crystalline and metamorphic rocks exhibit a Himalayan facies as regards the crystalline schists and intrusive sills of gneissose-granite and the basic dyke rocks; but the great thickness of subaerial volcanic rocks of Palaeozoic age, exposed in Kashmir, are not known in Hazara.

M/223. Middleton, D., 1984. Karakoram history, early exploration. In: Miller, K.J. (eds.), The International Karakoram Project, Volume 2. Cambridge University Press.

The Karakoram is the most heavily glaciated area outside the Polar Regions and contains some of the world's highest peaks. It is also the most formidable of the parallel mountain ranges dividing the Indian subcontinent from Central Asia. Early exploration was directed to finding a way beyond the Karakoram to trading centers in Eastern Turkestan (now Sinkiang). Attention focused first on the route from Leh to Yarkand by the Karakoram Pass, later on the Gilgit road into Hunza (William Moorcroft 1765-1825). G.T. Vigne (1830-1878) was the first official among the pioneer who opened up the Karakoram, and the first official maps were made by the Survey of India operating in Kashmir between 1857 and 1864. T.G. Montgomerie (1830-1878) was the first to see K2 and H.H. Godwin-Austin (1834-1923) the first actually to put it on the map with its surrounding peaks. The explorations of George Hayward (d. 1870) and the Intelligence work of Francis Younghusband (1863-1942) helped to build up a general picture of the region, and so paved the way for private enterprise and the scientific exploration of the twentieth century. Lord Conway, T.G. Longstaff, the Duke of the Abruzzi, Filippo De Filippi, the Duke of Spoleto, Giotto Danielli, Ardito Desio, Dr and Mrs Visser, Kenneth Mason and Eric Shipton were active in the Karakoram between 1908 and the outbreak of the Second World War.

M/224. Miehe, G., 1992. Recent climatic changes in the subhumid to arid regions of High Asia (Karakorum, Kunlun, Himalaya, Tibet) as indicated by vegetation features. In: Zheng, D., Zhang, Q. & Pan, Y. (eds.), Proceedings of International Symposium on the Karakorum and Kunlun Mountains, Kashi, June 1992., pp. 333-346. China Meteorological Press, Beijing.

In the context of environments changes in High Asia, indications of dessication are described. They refer to different periods and are caused by different climate changes. In southern Tibet, the plant relics of one of the younger Holocene phases of higher humidity (Kobresia pygmaea age) have been widely destroyed by Himalaya-front, giving way to semiarid alpin steppe on stone pavements. A decrease of plant vigor at climatically sensitive vegetation borders (upper treeline, drought limit of forests, transition zone between alpine Cyperaceae mats and the free gelifluction belt, transition zone between humid alpine mats and alpine steppe) gives evidence of diminishing winter precipitation during the last 30 to 40 years in the Karakorum.

M/229. Mikoshiba, M.U., Takahashi, Y., Kausar, A.B., Khan, T., Kubo, K. & Shirahase, T., 1999. Rb-Sr isotopic study of the Chilas igneous complex, Kohistan, northern Pakistan. In: Macfarlane, A., Sorkhabi, R.B. & Quade, J. (eds.), *Himalaya and Tibet: Mountain root to mountain tops*. Geological Society of America, Special Papers 328, 47-57.

The Chilas Igneous Complex is one of the major geologic units in the Kohistan terrane of the Himalaya of northern Pakistan. The Kohistan terrane is regarded as a tilted island-arc sequence. The Chilas Complex is a 300-km-wide-long, 40-km-wide plutonic body that intrudes the Kamila Amphibolite. The Main facies rocks of the Chilas Complex consist of gabbro norite, diorite, and quartz diorite. Small bodies of ultramafic-mafic association composed mainly of peridotitic-gabbroic cumulates, and a layered gabbro norite body, are also present, probably as xenoliths. A few samples are considered to have been contaminated as a result of assimilation of xenolithic materials and country rocks: Excluding them, 14 whole-rock samples of the Main facies have an Rb-Sr age of 111 ± 24 Ma and an initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.70403 ± 0.00006 . Gabbroic rocks from the ultramafic-mafic association, from the layered gabbro norite body, and from mafic dikes, have $^{87}\text{Sr}/^{86}\text{Sr}$ ratios between 0.7039 and 0.7044, interpreted to be close to the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios at the time of their generation. The whole-rock isochron age for the Main facies is regarded as the age of intrusion. The initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio for the Main facies is within the range of typical arc magmas, suggesting that the igneous activity occurred within an island arc or orogenic belt close to a continental margin. The age of intrusion of the Chilas Complex is similar to that of the earliest magmatism in the Kohistan batholith and to the Cretaceous plutonism in Ladakh and Karakoram, indicating large-scale generation of subduction-related magmas in the western Himalayan region and Karakoram during the mid-Cretaceous.

M/230. Mikoshiba, M.U., Takahashi, Y., Kubo, K., Kausar, A.B., Khan, T., Takahashi, Y. & Shirahase, T., 1998. Petrochemical characteristics of the eastern part of the Chilas Igneous Complex, Kohistan, northern Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 129-131.

The Kohistan terrane of the western Himalaya, northern Pakistan, is regarded as an island-arc sequence sandwiched between the Asian and Indian continental crusts. Deep crustal members are now widely exposed in Kohistan, which makes it an ideal area to study the genesis and evolution of subduction-related crustal structures and rocks.

The Chilas Igneous Complex is one of the major geological unit in the Kohistan terrane, and it is exposed in a large area of 300 km long and 40 km wide. Most of the complex consists of generally homogeneous gabbro-norite, pyroxene diorite and pyroxene quartz diorite. They can be called as the Main Facies, which was termed the gabbro-norite association by Khan et al. (1989). Rocks with layered structure are also found within the Chilas Complex, which often occur in km-scale masses. One gabbro-norite mass is characterized by well-developed rhythmic layering. Some of the masses are abundant in peridotites associated with layered gabbroic rocks (UMA, ultramafic-mafic association), which are deduced to be crystal accumulates. These layered rocks are considered to be intruded by the Main Facies rocks.

The rocks of the Chilas Complex (the Main Facies) have a calc-alkaline nature. The UMA rocks have chemical compositions reflecting their cumulate characteristics. Here we present detailed geochemical data of the constituent rocks in the eastern part of the complex, to discuss the evolution and crystallization processes in the Chilas Complex.

The Main Facies rocks have continuous variation of chemical compositions. Their SiO₂ content ranges from 49 to 60wt% in almost all samples. The concentrations of K₂O, Y, Zr, Th and rare earth elements (REE) are positively correlative with the SiO₂ content, while the concentrations of Ga, Sr, Cr and Ni do not vary with SiO₂ content. The chondrite-normalized REE patterns of many of the rocks with SiO₂ content less than 52 wt.% have a positive Eu anomaly, while those of some rocks with SiO₂ content more than 56 wt.% have a negative Eu anomaly. The light REE are enriched relative to the heavy REE, and the enrichment is clearer in the rocks with higher SiO₂ content.

Samples from the layered gabbro-norite mass have chemical compositions resembling with the Main Facies, although their compositions are scattered reflecting their modal variation. In the case of the UMA, major chemical compositions of ultramafic rocks support the petrographic observation implying that they consist mainly of olivine-clinopyroxene cumulates. Some of layered gabbroic rocks in a UMA indicate accumulation of plagioclase, having low REE contents with a clear positive Eu anomaly. Ultramafic rocks and layered gabbroic rocks from the UMA have low incompatible element concentrations.

The chemical composition of the Main Facies rocks support the idea that they solidified from a single evolving magma or from magmas having similar origin. Chemical compositions of a large part of the Main Facies may be similar to those of the magma(s), rather than the crystal cumulates, and they have characteristics of magmas relating to a subduction zone. A part of the Main Facies rocks with low SiO₂ content, may have lost the residual liquid at the late stage of solidification, or may have been enriched in the early-formed crystals. Therefore, it is possible to explain the chemical variation in the Main Facies by a weak segregation of melt and early-formed crystals composed of plagioclase, orthopyroxene and clinopyroxene. The relatively low concentrations of Cr and Ni in the mafic rocks suggest the magma had more evolved characteristics than the primary magmas from mantle.

The rocks of the layered gabbro-norite mass have petrographical and chemical characteristics which resemble those of the Main Facies, suggesting a common origin. In the case of the UMA, chemical composition of the layered gabbroic rocks and ultramafic rocks clearly have characteristics of cumulates, implying the separation of the melt and crystals were effective. Their chemical and petrographical characteristics suggest that they were crystallized from more primitive magma, probably at the earlier stage than the crystallization of the Main Facies rocks.

Key words: Petrochemistry, gabbro norite, Chilas complex, Kohistan island arc.

M/231. Mikoshiba, M.U., Takahashi, Y., Takahashi, Y., Kausar, A.B., Khan, T. & Kubo, K., 1996. Rb-Sr dating of the Chilas igneous complex, Kohistan, Northern Pakistan. Abstract volume, 11th Himalaya-Karakoram- Tibet Workshop, Flagstaff, Arizona (USA), 102.

The Chilas igneous complex is one of the major geological unit in the Kohistan terrane of the western Himalaya, northern Pakistan. The Kohistan terrane is regarded as a tilted island arc sequence, sandwiched between Asian and Indian continental crust (Coward et al., 1982).

The Chilas complex is a 300km long and 40km wide plutonic body (Khan et al., 1989). The rocks of the Chilas complex intrude into the Kamila amphibolite which is mainly located in the southern side. In the north, quartz diorite to tonalite of the Kohistan batholith intrude into the Chilas complex.

Most of the complex consist of generally massive gabbonorite, diorite and quartz diorite. They can be called as the main facies. There are also small masses of ultramafic-mafic association (UMA, Jan et al., 1984) in the complex. The rocks of the UMA are mainly composed of peridotite and gabbonorite, often showing layered structure. The rocks of the main facies intrudes into the UMA in several outcrops.

Rb-Sr isotopic study is applied to the Chilas complex. The analyzed samples are mostly collected from the eastern part. Gabbonorite and quartz diorite or the main facies are analyzed. In these samples, main constituent minerals are plagioclase, orthopyroxene and clinopyroxene, but small amounts of hornblende, biotite, quartz or K-feldspar are often associated with them, especially in quartz diorite. Gabbonorite of the UMA are also analyzed, in which hornblende, olivine or spinel are often associated

Ten whole-rock samples of the main facies give a Rb-Sr age of 8914 Ma with an initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.704004 ± 0.00005 . Their $^{87}\text{Rb}/^{86}\text{Sr}$ ratios are less than 0.65. Six whole-rock samples of the UMA have $^{87}\text{Sr}/^{86}\text{Sr}$ ratios with the range of 0.7039-0.7044. Their $^{87}\text{Rb}/^{86}\text{Sr}$ ratios are less than 0.1

The whole-rock isochron age for the main facies is concordant with the Ar-Ar and K-Ar age of hornblende from the Chilas complex around 80 Ma which may date cooling through 500°C (Treloar et al., 1989). This Rb-Sr age can be regarded as the intrusive age. The results of the Rb-Sr analysis indicates that a large amount of magma intruded in the Cretaceous time, which produced the thick mafic crust in the Kohistan. The initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio for the main facies is higher than the range in MORB, and it is within the typical range in the arc magma. The initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios in the rocks of the UMA are also deuced to be higher than the range in MORB.

M/233. Miller, D.J. & Christensen, N.L., 1994. Seismic signature and geochemistry of an island arc: A multidisciplinary study of the Kohistan accreted terrane, northern Pakistan. *Journal of Geophysical Research* 99, 11623-11642.

Systematic sampling and mapping in the Kohistan accreted arc terrane of northern Pakistan has provided a sample suite representing the lithologic diversity of the section from its base along the Main Mantle Thrust upward through several stacked intrusions and their metamorphosed equivalents into the Kohistan batholith. A new lithologic column for the terrane has been developed during the course of this study using geothermobarometry based on elemental exchange reactions calculated from electron microprobe analyses of mineral assemblages. The pressures calculated from the chemical analyses of various mineral assemblages are constrained by recently published activity-composition models and an internally consistent thermodynamic data base. Compressional and shear wave velocities and densities have been measured on samples that represent the diverse lithologies in this section and have been correlated with the new lithologic column. This data set has been augmented with published compositions and values for the uppermost part of the arc, not sampled in this study. Compressional wave velocities range from 4.3 km s⁻¹ in supracrustal volcanogenic sediments to 7.5 km s⁻¹ in lower crustal mafic cumulates. Underlying ultramafic rocks with velocities of 8.0 to 8.4 km s⁻¹ define a sharp seismic Moho. The strong inflection in the velocity profile to greater than 8.0 km s⁻¹ is due to the transition from plagioclase-bearing to plagioclase-free cumulate rocks in a continuous ultramafic-mafic intrusion. The base of the crust lies at least four kilometers below this transition. Correlation of these laboratory-measured values and the new lithologic column has allowed development of a velocity profile comparable to profiles developed through more conventional field seismic methods. Geochemical indices of fractionation exhibit a reasonable correlation with Compressional and shear wave velocities. An estimate of mean crustal V_p is remarkably similar to models for other cordilleran terranes at 6.7 plus or minus 0.05 km s⁻¹. An estimate of the bulk chemical composition of the Kohistan terrane does not compare favorably with most

published assessments of bulk continental crustal chemical composition, but is significantly more mafic than the latter. The striking resemblance of our reconstructed velocity profile to models generated from field seismic studies not only addresses the veracity of these models, but suggests that the Kohistan arc is a superbly well-preserved analog for other arc terranes.

M/234. Miller, D.J., Loucks, R.R. & Ashraf, M., 1991. Platinum-group elements mineralization in the Jijal layered ultramafic-mafic Complex, Pakistan Himalaya. *Economic Geology* 86, 1093-1102.

Notable enrichments of gold and platinum-group elements (PGE) have been found during the course of our petrochemical enrichment within the Jijal Complex, Northwest Frontier Province, Pakistan. To our knowledge, the only prior documented report of PGE minerals in Pakistan is by Ahmed and Bevan (1981), who described Ir-Ru-Os-Ni-Fe alloy in one sample of serpentinized chromitite from the Sakhakot Qila ophiolite (also called the Dargai complex), ca. 50 km northeast of Peshawar. The chromite deposits were described by Ahmed (1984). Page et al. (1979) reported whole-rock assays of Pt, Pd, and Rh totaling 5 to 25 ppb in six samples of dunite, harzburgite, and chromitite from the Dargai Complex. They also assayed 30 samples from the Zhob valley ophiolite near Quetta, reporting up to 375 ppb Pt + Pd + Rh in a gabbro sample and <3 to 81 ppb in the other 29 samples, which are mostly chromitites.

M/237. Mirza, A.R., 1981-83. *Geology of Paras-Bela-Jared Area central Kaghan Valley*. M.Sc. Thesis, Punjab University, Lahore, 148p.

This report covers a comprehensive study of a part of central Kaghan Valley. The principal emphasis has been on detailed lithostructural mapping of the area of the scale 1:8333. The rocks range in age from Pre-Cambrian Salkhallas to Miocene Murrees. Stratigraphically, the geology is in many ways different from that in the Abbottabad-Murree-Tarbela-Attock area further south. Part of the Mesozoic and part of the Tertiary sequence is missing in the project area. Furthermore, the equivalents of Panjal Trap and associated limestone are not found in the above mentioned area southwards. Structurally except for some folding in the blocks and nearly all contacts are faulted. The succession in the area is overturned. A fairly detailed account of the stratigraphy is being given and the report also includes a detailed account of the petrography of all the units based on extensive sampling. Tectonically the area is very interesting and the Panjal Traps appear to represent Ophiolites while the agglomerate slates appear to indicate volcano-sedimentary material with island arc affinities. There is, thus some evidence of a Paleozoic subduction zone in this area. Numerous photographs and sketches have also been included to illustrate the geology of the area.

M/238. Mirza, K., 1994-96. Geology of Dubran Area, District Haripur with special reference to palynology, micropalaeontology and biostratigraphy of some Paleocene-Eocene rocks. M.Sc. Thesis, Punjab University, Lahore, 219p.

Geological mapping of some 64 sq. Km area around Dubran in District Haripur has been carried out at the scale 1: 12500. The geomorphology, stratigraphy, structure, palynology and micropaleontology have been described. Stratigraphically a Mesozoic Tertiary sedimentary cover is overlying a Precambrian to Eo-cambrian basement of Hazara group now metamorphosed in the lower green schist facies. Numerous faults, high angle, reverse and normal have now disrupted the sequence. High angle north dipping Nathia Gali Thrust is the main fault that passes through the area and has thrust the Precambrian Hazara Slates over the younger sedimentary sequence. Dubran syncline lying on top of a major anticlinorium makes an interesting structure.

M/241. Mirza, M.A., 1980. A preliminary report on the interpretation of seismograms observed at Tarbela-Network of seismic stations. Geological Survey of Pakistan, Information Release 120, 12p.

A deep seismic sounding profile was observed in northern Pakistan in August 1975 under a programme of joint Pak-Italian Karakorum Geophysical Project. Two charges of 1600 kg and 2000 kg were detonated at Astore and Lawrencepur on August 15 at 0300 and 0400 GMT. On August 20 detonation of two more charges of 2400 kg and 2000 kg was repeated at Astore and Lawrencepur. The Russian seismologists followed a similar programme of explosion seismology and blasted charges of 10 tons at Karakul on August 15 and 20, and of 20 tons on the same dates at a site 30 km northeast of Zorkul. The observation timings of these blasts were 0100 and 0200 GMT respectively (Table I).

The detonation at Astore, Lawrencepur, Karakul and northeast of Zorkul for deep seismic studies along a profile joining Astore - Ishkuman and Astore- Lawrencepur was also recorded by seismic stations at Terbela (Fig. I) which were preinformed and alerted to receive the signals. The present report describes the results of seismograms observed at these stations, on 15th and 20th August 1975.

M/245. Mirza, M.A. 1995. Magnetic polarity stratigraphy of Soan Formation (Plio- Pleistocene), Mujahid village, Rawalpindi district, Punjab, Pakistan. Abstract volume, International seminar and field work on quaternary stratigraphy of the North – Eastern part of the Indian subcontinent Dhaka. 9-12 December, 1995. (IGCP – 347, Quaternary stratigraphic correlation of the Ganges – Brahmaputra sediments and of the Indian subcontinent. P.11.)

The Mujahid section is the type locality of Soan Formation (Plio-Pleistocene) of the Siwalik Group in Pakistan. The section is located on the road from Galijagir to Sihal, about half a kilometer short of Mujahid village, Rawalpindi District, Punjab Pakistan. It lies to the north of Soan River. The section is comprised of an alternation of pale-pinkish, orange-brown, grey silt shale and sand. The sand is greenish grey, fine, medium grained, having 1.5 to 3 meter thick beds of conglomerate. The conglomerate is dark grey, coarse, densely packed, containing rounded pebbles and boulders of grey limestone with the size of 5-25 cm. The formation possesses a thickness of 300 to 400 metres. Horizontally stratified magnetic zones have been studied for establishing the magnetic stratigraphy of the formation. Within 400 metres of the stratigraphic section, eleven magnetic polarity zones are identified. These zones represent the time from the upper Gauss Epoch (2.3 my.) through the Olduvai Event in Matuyama Epoch (1.6.m.y.) as determined from sedimentation rate of about 0.5 m/1000 years. The Gauss-Matuyama correspond to the Pliocene-Pleistocene chronology of the Soan Formation in general as indicated by the lithological and faunal correlation.

Key words: Magnetic polarity, stratigraphy, Soan River, Rawalpindi.

M/246. Mirza, M.A., 1997. An overview of mineral resources of Pakistan. Geological Survey of Pakistan, Information Release 644.

In 1947, when Pakistan came into existence only 6 mineral commodities were being mined on small scale and potential of finding minerals in the area which constituted Pakistan was not known. The Geological Survey of Pakistan (GSP) , through its endeavours, has proved that Pakistan is geologically a unique country . Its landmass consists of rocks which were formed at oceanic centers, continental and oceanic island arcs, deep oceanic to shallow marine and even continental sediments . These rocks, as elsewhere in the world, have been proved by the GSP to contain a large variety of mineral deposits.

Chromite is the only metallic mineral which is being produced on small scale since before independence but large scale production of copper from Saindak porphyry copper deposit will be starting very soon and large scale mining of zinc/lead deposit of Duddar is not very far.

Favourable areas of mineralization of aluminum, chromium, copper, lead-zinc, gold, silver, iron, platinum and tungsten have been identified and it is expected that soon Pakistan will emerge as an important country on the map of metal producing countries of the world.

It has now been proved that very large deposits of industrial minerals such as gypsum and anhydrite, limestone and dolomite, building stones, rocks salt, silica sand, barite, fuller's earth, industrial clays and soap stone and medium sized resources of magnesite, china clay, and bentonite occur in the country.

Only a couple of years back Pakistan had no position on the global map showing countries having substantial coal resources but with the discovery of over 175 billion tonnes of good quality lignite in Thar Coal Field, Pakistan has achieved 11th position among the countries having large coal reserves. The coal is found suitable for power generation. The prospect of making Pakistan an important mineral producing country are quite bright.

Geological Survey of Pakistan is doing its best to explore the mineral potential and disseminate data, so as to make people interested in exploration and exploitation of mineral wealth of the country. A National Mineral Policy will be adopted during 1995 to attract local and foreign investment in the mineral sector.

In the Nanga Parbat area (Northwest Himalayas) a thick group of presumably pre-Cambrian argillites with thin calcareous and basic bands is overlaid by Cretaceous-Eocene volcanics, and both are bordered by extensive Eocene norite masses. These rocks have undergone regional metamorphism during Early Tertiary orogeny. Synkinematic metamorphism of the argillites progresses from slates and phyllites through mica schists, biotite-paragneisses, kyanite-schists and –paragneisses to sillimanite-paragneisses. The metamorphic zones in the argillites are matched by those in the calcareous bands.

Synkinematic granitization of the potash-predominant variety begins within the kyanite zone with microperthite-porphyroblast-schists passing to potash-rich augen gneisses of granitic appearance which contain relict kyanite in their groundmass. Lit-par-lit replacement—as against mechanical injection—along active foliation planes makes banded gneisses. In the interior of the Nanga Parbat massif, granitization becomes more complete, and coarse-grained granitic gneiss forms. Here only small quantities of argillite altered to sillimanite-schist have escaped transformation into granitic rock. The calcareous bands are not granitized, and are preserved as conformable intercalations in the gneissose granite which has replaced the argillites. Metamorphism and granitization progress both along and across the strike of the altered sediments. There is complete structural continuity from the weakly metamorphosed sedimentary areas to the intensely granitized region. Also the type of tectonic deformation is the same throughout these areas, and is that characteristic of the deformation of solid rocks during orogenic metamorphism. The granitized body as mapped measures 25 by 60 miles.

The chemical nature of the granitizing agent is discussed. The metamorphic isograds (approximately vertical in this region) are shown to be independent of depth, and a function of differential introduction of heat from below. It is stressed that degree of metamorphism and granitization are systematically linked and convection of heat by the granitizing solutions is held responsible for high grade regional metamorphisms in the upper part of the crust.

M/257. Misch, P., 1964. Stable association wollastonite-anorthite, and other calc-silicate assemblages in amphibolite-facies crystalline schists of Nanga Parbat, Northwest Himalayas. *Beitrage zur Mineralogie und Petrographie* 10, 315-356.

Progressive regional metamorphism and granitization of a dominantly pelitic sequence was essentially isobaric and proceeded on a level of rather high P within the field of amphibolite facies. The transition from kyanite to sillimanite zone does not coincide with the boundary between medium and high-grade rocks but is displaced toward higher T. Many of the Al-Si-rich high-grade rocks carry stable muscovite. Staurolite, andalusite, and cordierite are characteristically absent. Green hornblende occurs throughout the high-grade zone in rocks of appropriate composition.

Calcareous intercalations permit recognition of three distinct zones of high-grade metamorphism. They, and the reaction defining their boundaries, are:

a) "Wollastonite-anorthite zone"; highest attained.

b) $\text{CaCO}_3 + \text{SiO}_2 = \text{CaSiO}_3 + \text{CO}_2 \uparrow$ "Calcite-quartz-grossularite (bytownite) zone"

(lower limit defined by lower limit of bytownite).

Reaction (b) is sensitive to PCO_4 . It is suggested that most of the rocks, especially those with excess silica, were open systems for CO_2 , so that $\text{PCO}_4 \ll P_{\text{total}}$. Locally, as in some tight marbles, CO_2 was retained, and the wollastonite reaction was arrested or altogether prevented, in zone (2) and even in zone (1). Reaction (a), involving no gas phase, is dependent only on P, T. Under the prevailing high pressures, the temperatures required to make reaction (a) proceed to the right, must have been rather high.

Quartz-excess and calcite-excess, diopside-bearing assemblages of the three zones are described. Associate K-feldspar is orthoclase with very small — 2V. Metamorphism of argillaceous dolomitic limestones illustrates the principle of preferential decarbonation of Mg. Assemblages include (omitting dominant calcite): forsterite-spinel-phlogopite, found only in zone (1); phlogopite-diopside-(tremolite); diopside-(tremolite)-orthoclase; diopside-(tremolite)-anorthite-(orthoclase); diopside-wollastonite-grossularite (zone 2); diopside-grossularite-quartz (zone 3). Relations of mineral assemblages found in the three calc-silicate zones to bulk compositions are discussed. Boundary layers between diopsidic calc-silicate rocks and associated pelitic schists are described. As a rule, a thin band of para- amphibolite is developed at the contact, characterized by the garnet-free assemblages, green hornblende-anorthite (bytownite)-quartz. In adjacent, partly almandine-bearing biotite-quartz-plagioclase schists, plagioclase ranges from sodic andesine to bytownite. Widespread reverse zoning of this plagioclase is attributed to slow, short-range (a few centimeters) diffusion of anorthite-building substance from the adjacent Ca-richer rock into the schist. Locally, the amphibolite band is lacking, and diopside and biotite mingle in the boundary layer. Although this local association recalls pyroxene hornfels facies, nearby rocks have amphibolite facies mineralogy.

Part of the diopsidic calc-silicate rocks of zone (1) show incipient retrogression under conditions of zone (2) or (3), the pair, wollastonite-anorthite (bytownite), being "parasitically" replaced by grossularite. Retrogression below the limits of zone (3) locally displays the assemblage, zoisite-labradorite-grossularite. Calcic scapolite found in some of the high-grade calc-silicate rocks is retrogressive, replacing anorthite (bytownite).

Calc-silicate mica schists of higher-medium grade carry mutually stable calcic scapolite, andesine and zoisite, associated with calcite, quartz, local epidote, biotite, muscovite, and garnet. Much of their plagioclase is zoned. Reverse followed by normal zoning is interpreted as a record of the thermal history of metamorphism. Associated non-calcareous mica schists, commonly with almandine and kyanite, carry more sodic plagioclase which is unzoned. Garnet amphibolites of this zone have andesine plus zoisite or epidote, and some contain diopside.

Physical conditions of the metamorphism of the high-grade calc-silicate rocks are discussed further, in the light of available experimental data.

M/258. Miyata, T., 1988. An Introduction to gem mines of Pakistan. (Japanese with English abstract). Journal of the Gemmological Society of Japan 13, 31-42.

Pakistan has 4 main mining areas in its territory. In Hunza valley, specimen- and gem-quality crystals of corundum occur in bed of marble. This area is not in operating at present. However, small, intensely coloured emerald crystals occur in dolomitic talc schist in the Swat valley. So many kinds of gemstones, aquamarine, topaz (F-type), tourmaline, zircon, quartz, are found from the pegmatite in Shingus-Dusso areas. Katlang area is the only place in the world to produce natural pink topaz.

White and gray coloured crystalline limestone and pink fossiliferous dense limestone are extensively quarried in Peshawar Division for dimension stone. The deposits belong to a reef belt which developed at the northern margin of Indo – Pakistan landmass during Silurian-Devonian. They are metamorphosed and dolomitized to varying degrees. White crystalline limestones are calcite marble of high purity comparable to world class marbles. Dolomite marbles are of inferior quality however they constitute only a small part of the deposits. A number of physical tests prove the soundness of the Peshawar marbles in confirmation to the ASTM standards.

Conodonts (62 species and subspecies) from acid-leaching of 226 samples from four sections through the Ali Masjid Formation west of Misri Khel in the former South Khyber Agency, north-west Pakistan, are documented by illustrations and distributional data. These indicate that most of this unit, at least in that area, spans the interval Middle *crepida* Zone (low in the Famennian) to at least Early *crenulata* Zone (mid-Tournaisian), though a fauna from low in one of the sections produced conodonts indicative of the Late *falsiovalis* Zone (early Frasnian). Two major hiatuses are inferred: between the Late *falsiovalis* and Middle *crepida* zones, and between the Late *expansa* and Early *duplicata* zones. Coherence of the conodont biostratigraphy accords with lithologic alignments between the sections.

M/270. Molnar, P., 1988. A review of geophysical constraints on the deep structure of the Tibetan plateau, the Himalaya and the Karakoram and their tectonic implications. *Philosophical Transaction, Royal Society London, Special Publication A-326*, 33–88.

The Tibetan Plateau, the Himalaya and the Karakoram are the most spectacular consequences of the collision of the Indian subcontinent with the rest of Eurasia in Cainozoic time. Accordingly, the deep structures beneath them provide constraints on both the tectonic history of the region and on the dynamic processes that have created these structures. The dispersion of seismic surface waves requires that the crust beneath Tibet be thick: nowhere less than 50 km, at least 65 km, in most areas, but less than 80 km in all areas that have been studied. Wide-angle reflections of P-waves from explosive sources in southern Tibet corroborate the existence of a thick crust but also imply the existence of marked lateral variations in that thickness, or in the velocity structure of the crust. Thus isostatic compensation occurs largely by an Airy-type mechanism, unlike that, for instance, of the Basin and Range Province of western North America where a hot upper mantle buoys up a thin crust.

The P-wave and S-wave velocities in the uppermost mantle of most of Tibet are relatively high and typical of those of Precambrian shields and stable platforms: $V_p = 8.1 \text{ km s}^{-1}$ or higher, and $V_s \approx 4.7 \text{ km s}^{-1}$. Travel times and waveforms of S-waves passing through the uppermost mantle of much of Tibet, however, require a much lower average velocity in the uppermost mantle than that of the Indian, or other, shields. They indicate a thick low-velocity zone in the upper mantle beneath Tibet, reminiscent of tectonically active regions. These data rule out a shield structure beneath northern Tibet and suggest that if such a structure does underlie part of the plateau, it does so only beneath the southern part. Lateral variations in the upper-mantle structure of Tibet are apparent from differences in travel times of S-waves from earthquakes in different parts of Tibet, in the attenuation of short-period phases, P_n and S_n that propagate through the uppermost mantle of Tibet and in surface-wave dispersion for different paths. The notably lower velocities and the greater attenuation in the mantle of north-central Tibet than elsewhere imply higher temperatures there and are consistent with the occurrence of active and young volcanism in roughly the same area.

Surface-wave dispersion across north-central Tibet also requires a thinner crust in that area than in most of the plateau. Consequently the relatively uniform height of the plateau implies that isostatic compensation in the north-central part of Tibet occurs partly because the density of the relatively hot material in the upper mantle is lower than that elsewhere beneath Tibet, the mechanism envisioned by Pratt. Several seismological studies provide evidence consistent with a continuity of the Indian Shield, and its cold thick lithosphere, beneath the Himalaya. Fault-plane solutions and focal depths of the majority of moderate earthquakes in the Himalaya are consistent with their occurring on the top surface of the gently flexed, intact Indian plate that has underthrust the Lesser Himalaya roughly 80-100 km or more.

P-waves from explosions in southern Tibet and recorded in Nepal can be interpreted as wide-angle reflections from this fault zone. P-wave delays across the Tarbela network in Pakistan from distant earthquakes indicate a gentle dip of the Moho beneath the array without pronounced later variations in upper-mantle structure. High Pn and Sn velocities beneath the Himalaya and normal to early S-wave arrival times from Himalayan earthquakes recorded at teleseismic distances are consistent with Himalaya being underlain by the same structure that underlies India.

Results from explosion seismology indicate an increase in crustal thickness from the Indo-Gangetic Plain across the Himalaya to southern Tibet, but Hirn, Ltpine, Sapin and their co-workers inferred that the depth of the Moho does not increase smoothly northward, as it would if the Indian Shield had been underthrust coherently beneath the Himalaya. They interpreted wide-angle reflections as evidence for steps in the Moho displaced from one another on southward-dipping faults. Although I cannot disprove this interpretation, I think that one can recognize a sequence of signals on their wide-angle reflection profiles that could be wide-angle reflections from a northward-dipping Moho.

Gravity anomalies across the Himalaya show that both the Indo-Gangetic Plain and the Himalaya are not in local isostatic equilibrium. A mass deficit beneath the plain is apparently caused by the flexure of the Indian Shield and by the low density of the sedimentary rock in the basin formed by the flexure. The mass excess in the Himalaya seems to be partly supported by the strength of the Indian plate, for which the flexural rigidity is particularly large. An increase in the Bouguer gravity gradient from about 1 mGal km⁻¹ (1 mGal = cm sCZ) over the Indo-Gangetic Plain to 2 mGal km⁻¹ over the Himalaya implies a marked steepening of the Moho, and therefore a greater flexure of the Indian plate, beneath the Himalaya. This implies a northward decrease in the flexural rigidity of the part of the Indian plate underlying the range. Nevertheless, calculations of deflections of elastic plates with different flexural rigidities and flexed by the weight of the Himalaya show larger deflections and yield more negative gravity anomalies than are observed. Thus, some other force, besides the flexural strength of the plate, must contribute to the support of the range. A bending moment applied to the end of the Indian plate could flex the plate up beneath the range and provide the needed support. The source of this moment might be gravity acting on the mantle portion of the subducting Indian continental lithosphere with much or all of the crust detached from it.

Seismological studies of the Karakoram are consistent with its being underlain by particularly cold material in the upper mantle. Intermediate-depth earthquakes occur between depths of 70 and 100 km but apparently do not define a zone of subducted oceanic lithosphere. Rayleigh-wave phase velocities are particularly high for paths across this area and imply high shear wave velocities in the upper mantle. Isostatic gravity anomalies indicate a marked low of 70 mGal over the Karakoram, which could result from a slightly thickened crust pulled down by the sinking of cold material beneath it. Geophysical constraints on the structure of Tibet, the Himalaya and the Karakoram are consistent with a dynamic uppermost mantle that includes first, the plunging of cold material into the asthenosphere beneath southern Tibet and the Karakoram, as the Indian plate slides beneath the Himalaya, and second, an upwelling of hot material beneath north-central Tibet. The structure is too poorly resolved to require such dynamic flow, but the existence for both a hot uppermost mantle beneath north-central Tibet and a relatively cold uppermost mantle beneath southern Tibet and the Karakoram seem to be required.

M/273. MonaLisa, & Khawaja, A.A. 2001. Seismic zonation based upon peak ground acceleration (PGA) values of a part of Northern Pakistan. Ten years of paleoseismicity in the ILP: progress and prospects, 17-21 December, 2001, Kaikowa, New Zealand.

A part of Northern Pakistan bounded by Lat: 32° - 35° $30'$ N and Long: 69° $45'$ - $75'$ - $15'$ E has been divided into 360 grids of 0.15° X 0.15° size for carrying out seismic zonation. Instrumental data of $M_b > 4.5$ have been used. It comprises of 3197 events that occurred during the period April 1905 to April 1998. Peak ground accelerations (PGA) have been determined for the mid points of each grid applying the attenuation equation of the Public Works Research Institute of Japan (1990) for the return period of 100 years. These PGA values have been calculated using ERISA-P software. Contour map has been prepared for this return period and is discussed taking into consideration the geology of the region.

A number of distinct zones are observable in the PGA map of 100 years return period. In our area of interest (excluding Afghanistan), the highest PGA values correspond to the tectonically active hinterland zone of NW Himalayan fold and thrust belt. Besides containing localities like Dasu, Chilas and Mansehra, the important strategic link between Pakistan and China - the Karakorum highway also passes through this zone.

Another zone having high PGA values corresponds with the South Waziristan region and the Kurram Fault passes through the area. The other closure corresponding to the areas of Islamabad, Rawalpindi, Wah, Taxila, Tarbela have comparatively lower PGA values. According to our map the safest areas (with low PGA values) are in the Salt Range, Bannu and Peshawar Basins.

Key words: Seismology, PGA, North Pakistan.

M/274. MonaLisa, Khawaja, A.A., Ghazi, G.R. & Jadoon, I.A.K., 1997. Nature of faults and focal mechanism solutions of part of Northern Pakistan. Geological Bulletin, University of Peshawar 30, 143-151.

The area extending southwards from the MMT to Kohat/Potwar plateau in Northern Pakistan is considered to be one of the most seismically active region in the world. 13 earthquake events recorded during 1984-1995 from this area have been investigated for focal mechanism solution. Solution shows strike-slip faulting with a majority (eight) indicating a left lateral sense of motion. They mostly confirm the trend and behavior of the exposed faults with exception of one, which might be related with a blind fault.

Three right lateral strike-slip focal mechanism solution, one associated with the Thakot fault and other with the Kalabagh fault, support the active character of these faults or represent their buried offshoots. Two E-W trending right lateral focal mechanism solutions are considered to represent left lateral sheer at the western boundary of Indo-Pakistan Plate.

The P and T-axis orientation indicate NE-SW direction of compression for area located north of MBT, whereas in Kohat and Potwar area mixed trend of both NE-SW and NW-SE compressive directions are obtained suggesting more complexity. In this active zone of convergence i.e., thrusting dominated region, a kinematic change due to oblique collision is inferred.

Key words: Structure, faults, focal mechanism, Kohat-Potwar plateau, Kalabagh fault.

M/275. MonaLisa, Khawaja, A.A., Ghazi, G.R., Qureshi, S.N. & Boustani, M., 2000. Seismic risk analysis of Islamabad and its adjoining areas. Abstracts, Third South Asia Geological Congress, Lahore, p.51.

Earthquakes of $M_b > 4.5$ that occurred during the period from 1905 to April 1998 have been used to determine Peak Ground Acceleration (PGA) of an area of 200 Km radius around Islamabad. Midpoint of 1248 grids (0.065×0.065) established for this purpose were considered as sites and the PWRI attenuation equation used for the calculation at these midpoints. Raster maps for return periods of 50, 100 and 200 years have been prepared and seismic risk evaluation of the whole area undertake.

Key words: Seismicity, seismic risk, PGA, Peshawar.

M/276. MonaLisa, Khawaja, A.A. & Qureshi, S.N., 2001. Seismic zonation and peak ground acceleration of Peshawar and adjoining areas. Abstracts, 4th Pakistan Geological Congress, Islamabad, 70-71.

An area of 200 km radius around Peshawar has been divided into 360 grids of 0.150×0.150 size for carrying out seismic zonation of the area. Instrumental data of $M_b > 4.5$ have been used. It comprises of 3197 events that occurred during the period April 1905 to April 1998. Peak ground accelerations (PGA) have been determined for the mid points of each grid applying the attenuation equation of the Public Works Research Institute of Japan (1990) for the return periods of 50, 100 and 200 years. ERISA-P software has been used for calculating the PGA values. Contour maps have been prepared for these different return periods and are discussed taking into consideration the geology of the region. A number of distinct zones are observable in the PGA map of 50 years return period. The high PGA value zones in the northwestern quadrant of the map cover the area of Afghanistan. In our area of interest (excluding Afghanistan), the highest PGA values correspond to the tectonically active area i.e., hinterland zone of NW Himalayan Fold- and- Thrust Belt. Besides containing localities like Drosh, Chilas and Mansehra, which are highly populated areas, the important strategic link i.e. the Karakoram Highway also passes through this zone. Another zone having PGA values ranging from 70 gals ($0.07g$) to 290 gals ($2.9g$) corresponds with the Kalabagh fault thereby indicating the active nature of this fault. As such it is recommended that construction in this area should take into consideration the active nature of the faults. The other closures corresponding to the areas of Islamabad, Rawalpindi, Wah, Taxila, Tarbela have PGA values ranging upto a maximum of $0.08 g$ and may still be considered as hazardous area. According to our map the safest areas (with low PGA values ranging from $0.02g$ to $0.06g$) are Peshawar, Swat, Bannu, Thal and Mardan.

Key words: Seismicity, seismic zonation, PGA, Peshawar.

M/280. Montgomerie, T.G., 1860. Memorandum on the Great Flood of the River Indus which reached Attock on the 10th August. Journal of the Asiatic Society of Bengal 29, 128-135.

"At 5 A. M. on the 10th August, 1858, the Indus at Attok was very low. At 7 A. m. it had risen 10 feet. By 0.30 p. M. it had risen 50 feet, and it continued to rise till it stood 90 feet higher than it did in the morning. The Cabul River continued to flow upwards for ten hours." — Extract from the proceedings of the Asiatic Society for September 1858, Journal Vol. XXVII. p. 366.

The flood destroyed a large amount of property in British territory both above and below Attok; and the back water (on the Cabul river) destroyed the greater part of the private property in the cantonment of Naoshera.

After the subsidence of the water, numerous reports were current near Attok, viz.: that the river was still blocked up and that another similar flood might soon be expected. These reports were generally given out on the authority of the inhabitants far up the river, who had sent down word to say that the water was still dammed up. Such a sudden flood or cataclysm on such a gigantic scale, at all times an important and interesting subject of enquiry, was rendered still more so to me by the above mentioned circumstances. Being at the time of the flood in the territories of the Maharajah Rumbhir Singh. I was in a favorable position for making enquiries in the Upper Valley of the Indus as far as the Maharajah's territories and influence extended, and I consequently made all the enquiries that I could.

On applying to the Wazeer Punnoo, the governor of Kashmir, he told me that had any damage been done in the Maharajah's territories by a flood on the Indus, he would certainly have heard of it, but up to that time he had received no report on the subject. However I begged him to write to all the Maharajah's officials (on the Indus and on its tributaries)* to enquire whether any extraordinary flood had been noticed. The answers were all in the negative except that from Boonjee, (the Maharajah's most northerly fort and cantonment on the Gilgit frontier) the report was as follows, viz. :—

"That a great flood (bura sailab) was noticed by the sepoys at Boonjee on the 27th day of "Sawan Mahina," "derh pahar din gaiya" when it first arrived. Shortly afterwards the sepoys saw a mass of timbers floating down the stream, which they recognised as belonging to the gateway of the Numbul fort." The Nfimbul fort is said to have been on the Gilgit river below the point where the Naggar River joins the Gilgit river.

I understand "the 27th day of Sawan Mahina, derh pahar din gaiya" to mean the 11th day of August about 9 or 10 in the morning. Although this is the day after the flood was noticed at Attok, it is in my opinion sufficiently near the date to make it highly probable that it was the same flood that was noticed at Attok.

At a frontier outpost of the Maharajah's (where no one goes that has sense enough to make interest to keep away), a mistake of two or three days in the date would be no wonderful thing considering the general indifference of natives on the subject of dates and the numerous doubts as to when their months begin.

I am therefore of opinion that the flood (sailab) noticed at Boonjee was the same that passed Attok on the 10th of August, and for reasons given hereafter I am of opinion that the sepoys' date at Boonjee should have been the 25th of Sawan or the 9th of August about 9 or 10 a. ft. The Trigonometrical height of Skardo the capital of Little Thibet situated on the river Indus has been ascertained to be about 7700 feet above the sea and that of the G. T. Station eighteen miles above Attok has been found to be about 1050 feet above the sea, thus shewing a difference of height between the two places of about 6650 feet. The distance between Skardo and the above G. T. Station by the course of the river Indus is approximately about three hundred and ten miles, and consequently there is an average fall in the bed of the Indus between those places of about 21 feet per mile.

Similarly the height of Baramoola where the Jhelum river leaves the Kashmir valley is about 4930* feet, that of the river two miles below Jhelum is about 750 feet above the sea, shewing a difference in height between the two places of about 4180 feet. The distance by the course of the river Jhelum between those two places is about one hundred and ninety-four miles giving an average fall in the bed of the Jhelum of a little over 21 to 5 feet per mile. Consequently we may assume that the Indus and Jhelum rivers flow at (very nearly) the same average rate between the respective places mentioned. With the assistance of Lieut. Melville I measured the rate of the Jhelum river at Naoshera, one march below Baramoola, in as slow a part of the stream, as there is between Baramoola and Jhelum, and I found the rate to be nearly 690 feet per minute, or about seven miles per hour. And Lieut. Melville quite agreed with me that we had taken a place where the rate was far below the average. The river Jhelum between the points mentioned has in general such rugged and precipitous banks that it was with difficulty that even the above measurement was made.

The distance from Boonjee to Attok may be taken approximately as about two hundred and twenty miles, and if the flood in question was the one noticed at Boonjee it traversed the distance between those two places between 10 o'clock in the morning of some day before the 10th of August and say 6 A. M. of the 10th August, that is the flood

must have taken either twenty-one hours or forty - five or sixty-nine &c. to traverse two hundred and twenty miles, that is, it must have passed Boonjee on 9th, 8th or 7th of August. Had the flood passed Boonjee on the 5th August, it would have taken forty- five hours and would have travelled at the rate of hardly five miles an hour, but it has been shewn above that the average rate of the Indus must be above seven miles an hour in ordinary times, and of course much greater during a flood, so it may, I think, be fairly concluded that the flood would take only about twenty-one hours in traversing the two hundred and twenty miles, and that it passed Boonjee on the 9th August, 1855, about 10 a. m. If so it travelled at the rate of ten and half miles per hour, by no means an improbable rate* as the Ganges when it issues from the hills opposite Hurdwar is stated by the Canal officers to flow in ordinary times at nine miles an hour, and its pace looks slow compared with that of the Jhelum below Baramoola.

As soon as I got the report from Boonjee I sent for further information but could only make out that the flood was understood to come from Naggar, an independent district which the Maharajah's people called a part of Yaghistan! quite inaccessible to ordinary messengers. Nothing would induce a man to go there; and the Wazeer said that when a present was offered, the man took the money, but only went a short distance and returned after a time with a made-up-story. Though repeated enquiries were made, nothing further was elicited.

Indeed beyond the fact that the flood had come from the Gilgit river, as reported by natives and as shewn by its carrying away the well known gateway of the Numbul Fort, nothing positive was known as to the cause of the flood or of the exact site of the place dammed up, though the Boonjee sepoy believed that it came from the Naggar valley which is drained by an Eastern tributary of the Gilgit river.

"Whether the flood in question came from Naggar or not, I feel quite certain that it did not come from above Skardo. At the time of the flood two of my assistants were working round Skardo, and another was working on the Shayok River within a month afterwards. I asked them to make particular enquiries, but they heard nothing of a large flood from any of the inhabitants of those parts. A table taken from the Philosophical transactions gives 450 feet in one minute or nearly five and a half miles an hour as the velocity of absolute torrents with an inclination of only 3 feet 1.27 inches per mile. The table gives no greater inclinations. Had the flood been generated on any of the tributaries of the Shayok I must have heard of it, as the damage done by the water on first escaping from the barrier or dam would have been very great in the Shayok valley itself.

No report was prevalent at Boonjee or elsewhere in the Maharajah's territories as to any river being still dammed up or as to the prospect of another flood. Should the river Indus or any of its tributaries be hereafter dammed up in any part of the Maharajah's territories, there would not be much difficulty in getting information from the Maharajah's officials, if proper measures were taken for collecting the same. If timely warning were given, I think that the water might be eased off, if the place was accessible and labour was available for the necessary blasting, mining and other operations. If, however, an obstruction should arise on the Gilgit River or any of its tributaries, there is, in the present political state of those valleys, no chance of getting timely warning or any accurate information, and if such was forthcoming, nothing could be done as to easing off the water unless the Engineer was accompanied by troops.

M/281. Montgomery, D.R., 1994. Valley incision and the uplift of mountain peaks. *Journal of Geophysical Research* 99, 913-921.

Simple end-member models describe the effect of isostatically compensated valley incision on the elevation of mountain peaks. These models allow calculation of the maximum portion of mountain peak elevations attributable to the development of observed relief and predict general downstream patterns of ridgetop uplift in response to erosion by fluvial processes. Analyses of topographic profiles across major drainages of the central Sierra Nevada and the Tibetan Plateau indicate that isostatically compensated valley incision could account for at most 5–10% of the present elevation of mountain peaks. In contrast, analyses of topographic profiles across the Himalaya show that as much as 20–30% of the present elevation of Himalayan peaks could be explained by isostatically compensated valley incision. The degree to which valley incision is compensated locally, however, depends on the flexural rigidity of the lithosphere, the size of the range, and its tectonic boundary conditions. These results show that while a tectonic control is required for late Cenozoic surface uplift of the Sierra Nevada, a significant portion of the elevation of Himalayan peaks may reflect late Cenozoic valley incision on the margin of the Tibetan Plateau.

M/283. Moorcroft, W. & Trebeck, G., 1841. Travels in the Himalayan Provinces of Hindustan and the Punjab; in Ladakh and Kashmir; in Peshawar, Kabul, Kunduz and Bokhara; from 1819 to 1825, 2 vols, 495 + 508 p. Oxford University Press, Oxford.

William Moorcroft was a veterinary surgeon in charge of the stables of the British East India Company and on the pretext of finding better breeds of horses made a pioneering journey from the heart of India up to the icy plateau of Central Asia. The other side of Moorcroft's efforts was that of a spy who looked to survey the probable friends and foes of India in the face of a Russian invasion. He started this journey from Kullu in the foothills of the Himalayan and it ended with his murder outside Kabul deep into Central Asia. During the course of his travels he stayed for 2 years in Ladakh and his account of this place is unmatched by later travelers. Moorcroft also wanted to open up the Central Asian markets to British good, and in his enthusiasm signed treaties in the name of the crown with local chiefs of the lawless tracts of Central Asia. In this book one finds details of almost everything that he saw, experienced and heard. The lands, the people, the customs, the royalty, commercial potential, the flora and fauna, the river systems, the local religions. Moorcroft's account is not wanting in playing the role of being the eyes and ears in a foreign land. The journey took Moorcroft from the Punjab through to Bokhara via Ladakh, Kashmir, Peshawar, Kabul and Kunduz.

M/287. Morris, T.O., 1938. The Bain Boulder bed; a glacial episode in the Siwalik series of the Marwat Kundi Range and Sheikh Budin, NWFP, India. Quarterly Journal of the Geological Society of London 94, 385-421.

In October 1934, at the western end of the trans-Indus continuation of the Salt Range of North-West India, extensive outcrops of a deposit possessing all the characteristics of a typical boulder-clay were discovered in the middle of the strongly folded and faulted Siwalik series of the Marwat Kundi hills and on the northern slopes of Sheikh Budin. The

boulder-clay was named the Bain Boulder-bed, after the frontier village nearest to its most conveniently accessible outcrop alongside the frontier road from Bannu to Tank, through the Bain pass.

The occurrence of a glacial deposit in this area and at such an horizon was totally unexpected. Successive studies of Siwalik faunas, made since Falconer's pioneer work, have raised progressively the age of the Siwalik series in terms of the European and American time-scales, but no dating later than Middle Pliocene had been suggested for the thick sandy formation in which the Bain Boulder-bed occurs; neither is there any record of evidence of glacial conditions during the deposition of the Siwalik series (Colbert 1935, p. 11). Prior to the discovery of the Bain Boulder-bed, the age of the formation enclosing it had been regarded as Upper Miocene, following Pilgrim (1913), or Middle Pliocene, following Matthew (1929). The nearest place to Shekh Budin at which fossils had been collected from the formation was the type locality of Pilgrim's Nagri fauna (1913, pp. 267, 318). That fauna lies in the lower portion of the Nagri outcrop cis-Indus, about 100 miles from Shekh Budin.

M/288. Mostler, H., 1980. Zur mikro fauna der unterkambriums in der Hazara Formation, Hazara, Pakistan. *Annals Naturhistorisches Museum Wien* 83, 245-247.

The acetic acid residue showed a microfauna proving that the Hazira-formation (Hazara, Pakistan), which lies transgressively on the paleo-relief of the Sirban-formation, belongs to the lowest part of the Cambrian (Tommotian). Therefore the Sirban-formation is of pre-Cambrian age and so all further stratigraphic speculations concerning the classification of this formation are without support. The microfauna corresponds with the fauna-association known from the trilobitelacking stage of China. Its point of effort lies in the *Lapworthella tortuosa*-subzone respectively *Sachites-Zhijiinites-Turcutheca*-assemblage-zone. In this study eight new species of the genus *Sachites* (Cambroscleritida) are described.

Tangir covers 351 square kilometers area located between Kohistan in the South and Yasin in the North. According to plate tectonic concept it lies in between Indo-Pakistan and Eurasian plates comprising a part of Kohistan Island arc. The particular project area is mapped on a scale of 1:62500. In the thesis, an attempt is made to introduce the detailed Geology of the area. Bulk geological sequence of the area is consisted of Norite, Diorite, Amphibolite, Granodiorite and granite which is obducted on to the Paleozoic rocks of Indo-Pakistan plate in the South and subducted under the Eurasian plate towards the North. The Northern part of the area is in contact with Yasin Group which is volcanic. So Tangir area constitutes the lower sequence of Kohistan Complex.

Key words: Petrology, Tangir, Kohistan island arc.

M/292. Mughal, M.A., Sarhan, A.G., Gilmour, E.H. & Rahman, O., 1981. Carbonate petrography and microfacies of a portion of the Samana Suk Formation, Kohat range, Pakistan. *Geological Bulletin, University of Peshawar* 14, 73-84.

Five carbonate microfacies occur in a portion of the Jurassic Samana Suk Formation of the Kohat range, Pakistan. These microfacies are widespread over the area in the sections measured and indicate carbonate deposition in shoal environment in agitated water, restricted marine shoals and restricted marine shelf lagoons. The detailed petrographic study uncovered a duplication of section which had been caused by faulting and was previously unrecognized.

Key words: Carbonates, petrography, microfacies, Kohat range.

M/293. Mughal, M.Y., Baig, M.A.S. & Syed, S.A., 1997. Siwalik Group: A potential host for uranium. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, p38.

Siwalik Group of rocks, Middle Miocene in age are exposed in part of AJK, Potwar, Bannu Basin and Sulaiman Range all along the foothills of NW and Western Himalayas. The Group basically comprises sand-shale interlayering with occasional development of conglomerates as channel lags or terrace deposits. The sand-shale ratio, their colour and horizontal distribution varies greatly within its four subdivisions i.e. Chinji, Nagri, Dhok Pathan and Soan formations. Uranium occurrences have been discovered over a major part of its exposures within Nagri and Dhok Pathan formations yet U-deposits could only be found in Bannu Basin and Sulaiman Range.

To develop a U-deposit three pre-requisites are essential i.e. U-source, U-mobilization, and U-precipitation and its stabilisation. Due to widespread syn-deposition of volcanic ejects and feldspar the U-source is available indiginously. The movement of meteoric water, through the preamble strata, during diagenesis and upheaval mobilized the Uranium by leaching it from the volcanics as well as feldspars. The Siwalik rocks contain grey facies which is indicative of deposition in reduced environments. As a result reductants such as organic trash and pyrite were also deposited at more humid sites favourable for precipitation of U-from the solution.

The Himalayan Orogeny being still active imparted a very unstable character to the area with Siwalik rocks. Large scale thrusts and fold belts caused upheaval of strata due to which fluctuations of water table caused unstability for U-accumulation due to which the newly formed deposits in the uplifted blocks got mobilized. Areas still exist where upheaval movements were minimal as such chances of getting good quality U-deposits exist therein.

M/305. Mujahid, W.K., 1982-84. Structural studies of Chinarkot-Galigada Area, District Mansehra. M.Sc. Thesis, Punjab University, Lahore, 87p.

The landforms bear a specific relationship with geological structure and climate which can be worked out by qualitative as well as quantitative analysis of the topographic map. The most predominant lithologies of the project area are garnet mica schists and Susalgali granite gneiss. The rocks of the project area have been classified into eight lithologic units for the sake of mapping purpose at a scale of 7 cm to a kilometer.

Mesoscopic deformational structures are well exhibited in the project area including both planar and linear structures. The rocks have been folded isoclinally and later being refolded into open folds. The area is traversed by a shear zone, the Chalundri fault and is divisible into two structural domains.

The area lies in the core zone of the regional synformal structure of the Mansehra Complex, which has experienced metamorphism in Barrovian style. The project area has been metamorphosed upto garnet grade with local contact metamorphic effects along the contacts of granites.

Key words: Structure, granite gneiss, schists, Mansehra.

M/306. Mujtaba, G., 1970-71. Geological mapping of Lawari Pass Area with special reference to engineering geological aspects. Institute of Geology, Punjab University, Lahore, (M.Sc. Thesis), 84p.

The aim of the project was to map the Lawari Pass area and to investigate about its engineering geological aspects. The area has never been geologically mapped before and no considerable work has been done there. The field work was carried out in the months of October and November, 1971. Field partner was Mohammad Ilyas. The area was again visited in September, 1972. Only the adits were examined during this. The thesis is divided into two parts. First part comprises of the introduction, physiography. Petrographic and structural studies. The second part relates to the engineering properties of rocks, tunnel and the location of a best route.

An area of about 40 square miles has been mapped. The area includes the following rock units:-

1. The granodiorite,
2. The granite,
3. The gneiss,
4. The quartz-amphibole schist,
5. The chlorite schist.

Their megascopic as well as microscopic features have been studied. A little description about their petrogenesis is also included. Regional geology has been summed up separately in Chapter-III.

Dikes and Vein are described in Chapter VII. A different chapter about the structural studies is written. Stereographic projections of the foliation and the joint planes for the major rock zones are produced.

The results of the engineering tests performed on almost all rock types have been discussed in Chapter VIII. The data is included in the appendix. Chapter IX is a summary of the data from subsurface explorations through drilling and aditing. Separate writing of Chapter X about tunnel and tunneling was considered necessary to get familiar about its theoretical aspects only related to the project. Prospecting for the construction of the proposed Lawuri pass tunnel has been discussed in detail in Chapter XI A few sketches have been drawn here.

Chapter XII discusses the location of best possible route. In addition, some measures have been suggested to keep the road clear of snow, throughout the year. The proposed location of the route is shown on Map 1.

Photographs show different features from the field area as well as the laboratory work. Conclusions have been drawn in the last chapter and also recommendations have been made.

The author has found a great shortage of the literature relating to the tunnels and the highway problems in the mountainous regions.

M/307. Mujtaba, M., 1968. Field report of eastern Buner and Northern Chamla (Lower Swat Area). Institute of Geology, Punjab University, Lahore, (M.Sc. Thesis), 76p.

A detailed geologic and petrologic study of the eastern Buner and a part of northern Chamla was done with a special stress on granite complex. Granite rocks of the area are very complex mineralogically, compositionally as well as in field occurrence. The rock is composed of both granodiorite and granite but no sharp contact was found in the field to separate them. A third type of granite, known as Dumbukia Granite was noticed near the village Dumbakia, which is in the form of an oval body with a distinct weathering and gradational contact with the host granite. Due to this complexity of the granite, fifteen thin sections of the rocks were studied but the problem is still unsolved. Therefore, to solve the problem of the granite a very careful study and detail mapping must be carried out.

Metamorphic rocks of the area are also very complex. This complexity is due to thermal retrogressive and metasomatic metamorphisms which are superimposed on a previously regionally metamorphosed rocks. The highest grade of metamorphism in the area is found to be of staurolite and sillimanite grade of Amphibolite facies.

Basic dykes are very common in the area. There are younger than metamorphics but older than granite. These dykes are also metamorphosed along with the country rocks.

Dolerite dykes in granite have partly granitized. Three outcrops of iron-ore were noticed in the area. These ores, in the form of siderite and field evidences indicate that the ores are of magmatic in origin. A detail mapping must be done of these ores, in and outside the area so that it can be found whether these are economically useful or not.

The Lower Tertiary shallow water marine sequence of Bagla-Kohala-Bala area overlies unconformably on the Late Cretaceous deep water marine Kawagarh Formation. The Lower Tertiary shaly, marly and limestone sequence of Lockhart Limestone, Patala Formation, Margala Hill Limestone, Chorgali Formation and Kuldana Formation yields rich foraminiferal assemblages. The study of four stratigraphic sections yield 19 age diagnostic benthonic larger foraminiferal species. These foraminiferal species include Lockhartia tipperi, Lockhartia conditi, Assilina granulosa, Assilina subspinosa, Assilina laminosa, Daviesina khatiyahi, Miscellaneous miscella, Miscellaneous stampi, Nummulites atacus, Nummulites boninensis, Nummulites globulus, Nummulites sp., Operculina canalifera, Operculina complanta, Operculina salsa, Operculina subsalsa, Daviesina lunghami, Ranikothalia nuttalli and Bigenerina sp. The

analysis of these benthic foraminifers suggests that the deposition of the Lower Tertiary sequence occurred in an open sea upper slope to outer shelf shallow marine environment.

The pegmatite of Khadang Banda near Talash, Dir State, was mined by the locals for extracting muscovite. According to the information, about 15 to 20 maunds of white mica had been extracted from the pegmatite veins, which were sold at Lahore and Karachi, during the last five years. A partly M. Sc. students under the supervision of the author conducted geological investigation of this area to study the mineralization in these veins and to assess their potential for large scale economical exploitation muscovite.

Key words: Pegmatite, Talash, Dir.

N/2. Nadeem, M., Chaudhry, M.N. & Baig, M.G., 2000. Sedimentological studies of Lumshiwal Formation at Kalas, Attock Hazara fold and thrust belt, Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, 64-65.

A preliminary study of facies, microfacies, diagenesis, provenance and environment of deposition of Lumshiwal Formation of Early Cretaceous age from Kalas, Attock Hazara Fold and Thrust Belt, was carried out for the first time. The objective was to study the formation in the northwestern part of the oil and gas producing Indus Basin. The formation is producing gas from Punjab Platform.

The Kalas section (Lat: 33° 02' 45" N; Long: 73° 25' 30" E) of Lumshiwal Formation near Barian is 33.55 meter thick. The formation at Kalas comprises mainly of fine to medium grained sandstone which is medium grey, light brown, medium to dark grey, light grey and greenish to medium grey on fresh surface. At places fresh surface shows greenish tinge which becomes darker green on wetting. The sandstone weathers to rusty brown, dirty grey, yellowish brown, light to medium rusty brown, dark brown and greenish grey.

The Kalas section of Lumshiwal Formation comprises of six facies and sixteen microfacies. Compositionally all the sandstone horizons are mature. Texturally four microfacies are immature and rest of the microfacies are mature to submature. The sandstone is predominantly medium grained and only four microfacies are fine grained. Quartz, carbonate and glauconite are the common cements while iron oxides and clay occur as subordinate cements. Accessory to rare amounts of tourmaline, epidote and sphene which may occur either as discrete grains or as inclusions within quartz grains suggest an ultimate derivation from sialic metamorphic-igneous basement with minor contribution from basic sources. The source granitoids were mainly S-type. However restricted suite of heavy minerals, compositional maturity and rounded to subrounded shape of tourmaline grains strongly suggest significant recycling. Diagenetic history indicates that glauconite formed from clay during early diagenesis. The formation of glauconite suggests slow rate of sedimentation and mildly reducing conditions. Suturing of quartz grains occurred during deep burial. Fracturing of quartz grains occurred during tectonic deformation in a brittle regime. Calcite cement appears to have formed during shallow burial. Silica cement in the Lumshiwal Formation owes its origin mainly to pressure solutioning and secondarily to water rising from the underlying Chichali Formation which is composed predominantly of shale. Iron oxide is believed to have formed during halmyrolysis as well as during uplift. The section of Lumshiwal Formation at Kalas is different in terms of environment of deposition compared with Lumshiwal Formation at other parts of Hazara where it shows low energy, subtidal zone. At Kalas, presence of oolites in Lumshiwal Formation indicates shallowing and shoaling of basin and high energy environment while glauconite indicates reducing subtidal environment. Lower part of the Lumshiwal Formation was deposited in reducing subtidal environment, but afterward it was followed by two periods of regression during which oolites were formed. Towards the upper part of the Lumshiwal Formation there is evidence of progressive deepening. This is shown by the absence of oolites and presence of glauconite.

Key words: Sedimentology, structure, Lumshiwal Formation.

N/3. Naeem, A., 1988. Report on Geology and Structure of Balakot-Kummi Area. M.Sc. Thesis, Punjab University, Lahore, 78p.

The present work constitutes a comprehensive report on the geology of Balakot-Kummi area and is submitted in partial fulfillment of the requirements for the degree of M.Sc. at the University of the Punjab. The report includes a detailed geological map at 1:6,000 of about 65 Km² area along with a number of geologic sections and sketches. The various chapters include geomorphology, stratigraphy, structure and tectonics. Stratigraphically, the Balakot-

Kummi area includes a number of diverse sedimentary and metamorphic elements ranging in age from Precambrian to Miocene with a fairly large gap in the Mesozoic period. Structurally, the area incorporates part of the core and western limb of the Hazara-Kashmir syntaxis and through it pass the major Murree and Panjal Faults. The Balakot-Muzaffarabad anticline is the major fold overturned and overthrusts to the southwest. No major economic mineral deposit was found within the project area, although a lot of material is available as rock crush, aggregate components and building stones.

N/10. Nagappa, Y., 1959. Foraminiferal biostratigraphy of the Cretaceous-Eocene succession in the India- Pakistan- Burma region. American Museum of Natural History, Micropaleontology 5(2), 145-177.

A synthesis of the available stratigraphic and foraminiferal evidence from the upper Cretaceous-Eocene sequence of various parts of the India-Pakistan-Burma region "shows that there were four main cycles of deposition. Each cycle is shown to have started with a transgression and ended with a regression. Evidence of minor local regression is present in some places. The earliest of these cycles ended with the Maestrichtian, and this is taken to indicate the

end of the Cretaceous period. The next cycle started with the Danian, which is now placed in the lowermost Tertiary (basal Paleocene), and continued into the Ranikot stage (Paleocene). The third and fourth cycles began with the Laki and the Khirthar stages, respectively, the two cycles together representing the whole of the Eocene."

N/15. Naka, T., Hirayama, J. & Karim, T., 1995. Phosphorite-bearing Cambrian formations in the Himalayan fold and thrust belt, Hazara Division, northern Pakistan. Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad, 11, 148-179.

The Abbottabad area is underlain by Precambrian to Cretaceous partially metamorphosed sedimentary rocks deposited on shelves surrounding Gondwana. The Cambrian formations are thrust southeastward over the Precambrian metamorphic rocks (Hazara/Tanawal Formation) along the Panjal Thrust and are unconformably overlain by Jurassic to Cretaceous formations.

The Cambrian rocks in the study area are divided into two: the Abbottabad and Hazira Formations. The phosphorite deposits occur mainly in the uppermost part of the Abbottabad Formation and also in the Hazira Formation in a minor amount. The upper part of the Abbottabad formation, Sirban Dolomite Member, is subdivided into three units: the Lower Middle, and Upper. The Lower Unit consists of micritic dolomite and the Middle Unit of dolomite and quartzite. The Upper Unit is characterized by numerous chert intercalations in the dolomite. The economically important phosphorite deposits are recognized at least three levels in the upper part of the unit. The phosphorite deposits show generally nodular or ooid-like structure and are intercalated in dolomite. The phosphorite horizons are variable in thickness, reaching 5 m thick in maximum.

The Hazira Formation is 125 m thick and overlies the Abbottabad Formation with a minor sedimentary gap. It is subdivided into two facies: Hazira and Galdanian Facies. The Hazira facies consist of glauconite-bearing calcareous mudstone in the lower part, and sandstone in the upper part. The Galdanian Facies is composed of hematitic red mudstone, siltstone and then breccia Thin phosphorite beds occur in the lower part of the formation. Many of the thrust faults developed in the area generally parallel to the Panjal Thrust and bedding planes. The faults strike NNE-SSW, and their inclinations are moderate to steep with westward or eastward direction. Folds are divided into two

type: symmetrical open folds and asymmetrical light folds. and their half wavelengths are about 150 m and 100 m, respectively.

Key words: Tectonics, Cambrian, phosphorite, Himalayan Fold and Thrust belt, Abbottabad.

N/19. Nanda, A.C., 2000. Some observations on the linkage, migration and extinction of the Siwalik fauna. Abstracts, Third South Asia Geological Congress, Lahore, 72-73.

The known mammalian fauna from the Ladakh Molasse Group and Murree Group indicate that during the Upper Oligocene - Lower Miocene Himalaya was never a barrier for the to- and from- migration of the fauna. The fauna shows linkage with Europe and Central Asia and with the Bugti fauna of Pakistan. Siwalik Group (18.3 Ma to 0.22 Ma) overlies the Murree Group and is known for very rich occurrence of vertebrate remains. Fauna from the Lower Siwalik of Ramnagar, Jammu or even from Potwar plateau show a poor linkage with China or Central Asia, but good linkages with Europe and Africa. However, in the Middle Siwalik, fauna do not show linkage with Central Asia, and Himalaya was a barrier for the migration. Thus river valleys which might have formed convenient routes for migration in Oligo-Miocene became inaccessible to the fauna, either due to the high altitude of the Himalaya or energy in the river system was much more to permit migration of the fauna.

In the Upper Siwalik, rich mammalian collections have been made from Chandigarh and Jammu regions and sequence yielded both Tatrot and Pinjor Faunas. The collection made in the last 35 years near Chandigarh includes 31 marker taxa for the Pinjor Formation. In addition there are 14 taxa which although are characteristic of the Pinjor Fauna but occur in the transitional zone between the sequences which yielded Tatrot and Pinjor Fauna. The process of migration or extinction of the Pinjor Fauna ranges from 1.72 Ma to 0.6 Ma. The unfossiliferous Boulder Conglomerate Formation which overlies conformably on the Pinjor Formation is having thick sequence mainly of boulder and cobble conglomerates. The river system at that time became very furious with the abrupt rise of the Himalaya, and the energy of the rivers was enormous which forced the animal life either to migrate or to become extinct.

Thus evidence indicate that faunal migration across the Himalaya took place in Oligo-Miocene when the Himalayan rivers probably formed the favorable routes of migration. With the formation of the Siwalik Foredeep, the Himalaya started gaining rapid heights and became a barrier, and migration of the fauna along its valleys stopped. Routes of migration shifted along the southern foothills. With the extinction or migration of the Pinjor Fauna, the rivers became very furious and were having enormous energy. This inhospitable environment had caused extinction of the Siwalik fauna.

Key words: Fauna, siwaliks.

Detailed geological mapping was carried out in the Besham and allied areas on the toposheet 43 B/13 of the survey of Pakistan. The mapping has revealed the following rock units in the project area; granites, pegmatites, metamorphics of the Thakot and Salkhala groups, and a number of amphibolite dikes.

The granites and metamorphics of the area depict the varying types of conditions which affected the rocks of the area probably in Precambrian time. The granites of the area have both granular and microphyritic textures. The two kinds have been assigned different origins.

Greater emphasis has been paid to the study of the skarn bodies. These contain significant amounts of magnetite, sphalerite, galena and molybdenite. The skarn bodies have developed by the interaction of granite with the surrounding metamorphics. Some mineralization has also resulted through a hydrothermal action. The hydrothermal mineral veins are of hydrothermal to mesothermal type. Disseminated sulphide are also occurs within the altered granite.

Key words: Mineralogy, petrology, sulphide mineralization, Lahore-Pazang, Kohistan.

Lockhart Limestone is the name given by Lt.-Col. L. M. Davies' to a compact, massive, grey limestone of some 200 feet in thickness, occurring in the region of Fort Lockhart on the Samana Range between Kohat and Thal. The Samana series as worked out by him consists of 12 beds; beds 8-12 (uppermost members of the sequence) are of Ranikot age, while the base of the series.(bed 1) extends down to the Jurassic (or even the Triassic). The Lockhart limestone (bed 10) represents the uppermost portion of the Lower Ranikot and the lower portion of the Upper Ranikot.

Key words: Stratigraphy, Lockhart limestone, Ranikot, Samana Range, Hangu.

This paper describes the hydride formation system analytical technique. It is intended to determine the optimization of a suitable procedure for the determination of As and Sb. Field survey was conducted in the Swat area for collection of geochemical samples from kaolinite deposits. The area went through a hydrothermal activity and the sampling of B horizon of the Shahdheri China clay deposit was done for the path finders As and Sb for Au. The samples from Swat showed good agreement with recommended value.

N/32. Nasir, M., 1985-87. Electrical resistivity survey for groundwater potentials in Masal Talao, Amir Khan Talao, Khachar Talao and Haji Talao, District Peshawar. M.Sc. Thesis, Punjab University, Lahore, 90p.

Electrical resistivity survey in Masal Talao, Amir Khan Talao, Khachar Talao and Haji Talao (District Peshawar) was carried out in collaboration with Hydrogeology Directorate WAPDA Peshawar. The main purpose of the survey was to determine hydrogeological features such as depth to the bed rock, nature and thickness of aquifers, the quality of groundwater, and to select suitable sites for tubewell installation in the project area.

According to resistivity survey and drilling data the entire area is underlain by low resistive clay with occasional gravels. The overlying alluvium is composed of alternating layers of gravels and clays.

Ground water appears to be quite fresh in the entire project area. Water table depth varies from 13m to 40m in the area under investigation. In the project area, twenty seven probes were carried out. After interpreting the data, the V.E.S. No. 95, 93, 51, 40, 15 and 17 have been selected for the test drilling, however other probe sites also indicate the presence of aquifers in the area but of varying thickness. The entire area appears to be favourable for tubewell installation, however the yield of water depends upon the nature of aquifers, may range from half cusec to one and half cusec project area.

Key words: Geophysics, groundwater, resistivity, Peshawar.

N/33. Nasir, M.A., 1985-87. Geotechnical studies of land slides with special emphasis on slope stability along Karakoram Highway (From Batgram to Thakot, District Mansehra). M.Sc. Thesis, Punjab University, Lahore, 96p.

The project area is related to Hazara and Kohistan region of North West Frontier Province. Topographically the area is occupied by rugged rocks consisting of high peaks and alluvial deposits. The predominant rock types are granite, granite gneiss, schists and various other minor bodies as dykes and sills. All the structure features consider excellently to give NE trend that indicates NW-SE direction of tectonic forces.

The main objective of "Geotechnical Studies" is to analysis the scope of stability of rocks along roadside. For this purpose, various modes of failure, i.e., plane failure, wedge failure, toppling failure, rock fall, and circular failure etc., were observed. Theoretical models based on the actual readings (data) presented in the forthcoming chapters are intended to provide rational bases for the design of rock slope. It should however, be made clear that successful design of slope depends not only on the choice of correct theoretical model but also upon a number of other considerations which cannot be conveniently quantified.

A map has been provided which classifies the road segments as stable, unstable and potentially unstable. Stable segments are those which geometrically do not manifest any sign or chance of failure or show a high factor of safety i.e., 2.5 or 3. Unstable segments are those where small-scale failures are kept on taking place with every successive rainfall. Similarly potentially unstable segments are those which are stable in actual practice but ratio of their resisting forces to driving forces is less than one.

Study of various roads alignment was made to emphasize on the effects of sliding. Different modes of failure were encountered, and their factors of safety were calculated. Finally, it was decided whether dangerous road or not and an attempt have been made to give remedial measures.

N/39. Nawaz, S., 1989-91. Geological study for petrography and geology of Fatehpur Miandum (District Swat). M.Sc. Thesis, Punjab University, Lahore, 60p.

Miandum area (Lower Swat) are part of metamorphic hornblende complex. The area lies within the Southern portion of Lower Swat. These rocks are probably the extensions of rocks of Dir in the form of a belt running approximately in East-West direction. The area given field work comprises 30 miles in the North- West of Saido-Sharing. The area mainly comprises the main rock units are amphibolite, Norite, Diorite, quartz-o-feldspar and pegmatite veins amphibolites have been metamorphosed basic rocks probably Norite gabbro. As the field evidences, and the Laboratory study shows that the amphibolites were formed from basic magma, which has undergone regional metamorphism under the intense orogenic conditions. Quartz-o-feldspathic and pegmatite veins are extensively distributed all over the area, indicating the evidence of diorite magma. Major minerals are plagioclase, Hornblende, epidote and quartz with accessories as sphene and magnetite. These are products of regionally metamorphosed igneous rocks.

N/45. Ni, J.F., Ibenbrahim, A. & Roecker, S.W., 1991. Three-dimensional velocity structure and hypocenters of earthquakes beneath the Hazara Arc, Pakistan: Geometry of the underthrusting Indian Plate. *Journal of Geophysical Research* 96, 19865-19877.

The three-dimensional P and S wave velocity structures and hypocenters of 420 events beneath the western Hazara Arc are obtained simultaneously by inverting travel time data observed at fifteen Tarbela seismic stations. In general, the P and S wave velocity distribution of the top layer (0–6 km depth) correlates well with surface geology. Within this layer we find a low-velocity region beneath the Hazara Thrust Zone (HTZ) corresponding to the underthrust Murree Formation, and there are high-velocity regions south of the Main Mantle Thrust (MMT) which are associated with the exposed Cambrian, late Paleozoic, and Tertiary granites. A low-velocity zone immediately to the west of the Hazara-Kashmir Syntaxis (HKS) indicates the existence of a Miocene foreland basin which is covered by late stage southeasterly directed thrusts along the Hazara Arc and is consistent with the idea that the HKS is detached from the lower crust. From the Salt Range to the HTZ, the Indian plate dips at a shallow angle, about 2°–3° to the northeast. North of the HTZ the underthrusting Indian plate dips gently to the northeast with an increased slope of 5° to 8° until it reaches the Indus-Kohistan Seismic Zone (IKSZ). Along the NW trending IKSZ the Indian plate bends more steeply to the northeast beneath a seismically active mid crustal wedge directed to the southwest. The larger events in the IKSZ are interpreted as occurring on a major thrust zone that can be followed to a depth of 24 km. The IKSZ appears to consist of an upper seismic zone (from the surface to about 8 km) and a lower seismic zone (12 km to 24 km) separated by an aseismic region about 4 km thick. The lower IKSZ may represent the leading edge of a southwestward directed slab which has not yet ruptured the surface. Hypocenters of relocated earthquakes indicate that the HTZ is about 30 km wide with most of the larger microearthquakes occurring at 12–14 km. Seismicity along the HTZ suggests that the Panjal, and Murree thrusts are active.

N/46. Nicora, A., Angiolini, L. & Gaetani, M., 1992. The Permian/Triassic boundary in Hunza valley (N. Karakoram). Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 61.

The Permo-Triassic sedimentary succession of the north Karakoram microplate is a typical succession of a passive continental margin and records the opening of Neotethys. The continental margin starts to be built up during Sakmarian-Artinskian with the deposition of a deltaic to subtidal terrigenous succession (Gircha Formation) and of a

thick carbonate platform (Panjshah Formation). During Murgabian the extensional tectonic related to the rifting of Neotethys results in the downwarping of the platform and in the deposition of pelagic limestones with white chert (Kundil Fm.), Late Permian in age.

In 1991 the Italian expedition to the Chapursan Valley (upper Hunza Valley) discovered new pelagic many formation overlying the Upper Permian cherty limestones and passing upward to the anoxic limestone with black chert of the Borom Formation (Early to Middle Triassic in age). This new stratigraphic unit has been named Wirokhun Formation (Wirokhun Pass,) 4300 metres a.s.l., on the right idiographic side of the Kundil Valley) and corresponds to the unnamed unit in Gaetani et al., 1990. Its lithology chiefly consists of thin bedded marly limestones alternating with black shales and marls. The Wirokhun Formation contains the Permo/Triassic boundary in its uppermost portion based on conodont associations. At present the basal Dorashamian and the Early Dienerian have been detected.

Key words: Sedimentation, Permo/Triassic boundary, Karakoram Hunza valley.

N/47. Nida, Y., Terai, Y., Khan, S.R. & Kausar, A.B., 1998. Origin of chromitites from the Jijal complex, Kohistan arc, North Pakistan. Geological Bulletin, University of Peshawar 31 (Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop), 140-141.

The Jijal complex is a tectonic wedge of layered ultramafic cumulates and garnet granulites exposed at the base of the Cretaceous Kohistan arc [1-2]. The lower half of the complex is composed of layered peridotitic and pyroxenitic rocks, which are strongly mylonitized and amphibolitized, especially along the Main Mantle Thrust. Towards the central part of the complex the rocks are fresh and the primary minerals, magmatic textures and structures are well preserved.

On the basis of chemical composition of constituent minerals, the ultramafic rocks are classified into two series. The orthopyroxene-free dunite-chromitite series is composed of dunite, wehrlite and chromitite having high-Mg#, high-Cr# and low-Ti. The second series is pyroxenite series, comprising dominantly of clinopyroxenite, websterite and small amounts of dunite, wehrlite, chromitite, with relatively low-Mg#, low-Cr# and high-Ti. Rocks of both the series occur irregularly and are mixed, suggesting magmatic interaction of crystal mushes during the process of crystallization. At places a number of clinopyroxenite dykes and veins cross-cut the dunite-chromitite series rocks.

The chromitite occurs as disseminated and massive bodies in close association with dunite and clinopyroxenite of both the series. Clinopyroxene-chromitites are rarely observed in the pyroxenite series. The mode of occurrence of the Jijal chromitites is similar to the stratiform-type chromitites and sometimes similar to podiform-type chromitites in ophiolitic sequences. Rhythmic layering, modal gradation of chromite and cross-bedded structure in disseminated chromitites, suggest gravitational control during the deposition of chromitite.

Olivine ranges from Fo(95.4-90.8) in chromitites to Fo(91.5-89.4) in dunites for the dunite-chromitite series, and from Fo(93.0-87.4) in dunite, Fo(90.6-89.2) in wehrlite, Fo(89.286.1) in clinopyroxenite, to Fo(84.1-80.6) in websterite for the pyroxenite series. The variation in NiO wt.% of olivine with decreasing Fo content in the dunite-chromitite series shows a fractionation trend clearly distinctive from that in the pyroxenite series. The systematic Mg# change of spinel and clinopyroxene cores with the lithological change from chromitite through dunite to pyroxenite also suggests a fractional crystallization in separate magmatic processes. The range of Cr# of spinel cores from the dunite-chromitite series (Cr#=86.1-66.3) is higher than that of the pyroxenite series spinel cores (Cr# = 73.5-42.6). The Cr# and Mg# variations also display separate fractionation trends from chromitite, through dunite and wehrlite, to pyroxenites. The TiO₂ contents in spinel cores are 0.62-0.10 wt.% for the dunite-chromitite series, and 2.08-0.20 wt.% for the pyroxenite series. Clinopyroxene mineralogy also supports the above explanation.

The chemistry of the constituent minerals suggests that the magmas for the formation of Jijal ultramafic cumulates can be explained as boninitic for the dunite-chromitite series and island-arc basaltic for the pyroxenite series. The very high Cr# range of the dunite-chromitite series spinels is consistent with that of spinels in boninites [21], whereas the pyroxenite series spinels also have high Cr# range which is consistent with that of island-arc basalt magma derived from highly depleted mantle peridotites [31]. Extremely high Fo content in the dunite-chromitite series olivines and a moderately high Fo content in the pyroxenite series are suitable to the parentage described above. The extremely low content of TiO₂ in spinels (< 0.5 wt.%) and in clinopyroxenes (< 0.03 wt.%) from the dunite-chromitite series rocks characterizes the magma type as boninitic one. It can be assumed that an interaction process between two different magma types "boninitic and island-arc basalt" has taken place within a single, large-scale magma chamber.

N/48. Niida, K., Kausar, A.B. & Khan, S.R., 1996. Ultramafic crystal mush intrusion into crystallization magma chamber: Field evidence from the Chilas complex, northern Pakistan. In: Kausar, A.B. & Yajima, J. (eds.), *Geology, Geochemistry, Economic Geology and Rock Magnetism of the Kohistan Arc*. Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad, 15, 157-171.

Modes of occurrence of the dunite-wehrlite intrusions and the field relationships between the intrusion and the gabbroic host rocks were reported from the Chilas complex of the Kohistan island arc, northern Pakistan.

A model of ultramafic crystal mush intrusion into crystallizing gabbroic magmas was discussed to examine the heterogeneous lithology of ultramafic-mafic associations in the main gabbroic rocks of the complex. The well-developed layering of gabbroic to anorthositic rocks, dyking of wehrlite in gabbroic hosts, incorporation of wehrlitic xenoblocks and xenocrysts into gabbros, and other heterogeneous lithology are closely associated with the dunite-wehrlite intrusions. This suggests that the ultramafic crystal mush intrusions generated during crystallization of the gabbroic host magmas.

N/49. Ninglian, W., Tandong, Y., Zongtang, F. & Zhiqiang, 2000. Chemical weathering in the Batura glacier basin, Karakoram Mountains. Abstract Volume, 15th Himalaya-Karakoram-Tibet Workshop, (Chengdu) China, 440.

Glacially driven chemical weathering could make concentration of CO₂ in the atmosphere decrease, and the process might play a significant role in climate change and the carbon cycle. So the study of chemical components and their contents of glacial meltwater in an alpine glacier-covered catchment has important geochemical and climatological significance.

Batura Glacier is large glacier located in the Karakoram Mountains. Its length is about 59.2 km. The glacier basin is 687 km², in which 332 km², nearly a half of the basin, is occupied by glacier. The lowest limit of the glacier is 2540 m.a.s.l., where mean annual temperature is about 10°C, and annual precipitation is about 97 mm. According to the hydrological measurement in 1974-1975, the runoff of Batura River was about 9.3X10⁸m³ at the terminus of the glacier.

In 1994, the Batura Glacier was investigated again for its variations. Meanwhile, the discharge of the Batura River was measured, and ice and meltwater samples were collected during that field season. In this paper, we report the analytical results of major ions in the ice and meltwater of the Glacier. And based on these data, it is found that chemical weathering in the catchment of this glacier is intense (Table 1), and the cation denudation rate, reaching the level of the tropical very humid regions, is much larger than that in the arid regions.

N/53. Nizam-din, 1998. Paleoclimatic reconstruction of the Late Pleistocene loess-paleosol deposits in the Attock Basin, North Western Himalayan Foothills, Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 50-51.

Late Pleistocene (approx. 18-130ka) loess-paleosol deposits exposed along the Haro river, Attock basin Pakistan, north western Himalayan Foothills has been studied for stratigraphy, particle-size distribution, geochemistry and paleoclimatic investigation. The deposits cover approximately 30-km² area and are up to 20 meters in thickness. The deposits are mostly composed of less-weathered loess while at least seven highly-weathered paleosol beds, PS-1-7 in descending order, are intercalated. Loess beds are generally light brown to brown in color, poorly-stratified, porous, and calcareous. Paleosols are generally dark reddish brown in color and have vertical partings and solution cavities

Particle-size distribution analysis of the loess-paleosol deposits shows that loess beds have generally unimodal, well-sorted, leptokurtic, and negatively-skewed particle-size population whereas the paleosols have bimodal and poorly-sorted population. Loess deposits are generally composed of high percentage of silt-size particles while paleosols are rich in sand-size particles. On the basis of median particle-size (M_d in ϕ scale), silt content (in weight %), and modal analysis, the loess-paleosol sequence can be divided into two part: The lower part, below the PS-4 paleosol bed show relatively coarser population with smaller M_d ϕ values and larger sand-content (wt%) attribute to an increase of local input of coarser materials and/or aggregating fine particles caused by relatively active pedogenesis during the accumulation of loess deposits. On the other hand the upper part, above the PS-4, gives relatively finer population with larger M_d ϕ values and larger silt-content (wt%) representing lower pedogenic activity during the deposition. (Nizam-Din & Yoshida, 1997)

Geochemical analysis of the loess paleosol deposits shows that the loess has high weight percent Of SiO₂ and CaO with respect to the paleosol enriched in Al₂O₃ and Fe₂O₃. Stratigraphic variation of chemical composition and molecular weathering ratios (Retallack, 1990) in the loess-paleosol sequence also reveals a two fold division. The lower part shows high concentration of Al, Fe & Mn and a dominant effect of hydrolysis, hydration and Ca dissolution representing a humid and warm climate. Conversely the upper part shows relatively high concentration of Na, Ca, & LOI and is more oxidized, salinized, dehydrated which is probably caused by and cool climatic condition during the accumulation of upper part.

Similarly the magnetic susceptibility of the loess-paleosol deposits (Akram & Yoshida, 1997) also show a systematic variation. In the upper part show low values marking and climate and very high values in the lower part representing a comparatively warmer conditions.

These drastic change in particle-size distribution, geochemical characteristic and magnetic susceptibility between the upper and lower parts of the loess-paleosol sequence possibly provides a terrestrial record of continental paleoclimate in the area during late Pleistocene: i.e. it can be interpreted in terms of relative strength of paleo-monsoon winds by the model in Chinese loess plateau (Heller et al, 1991). That is, the lower part is marked by intense summer monsoon winds whereas the upper part is dominated by stronger winter monsoon winds. This climatic deterioration in the section may correspond to the climatic change from the Last Interglacial to the Last Glacial epoch of Himalayan glaciation.

An eleven meter thick section of the Quaternary loess deposit exposed along the Haro river was measured. The loess section comprises of twenty- less-weathered loess beds and four highly weathered beds called "paleosols" showing a change in climate and depositional environment of these deposits. Grain size distribution of the loess deposits shows that loess beds have generally unimodal, well-sorted leptocratic and fine skewed population whereas paleosols are bimodal and poorly-sorted. Loess deposits have high percentage of silt size particles while paleosols are rich in sand size particles.

N/58. Nizami, M.S. & Farooq, M.K., 1990. Geology and evaluation of recently exposed lower Jurassic glass sand deposits of Datta Formation in the Salt Range and Surghar Range, Pakistan. *Geological Bulletin, Punjab University* 25, 62-69.

A number of comparatively new glass sand deposits in the Salt Range and Surghar Range were studied geologically to know the nature of country rocks and feasibility of mining. Five representative specimens from the same deposits were analysed physio-chemically and evaluated regarding glass manufacture. Two of these were found suitable for producing general colorless such as container glass and sheet glass and third one for coloured glasses. The remaining two might find utilization in ceramic industry, as one was more fine-grained while the other contained less SiO₂ than required for glass melting.

N/60. Noetling, F., 1897. Fauna of Baluchistan and N-W Frontier of India. The fauna of the Neocomian belemnite beds. *Geological Survey of India, Memoirs, Palaeontologica Indica, Series* 16, 1(2), 5p, 2pls.

First paragraph of the book: The oldest formation seen in the sections of the Mari hills of Baluchistan is represented, according to Messrs. Griesbach and Oldham, by a massive limestone which is generally devoid of fossils, or at most contains some ill-preserved fossils here and there; commonest are Brachiopods belonging to the genera *Rhynchonella* and *Terebratulina*. It is clear that these two genera would not have been sufficient to determine the age of the " massive limestone " with certainty, but fortunately Lala Kishen Sing of the Geological Survey

discovered a rich fauna of ammonites in these deposits near Mazar Drik. It is, however, to be regretted that almost every specimen has suffered more or less from deformation by pressure, and that the finer structure of the sutural line has been completely destroyed in every case. Under these circumstances the specific determination would have been exceedingly difficult had I not been able to compare this collection with the type specimens from the Jurassic beds of Kutch, which have been so diligently worked out by Professor Waagen. The only fault which I have to find with this fine publication consists in the fact, that the figures of the specimens described do not always represent the original in its actual state, but that they are in many cases considerably, and not always happily, restored. The determination from the figures only, as given in Professor Waagen's publication, is therefore extremely difficult, and it may be noticed that my figures differ considerably from those of the species of the same name as shown by Professor Waagen. I have, however, convicted myself by actual comparison with the Kutch originals that the specimens here described under specific determinations attributed by Professor Waagen to forms from Kutch, are really identical with these species, notwithstanding the apparent difference of the figures. In two cases, however, I felt under an obligation to reproduce two of Professor Waagen's originals, in order to prove to the reader the identity of the Baluchistan forms with those from Kutch, as the published figure of the Kutch species differs considerably from the type specimen. The Jurassic limestone of Mazar Drik has up to the present yielded 22 species, of which 17 have been determined specifically, while of 5 only the genus could be determined. Out of the 17 species specifically determined, 16 could be identified with species already described, while one form, *Perisphinctes baluchistanensis*, could be recognized as new. The 22 species mentioned represent the following classes *Braehiopoia* 2 species (two especially deteruined), *Pelecffiioda*, 3, *Gastropoda* 1 (none), *Cephalopoda* 16, (15).

N/68. Nowroozi, A., 1972. Focal mechanism of earthquakes in Persia, Turkey, West Pakistan and Afghanistan and plate tectonics of the Middle East. Bulletin of the Seismological Society of America 62, 823-850.

Focal mechanism solutions are determined for 23 earthquakes that occurred from 1965 to 1970 in Persia, Turkey, Pakistan, and Afghanistan. These mechanisms were obtained from the long-period first-motion P waves recorded by the World-Wide Standardized Seismograph Network stations. Mechanism solutions for the earthquakes in the folded foothills of the Zagros are predominantly thrust faulting, but depending on the assumed crustal velocity, many have strike-slip components. Cross sections of the seismic zone of the folded foothills of the Zagros show that the earthquakes are confined to a possible lithospheric slab nearly 60 km thick dipping 10° to 20° toward the north. For the earthquakes with focal depth of about 200 km, in the Hindu Kush in Afghanistan, mechanism solutions are characterized by a nearly horizontal compressional axis and a steeper extensional axis. The seismic zone appears as a contorted slab-like structure 20 to 30 km in width. This lithospheric slab may be a remnant of the Tethys Sea floor. Consistent right-lateral strike-slip mechanism solutions are found for earthquakes on the Anatolian fault in Turkey. For earthquakes on the Ferdows fault in eastern Persia, mechanism solutions vary from pure left-lateral strike-slip faulting to pure thrust faulting. Mechanism solutions for earthquakes on the Kirthar-Sulaiman shear zone in West Pakistan show consistent left-lateral strike-slip motion on a fault plane that strikes north-south. This is in agreement with the northward movement of India with respect to Afghanistan. On the basis of seismic and geological evidence, the entire Middle East is divided into eight plates which are moving northward, at different rates, with respect to Eurasia. The differential motion between various plates can explain the sense of offset and other geological features.

O/1. O'Brien, P.J., Zotov, N., Law, R., Khan, M.A. & Jan, M.Q., 1999. Coesite in eclogite from the upper Kaghan valley, Pakistan: a first record and implications. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet workshop, Kloster Ettal, Terra Nostra 99, 109-111.

Coesite, recognized petrographically and confirmed by in situ Raman microprobe spectroscopy, is reported from an eclogite from the Upper Kaghan Valley, Pakistan and represents the first record of Ultra-High Pressure (UHP) metamorphism in the Himalaya. The formation conditions >25 kbar, implied by the presence of coesite, are also supported by garnet-pyroxene-phengite barometry. The mafic bodies of the Upper Kaghan Valley have been interpreted as the metamorphic equivalents of mafic lavas, dykes and sills of Permian age (Panjal Trap volcanics). The important implication is, therefore, not only that the leading edge of the Indian plate, i.e. continental crust, was subducted to extreme depths (<90-km) during the Himalayan collision phase but that part of it was also quickly exhumed. The coesite-bearing eclogite was discovered in the Loihalol Nala, north of Gittidas, opposite the settlement Faqir Shah di Baihk. This location lies only a few kilometers from the Indus Suture. The macroscopically fresh eclogite exhibits a massive, fine grained (mostly less than 1mm), red garnet and dark green omphacite matrix, sprinkled with mm-sized white mica grains and overgrown by randomly oriented, black amphibole crystal up to 1cm in length. The body is also cut by quartz-white mica veins. Microscopically, anhedral garnet, mostly under 0.5 mm and with conspicuous darker cores, sits with a weakly-defined foliation defined by elongate omphacite (mostly 0.5-1.5mm and commonly dusted with tiny rutile inclusions), phengitic white mica (0.5-1mm), aggregates of quartz, and chains of rutile (rimmed by titanite). The large amphiboles grow across the fabric and enclose garnet, phengite and rutile but only scarce omphacite. Regression is extremely minor. The coesite (largest grain is 60 microns) occurs as inclusions in omphacite and shows the characteristic breakdown to radiating (palisade-texture) quartz as well as the typical radiating network of fractures in the host pyroxene. Inclusion with just palisade quartz are also present as are omphacites with more than one coesite inclusion preserved. Optically, coesite shows a higher relief than its surrounding quartz as well as a lower birefringence. Microprobe analysis showed a pure SiO₂ composition for both phases of the inclusions and by use of raman spectroscopy, including a two-dimensional mapping technique, it was very easy to distinguish between clinopyroxene, quartz and coesite spectra. The distinct color zoning of garnet is reflected in compositional zoning. Element distribution maps allow distinction of a relatively Ca-rich core (Alm₅₀ Prp₁₈ Grs₂₉ Sps₃), surrounded by zone with lower Ca (Alm₅₀ Prp₂₁ Grs₂₁ Sps₁) and followed by a narrow- but distinct- overgrowth where Ca is again higher than Mg. The jadeite content of omphacite ranges between 25 and 33 mol% (aegirine content 4-13 mol% from charge balance) but individual grains appear to be unzoned. Phengite shows a maximum Si per formula unit of 7.2 (Mg/Mg+Fe=0.74) in grain interiors with both values falling towards the margins of grains. The large amphiboles are Mg-hornblende, zoned to barroisite close to garnet, whereas younger amphibole formed as a breakdown product of garnet plots in the field of sub-silicic ferroan paragonite. The geothermobarometric methods that would most commonly be applied to an eclogite of this kind are the garnet-clinopyroxene and garnet-phengite Fe-Mg exchange geothermometers and geobarometer based on the reaction albite + aegirine + quartz. Unfortunately, the jadeite geobarometer, in the absence of plagioclase (as is the case in eclogites), can only yield a minimum pressure. From these 'traditional' methods alone, equilibrium conditions of around 650°C and 14 kbar were estimated: values perfectly in line with what previous workers in the area have deduced. An additional, and very useful geobarometer, is that based on the reaction between garnet, omphacite and phengite described by: Pyrope (in garnet)+Grossular (in garnet) = Diopside (in omphacite)+inverse Tschemaks (=Al₂Mg₂Si₋₁) (in phengite). The inverse Tschemaks activity is derived as Muscovite/Celadonite. This water-absent geobarometer reaction, calibrated initially by waters and Martin (1993), has been successfully tested in the Dabie Mountains, China by Carswell et al. (1977), to distinguish phengite-bearing eclogites that formed in the quartz stability field. It was results from the application of this geobarometer to data from Kaghan Valley eclogites (taken from Spencer 1993). i.e. pressures well above 20 kbar, that prompted the new field work in this area. Interestingly, some of the eclogite samples described from the Tso Moriri area of Ladakh by de Sigoyer et al., (1977) also yield pressures in the coesite field. For the coesite-bearing sample described here, the estimated equilibrations fall on the coesite-quartz curve at around 27 kbar, 680°C. This first discovery of coesite, combined with the new pressure estimates obtained from garnet-clinopyroxene-phengite geobarometry, are strong evidence that at least this corner of the Indian Plate has been subducted to considerable depth (27 kbar is equivalent to 90-100 km i.e.

almost three times the normal thickness of the continental crust). More important for the tectonic interpretation, however, is that rocks from this depth have managed to reach the surface again without being completely overprinted. Exhumation rates and exhumation model for the various metamorphic rocks in this area had been estimated, before, the discovery of eclogites, based on the maximum pressure conditions deduced for garnet-kyanite-staurolite-bearing assemblages in metapelites-parameters not significantly modified if the conservative minima estimated for the eclogites (Spencer, 1993) were taken into consideration. Model parameters must now be corrected as the pressure (or depth) deduced from this study is greater by at least a factor of 2. As the age constraints on the timing of collision, metamorphism, exhumation and cooling are entirely unaffected by these results, the only possible conclusion is that exhumation of rocks from coesite-forming depths, and more importantly the metastable preservation of coesite in such rocks, may well be entirely due to the buoyancy of the relatively low density (compared to the mantle) subducted continental crust slice hosting the eclogites. Tectonic models promoting this aspect, such as that proposed by Chemenda et al. (1995), may therefore be directly applicable to the early part of the Himalayan collision event. The first definite eclogites in the Himalayan were reported only in the early 1990's and there are still only very few areas where eclogites (or their retrograded or overprinted equivalents) have been identified. In comparison to European continental collision belts such as the Alps, Variscides, or Caledonides, eclogites are extraordinarily scarce in the Himalayas and other characteristic high-pressure rocks, such as garnet peridotite, are completely unknown. Is this just a product of the lack of investigation or is the lack of high-pressure rocks a function of the pervasive amphibolite facies event? One thing is certain: the eclogites were encased in continental crust at these mantle depths and it is only a question of time before a high-pressure evolution is confirmed in these rocks as well. It should not be forgotten that easily accessible rocks preserving relics of ultra high-pressure metamorphism in the Dora Maira Massif, Western Alps, had been completely overlooked by generations of geologists before their true worth was discovered.

Key words: Eclogite, UHP metamorphism, tectonics, Kaghan, Kohistan.

O/2. O'Brien, P.J., Zotov, N., Law, R., Khan, M.A. & Jan, M.Q., 2001. Coesite in Himalayan eclogite and implications for models of India-Asia collision. *Geology* 29, 435-438.

Coesite, recognized petrographically and confirmed by in situ Raman microprobe spectroscopy, is reported from an eclogite from the Kaghan valley, Pakistan, and represents the first record of ultrahigh-pressure metamorphism in the Himalaya. The formation conditions of >27 kbar implied by the presence of coesite are supported by garnet-pyroxene-phengite barometry (27-29 kbar, 690-750 °C). If, as seems likely from previous field and geochronologic studies, the eclogites represent metamorphosed dikes, sills, and lava flows of Permian age within the granitic gneiss-metapelite-marble sequence of the Higher Himalayan crystalline nappes, then continental crust-the leading edge of the Indian plateaus also have been subducted to coesite-forming depths (90-100 km). This more than doubles previous depth estimates and, on the basis of available geochronological data for this area, requires average exhumation rates at least twice as fast (~10 mm/yr) as previously imagined. A further implication, based on interpretations of deep seismic data, is that the present-day shallow angle of subduction of Indian plate lithosphere beneath Tibet represents a significant change from an initially much steeper angle.

O/3. Odell, N.E., 1983. On the occurrence of granite in the Himalayan mountains. In: Shams, F.A. (ed.), *Granites of Himalayas, Karakorum, and Hindu Kush*. Institute of geology, Punjab University, 1-10.

The varying occurrences of granite in the principal regions of Himalaya proper and the Karakorum – Hindu Kush are considered and contrasted. Professor A. Desio's important work in the Karakorum in particular is cited. The older concept of there being on an 'axial granite core' in the Great Himalaya range is shown to be erroneous. Instead, later exploration and mountaineering in the main ranges have revealed that a large proportion of the high peaks are composed of sedimentary rocks, with intrusive granite appearing only very locally, while most, if not all, occurrences of granite, whether of the older granite gneiss or the newer

intrusives, are considered to be magmatic in origin, the special case of Nanga Parbat, claimed by Mish to be metasomatic and a major example of granitization is briefly discussed. The recent extensive geological survey of Nepal by Magen is touched upon and details given of important work in the area of Mount Everest and Makalu; with emphases made upon the earlier and significant studies of Wager in the injected granite sheets of Everest and vicinity, their role and their radiometric ages. Gansser's current work in Bhutan is also cited, apart from references to his outstanding and comprehensive studies of the better-known portions of the main Himalaya.

O/11. Ogasawara, M., 1998a. Interpretation of JERS-1 remote sensing data on Karakoram, northern Pakistan. Geological Bulletin, University of Peshawar 31 (Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop. Abstract Volume, Geological Bulletin, University of Peshawar 31, 143-144.

Remote sensing data obtained by JERS-1 (Japanese Earth Resources Satellite) have been evaluated for lithological and structural interpretations in areas from the Karakoram, northern Pakistan. A comparison has also been made with similar images from Landsat TM. JERS-1 carries an optical sensor (OPS) which records seven spectral bands. Three bands around 2.2 micron wavelength have been designed to provide valuable information for lithological discrimination. The spatial resolution of JERS-1 (18m) is better than that of the Landsat TM (30m), and provide very detailed topographical and geological information [11. One scene of JERS - 1 covers an area of about 75 * 75 km, and for the purposes of this study, twenty scenes of JERS-1 data were examined. Excellent data have been obtained along two strips of JERS-1, i.e. paths 183 and 188 (Fig. 1).

Among the factors limiting the use of remote sensing data in the high mountain terranes are the snow cover and the cloudy weather. For instance, the Karakoram Ranges is largely covered by snow in the winter, but the highest mountains are also covered in the summer. An image of northern Karakoram, north of Gilgit, taken in middle of November, shows that more than 90 % of the area is covered by snow. The images of the similar area in the northern Karakoram taken at the end of June still indicates that it is covered by snow. Thus, in order to have a minimum snow cover, it is necessary to select appropriate remote sensing data, for instance, these obtained at the end of summer (e.g., from the end of August to early September). In addition to problem by the snow cover, cloud cover also provides limitation on the image selection. Despite the problem of the snow covers, the Karakoram range is an ideal area for interpreting the remote sensing data, since it is characterized by a scarcity of vegetation mainly due to the relatively dry weather conditions. The different rock types are easily distinguished using JERS- 1 data.

Four scenes of JERS-1 Path 183, covering the area from Nanga Parbat to Khunjerab pass, were collected at the end of September, and they contain excellent geological information. The Karakoram Highway runs in the middle of the images. These show very detailed topographic features and fine geological structures. The high spatial resolution of JERS-1 data is very useful especially in areas where there are no good topographic maps or air-photos. The JERS-1 images can be enlarged into 1/100,000 scale without the loss of image quality.

Distribution of carbonate rocks and acidic granitic rocks [2] in the area is clearly shown in the images. The carbonate horizons which are several tens of meters thick, can be easily detected. These horizons are important key beds for the structural interpretation of the area. The black slate formations, e.g., Misgar slate, can also easily traced because they are appeared with a distinct black tone on the false color image.

In conclusion, the satellite images with the high spatial and spectral resolutions are useful for making geological survey in the area with difficult access. Geological information of several limited traverse can be correlated on a regional scale by using remote sensing data. Although Landsat TM data provide useful geological information, remote sensing data with even higher spatial resolution, JERS-1 or possibly SPOT, can be utilized in the area like the Karakoram.

This study was supported by joint research program between Geological Survey of Japan and Earth Resources Satellite Data Analysis Center.

O/12. Ogasawara, M., 1998b. New muscovite Rb-Sr ages of mylonite from the Misgar Shear Zone, in northern Karakoram: implications for late Cretaceous tectonism in the

Eurasian plate. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 144-145.

The mylonite was found near Misgar in the northern Karakoram which consists largely of Permian to Jurassic sediments. The mylonite is well exposed on the road cut of the Karakoram Highway at a distance of about 5-km upstream of the Khunjerab River from the Khunjerab-Kilik Rivers junction with a width of 900m. It continues 7km northwest to north of Misgar with a N70°W trend. The mylonite separates the Misgar Slate to the north from the Kilik Formation to the south. The occurrence of such wide zone of the mylonite could indicate the presence of a major shear zone, Ogasawara et al. proposed to use the term Misgar Shear Zone (MSZ) to describe it. The MSZ consists of mylonitic rocks, gneiss and schist originated from granodiorite, granite, limestone, sandstone and mudstone. Cataclasites after the mylonite are also present. Pseudotachyite veins are found in the cataclastic rocks. Mylonite of plutonic origin is dominant in the northern portion of the MSZ, and augen texture is commonly observed in it. Calcareous and pelitic schists are present in the southern portion. A narrow calcareous mylonite with a width of 15m bounds the southern margin of the MSZ. The mylonitic foliation mostly dips 70-80° to the south. Horizontal to southeast shallow plunging lineation is commonly observed on the foliation plane. Several types of asymmetric microstructures, e.g. asymmetric pressure shadows, are observable in the mylonite and pelitic schist in the MSZ. All the asymmetric microstructures demonstrate a dextral strike-slip shear.

K-Ar ages of the muscovite and biotite of the mylonite are 66.5 ± 5.3 and 63.4 ± 3.4 Ma, respectively. New muscovite Rb-Sr ages of mylonite are 69.9 ± 1.7 and 66.6 ± 1.5 Ma. Though, these are slightly older than the K-Ar ages, all the ages obtained are clearly indicating that the mylonite was formed by a late Cretaceous tectonic event in the Eurasian plate.

The Kohistan-Ladakh arc collided with the Eurasian plate before the collision of India to Eurasia, and the northern suture is thought to have closed during late Cretaceous time between 95 and 75 Ma. Therefore, the late Cretaceous age of the MSZ suggests that the dextral strike-slip displacement of MSZ in the Karakoram terrane may be related to final movement of the collision of the Kohistan-Ladakh arc to the Eurasia. On the other hand, Klootwijk et al. suggested an early India-Asia contact before 55N1 (as early as 70Ma) from paleomagnetic constraints. Such early India-Asia contact may have led to deformation of the Eurasian continent even in the late Cretaceous. Late Cretaceous radiometric ages of the mylonite from MSZ could support this model.

The presence of cataclastic and pseudotachylite with dextral strike-slip sense of shear indicates that the dextral strike-slip displacement continued after several kilometers uplift of Karakoram terrane from the depth of mylonite formation. The dextral strike-slip Misgar fault which occurs at a distance of about 5 km south of the MSZ at Khunjerab River and merges into MSZ near Misgar, also records the same strike-slip displacement. Therefore, the continued convergence of the Indian and Eurasian plates led to the strike-slip displacement of the crust within the Eurasian plate and it started from the late Cretaceous.

Late Cretaceous igneous activity and tectonism of the Karakoram block in the Khunjerab valley, Northern Pakistan. In: Ahmed, R. & Sheikh, A.M. (eds.), Geology in South Asia--I. Proceedings of the First South Asia Geological Congress, Islamabad, 1992. Hydrocarbon Development Institute of Pakistan, Islamabad, 203-207.

In the Karakoram block of the Eurasian plate to the north of the Northern Suture in Pakistan, the Karakoram Batholith is a major body of granitic rocks. However, several smaller granitic bodies are present to the north of the Karakoram Batholith, which comprise the Khunjerab-Trich Mir granite belt. Some of the granitoids of this belt which occur in the Khunjerab Valley have been investigated. The Khunjerab pluton consists of hornblende-biotite granodiorite and granite. Its K-Ar hornblende and biotite ages are 107 ± 5 Ma and 96.9 ± 4.8 Ma, respectively. The K-Ar hornblende and biotite ages of 105 ± 5 Ma, and 95.0 ± 4.7 Ma respectively, for the Girag syenite are not different from the ages of the Khunjerab pluton. Slightly younger K-Ar biotite ages of 84.2 ± 4.2 Ma and 85.9 ± 4.3 Ma have been obtained for the North Sost pluton. These data and the age of the Tirich Mir pluton from the reference indicate that plutonism of the Khunjerab-Trich Mir granite belt took place during 120-85 Ma. The age is similar to the ages of the older plutonism found in the Karakoram Batholith. That plutonism could be generated by the northward subduction of the oceanic crust, which was present between the Kohistan Island Arc and the Karakoram Block.

O/19. Okrusch, M., Bunch, T.E. & Bank, H., 1976. Paragenesis and petrogenesis of a corundum-bearing marble at Hunza (Kashmir). *Mineralium Deposita* 11, 278-297.

A calcite-marble containing gem-quality ruby is exposed in the Hunza Valley, northwestern part of the Karakoram Mountains, Pakistan zone of Kashmir. The marble forms concordant intercalations within sillimanite- and garnet-bearing biotite-plagioclase gneisses and mica schists. The metamorphic sequence is cut by discordant aplite and pegmatite dikes. The following mineral assemblages are recognized in the marble:

- 1) Calcite+corundum+phlogopite±margarite±sheridanite±Al-rich pargasite±anorthite (An 96.7),
- 2) calcite+spinel±corundum+phlogopite+sheridanite.

Microprobe analyses are given for the essential minerals including corundum (ruby) and three different colour varieties of spinel. On the basis of recent experimental data, especially in the system $\text{CaO} - \text{Al}_2\text{O}_3 - \text{SiO}_2 - \text{H}_2\text{O} - \text{CO}_2$ (and related subsystems), we assume that, during the regional metamorphism, temperatures of about 600 – 620°C and a water vapour pressure of about 6 kb were realized in part of the Hunza area. The gas phase must have contained roughly 20 mole-% of CO_2 . Thus the total fluid pressure may have reached about 7 kb. Presumably, temperatures increased in northwest direction, perhaps up to about 700°C. The estimated P-T conditions are consistent with a geothermal gradient of about 25°C/km.

O/24. Oldham, R.D., 1893. Encyclopedia of Indian geology. 2nd edition, Government of India Press, Calcutta, 543p.

This is an edited and revised version of the manual of Indian geology by H.B. Medlicott and W.T. Blanford (1879-1887). It is based on all the data (essentially generated by the Geological Survey of India) up to 1892. The two volumes comprise 19 chapters containing many tables, 19 illustrations and 27 figures. The various chapters are titled as: I. Physical geography, II. Metamorphic and crystalline rocks, III. Transition systems, IV. Older Paleozoic (Cuddapah and Vindhyan) systems of the peninsular, V. older Paleozoic systems of the extra peninsular area, VI. Carboniferous and Triassic rocks of extra peninsular India, VII. The Gondwana system, VIII. Homotaxis of the Gondwanic system, IX. Marine Jurassic rocks, X. Marine Cretaceous of the Indian Peninsula, XI. Deccan trap, XII. Cretaceous rocks of the extra peninsular India, XIII. Tertiary deposits, XIV. Tertiary of the Himalayas, XV. Laterite, XVI. Pleistocene and recent deposits, XVII. The Indo-Gangetic plane, XVIII. The age and origin of the Himalaya, XIX. Geological History of the Indian Peninsula. These are followed by 14 pages of subject index. References to source literature are given in foot notes. Available information of the geology of the area of our compilation has been included. This manual is a valuable compilation and easy reference to the earlier publications of the GSI.

O/26. Oldham, T., 1882. Thermal springs of India. Geological Survey of India, Memoirs 19(2), 63p.

No abstract could be obtained by the authors about this account. But other authors (e.g. THERMAL SPRINGS OF DAKSHINA KANNADA - K.R. Chandrashekar, K.R. Sridhar, M. Rajashekar and K.M. Kaveriappa, Indian Institute of Science 2000) have referred to Oldham, T. as follows.

T. Oldham, a veteran geologist, catalogued the thermal springs of India as early as 1882. He located a thermal spring in a remote and inaccessible part of Puttur taluk in South Kanara district (cf. Radhakrishna, 1971). This spring, referred to as "Bendre Thirtha" by the locals, is located on the south bank of the Badantadka river, which emerges after the confluence of two tributaries, Balakku and Ermati (12° 43' N, 75° 13' S) (Fig. 1). The spring is located on a private areca garden. There are very few trees surrounding the spring viz., *Ficus benghalensis* L., *Mangifera indica* L., *Artocarpus heterophyllus* Lam., *Cocos nucifera* L., and *Areca catechu* L. Waring (1965) referred to the existence of this spring in U.S.G.S. Publication "Thermal springs of the United States and other countries of the world". Radhakrishna (1971) was impressed by a beautiful description of this spring in the Kannada novel "Karulina Kare" written by the noted Kannada writer Dr. Shivarama Karanth who had woven a beautiful story around this thermal spring. He carried out preliminary investigations on the geology of this thermal spring. Later, Chandrashekar et al. (1991) did some investigations on the aquatic hyphomycetes occurring in this spring.

Key words: Thermal Springs, India

O/27. Olson, T.M., 1982. Sedimentary tectonics of the Jalipur sequence, northwest Himalaya, Pakistan. M.A. Thesis, Dartmouth College, Hanover, New Hampshire, 152p.

This is a study of the young molasse sediments along the Indus River on the western flank of the Nanga Parbat massif. These rocks are dominantly immature sandstones with fragments of metamorphic rocks and feldspar derived from the massif and mafic rocks of the Kohistan arc. The observed tectonic deformation is interpreted as gravity collapse structures induced by uplift of the adjacent massif. Extensive soft sediment deformation, sandstone dikes, and deposits representing catastrophic events suggest deposition of the units of the sequence in an active tectonic environment. The presence of the once-buried Jalipur sequence and the overlying undeformed sediments on the flanks of the rapidly uplifting Nanga Parbat massif suggests that uplift is sporadic rather than continuous uplift would inhibit accumulation of a significant amount of sediment.

The Jalipur sequence consists of a series of alluvial fan, lacustrine, and braided stream deposits in the middle Indus Valley in the northwest Himalaya. Units in the sequence are similar in character to recent sedimentary deposits but have undergone extensive deformation. Stratigraphic relationships indicate a very young age for the sequence a conclusion which was suggested previously by fission-track dating of detrital zircons from a sandstone unit in the sequence.

The intermontane setting of the deformed sedimentary sequence and the proximity of the sequence to a branch of the Himalayan suture zone provided the initial framework for the study of these late-orogenic sedimentary rocks. Recent work on regional thermal history has indicated that the dominant structural element of the region, the Nanga Parbat- Haramosh Massif, is undergoing very rapid uplift.

A geologic map of the region was produced through a combination of field mapping and computer classification of digital Landsat spectral data. The dual approach to mapping proved effective in this area,

where ground access is difficult and air photographs and accurate topographic maps are not readily available.

No coherent structural style, such as might be expected in a thrust-dominated suture zone setting, is apparent in the deformation of the young Jalipur sequence. The observed tectonic deformation is interpreted as gravity collapse structures induced by uplift of the adjacent massif. Extensive soft sediment deformation, sandstone dikes, and deposits representing catastrophic events suggest deposition of the units of the sequence in an active tectonic environment.

Sandstones in the sequence are immature and contain large amounts of metamorphic rock fragments and feldspar grains. The petrology and heavy mineral compositions of these sandstones indicate that the detrital components were locally derived; sandstone composition was strongly influenced by the granitic rocks and metasediments of Nanga Parbat and by pyroxene granulite, the other major local bedrock type. The degree of lithification and the microstructures are evidence for some degree of burial of the sequence.

The presence of the once-buried Jalipur sequence and the overlying undeformed sediments on the flanks of the rapidly uplifting Nanga Parbat massif suggests that uplift is sporadic rather than continuous uplift would inhibit accumulation of a significant amount of sediment.

Sampling for paleomagnetic study has been carried out at seven localities in the Potwar Plateau region of Pakistan in the vicinity of the Salt Range. In all, 253 sites, consisting of three samples per site, were studied. The sites were taken from the Chinji, Nagri, Dhok Pathan and Upper Siwalik formations which span the last 14 m.y. of Earth history. The formations have been deformed in the ongoing Himalayan orogeny and are exposed today in sections which dip at angles of from 10° to 90° in different directions.

A characteristic direction of magnetization was isolated at all sections by thermal demagnetization at temperatures of from 550° to 650°C. The sediments have been folded within the last 2 m.y. and because of a positive fold test it can be shown that the characteristic magnetization of these sediments was acquired before folding. Four of the sections have directions of magnetization which have been rotated in a counter-clockwise fashion up to 40°; however, sections taken along the Indus River, the north flank of the Soan syncline and the south flank of the Salt Range show small counter-clockwise rotations of under 10°. These observations are in agreement with previous suggestions that strata in the Salt Range have been moved to the south and rotated in a counter-clockwise fashion. The observations reported here indicate that the paleomagnetic poles derived from Cambrian and Permian formations within the Salt Range have probably also suffered rotation and should be removed from consideration in Gondwanaland reconstruction of the Paleozoic.

O/33. Opdyke, N.D., Lindsay, E.H., Johnson, G.D., Johnson, N.M., Tahirkheli, R.A.K. & Mirza, M.A., 1979. Magnetic polarity stratigraphy and vertebrate paleontology of the Upper Siwalik Sub Group of northern Pakistan. *Palaeogeography, Palaeoclimatology, Palaeoecology* 27, 1-34.

Two hundred and fifty three sites consisting of three samples per site were taken from eight separate stratigraphic sections from sediments of the Upper Siwalik subgroup of northern Pakistan. All samples have been partially demagnetized in alternating fields of from 150 to 300 °c. The sediments are dipping at angles of up to 75° in a variety of directions, and the locality mean directions improve significantly after correcting for bedding attitude, providing a statistically significant fold test at the 95% level.

The magnetic stratigraphy was obtained based on the statistically significant well-grouped partially demagnetized data. Two prominent bentonitized tuffs occur in several sections above and below a prominent reversal of the earth's magnetic field. Radiometric dates of 2.3 ± 0.4 m.y.B.P. and 2.5 ± 0.4 m.y.B.P. have been obtained by fission track on zircons from these tuffs. This allows the magnetic stratigraphy to be correlated to the standard reversal chronology of the Pliocene and Pleistocene. The longest stratigraphic section (1.87 km in thickness) can be shown to span the time between 0.6 m.y.B.P. and 5.5 m.y.B.P.

The individual stratigraphic sections can be correlated on the basis of magnetic stratigraphy. All sections contain important vertebrate fossil localities which can be placed relative to each other in the time stratigraphic framework provided by the magnetic stratigraphy.

The change from the Pinjor fauna to the Tatrot fauna occurs at about 2.47 m.y.B.P. (the Gauss/Matuyama boundary) based on the simultaneous occurrence of *Equus*-*Elephas*, *Bos* and cervids with antlers. *Hipparion*, the three-toed horse, persists to the lowermost Pleistocene just after the termination of the Olduvai event. The ranges of other important vertebrate faunas are also discussed.

The folding of the eastern Salt Range has been very recent, beginning within the Brunhes normal magnetic epoch, since sediments of lower Brunhes age are folded on the flanks of the Pabbi and Rohtas anticlines and on the flanks of Chambal Ridge. The rate of uplift of these structures above the present base level is estimated to have a minimum rate of four meters per thousand years for the Rohtas anticline and three meters per thousand years for the Pabbi Hills. The rates of subsidence (i.e., rates of sedimentation) of the various sections are estimated to range from 0.35 m/103 yr to 0.50 m/103 yr. The first occurrence of conglomerate-containing clasts derived from the Himalayan uplift occurs just prior to the Olduvai event at the base of the Pleistocene.

The impulse radar technique used originally to sound the temperate Vatnajökull, Iceland ice cap and successfully employed on the Hispar and Ghulkin glaciers during the Karakoram Project is reviewed. Possible improvements to the system are discussed, with particular reference to the transmitting and receiving systems and to their implementation in the 'Subscan' impulse radar system. Attention is given to techniques for integrating successive output signals in order to reduce the effective noise level, and the statistical theory of a fast and simple digital integration technique is given. A brief description of the Subscan digital signal discrimination and recording systems concludes the paper.

O/37. Ottiger, R., 1985. Rocks of the Murree Formation: indicators of a descending foreland basin of lower to middle Eocene age. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

The red clastic sand and shale deposits of the Murree Formation have been regarded as continental deposits of Miocene age. A new and more detailed sedimentological and micropaleontological survey on a profile of fifteen-kilometer length, in the apex region of the Hazara-Kashmir Syntaxis in Northern Pakistan, has shown that these rocks were deposited in a very shallow marine (sub-supratidal) environment, on a 5tidal flat. This hypothesis is based on a reinterpretation of the cyclic sedimentation seen in these rocks. One can interpret a single cycle as the product of meandering tidal channels in a continuously descending foreland basin. Each cycle starts with typical channel fill deposits (microconglomerates, crossbedded sandstone) and passes upwards into tidal flat deposits (laminated and strongly bioturbated sand and siltstones). The uppermost part of a cycle is composed of red clayey silt with local horizons containing calcareous concretions and which are interpreted as a type of fossil Caliche. Evidence is presented that the formation of single cycle, of an average thickness of ten meters, lasted about 8-10000 years. It would take about 13.5 million years for the deposition of the complete fifteen-kilometer thick sequence. This deduction fits very well with age determination based on syndeositional Nummulites and Assilines. These fossils indicate an age of upper Illerdien (lowermost Eocene) at the base of the Murree Formation (Balakot region) and upper middle Lutetien at Kawal, at a position some two thirds from the base of the profile. In the North, the Murree Formation is therefore much older than it is in the South (Kohat, Potwar) where data suggest a lower Miocene age.

The Karakoram Mountains and the Nanga Parbat Himalaya are one of the most rapidly rising mountain areas in the world with uplift rates in the order of 2 mm/yr. Large-scale regional warping is the most likely form of uplift with the greatest rates around the Nanga Parbat-Haramosh Massif. Only two active faults have been recognised in the Pakistan Karakoram, the Rakhiot and the Misgar valley fault. The Rakhiot fault zone is a neotectonic expression of the rapid uplift centred around the Nanga Parbat syntaxis. Deformation structures in Quaternary and Recent sediments in the Rakhiot area are not produced solely by neotectonic processes but also by processes in the glacial depositional environment and slope related processes. Structures present vary from neotectonic shear zones, folds, thrusts and high-angled faults; glacially produced folds, thrusts, shears and joints; and debris slides bounded by discrete shear zones. The distinction between these structures is vital in making valid neotectonic models for high active mountain belts.

O/43. Owen, L.A. 1991. Mass movement deposits in the Karakoram Mountains and western Himalayas. *Zeitschrift fur geomorphologie* 35, 401-424.

Mass movement is a major process in the valleys of the Karakoram Mountains. Here very long and steep slopes, resulting from tectonically induced fluvial and glacial incision, and intense weathering help induce slope failure. These include rockfalls, avalanche, debris slides and rockslides, creep, rotational slips, debris flows and flowslides. Processes vary in scale from isolated small failures to extensive areas of complex movements. The most common and important processes are debris flows and flowslides. Sediments deposited by these processes are highly variable, consisting dominantly of coarse diamictos. These form a major component of the valley fills which frequently exceed several hundreds of metres in thickness. Distinctions between the different debris deposits and landforms are difficult to make in the Karakoram Mountains because of the polygenetic origin of many of these mass movement sediments.

However, distinctions can be made using their sedimentary characteristics including: sedimentary structures, microstructures, grain size characteristics, clay mineralogy, degree of compaction and petrology. Correct identification of sediments is particularly important in reconstructing accurate Quaternary histories and palaeoenvironments. Many of these deposits have originated from the resedimentation of glacial and non-glacial diamictos by debris flow and flowslide processes. A major phase of resedimentation occurred soon after the last major glaciation in the Karakoram Mountains (c. 50,000 years B.P.) resulting in thick deposits and creating many of the present valley landforms, such as fans and terraces. These processes are important in reconstructing the evolution of the Karakoram landscape.

O/46. Owen, L.A. 1996b. Quaternary lacustrine deposits in a high energy semi-arid mountain environment, Karakoram Mountains, northern Pakistan. Journal of Quaternary Science, 11, 461-483.

Impressive Quaternary lacustrine deposits are present as terrace remnants throughout the Karakoram Mountains, northern Pakistan. They are mainly the result of damming of drainage systems during glacial advances or by catastrophic mass movement deposits. The longevity of most lakes is relatively short, in the order of years to tens of years, but sedimentation rates are extremely high as a consequence of the high sediment loads within the rivers. This results in deposits that frequently exceed 10 m in thickness. The sediments comprise dominantly planar bedded, massive and, less commonly, planar laminated, silts, comprising detrital quartz, feldspar, mica, calcite, chlorite and illite. A facies model for lacustrine sedimentation in a high energy semi-arid high mountain region is presented, using case studies from a glacially dammed palaeolake (Glacial Lake Gilgit) and a debris-flow dammed palaeolake (Lake Serat). The rapid deposition and absence of organic material restricts the usefulness of these lacustrine Sediments as proxies for palaeoenvironmental reconstruction, but they are helpful in reconstructing the former extent of glaciers and illustrating the importance of high-magnitude-low-frequency events, such as landsliding, as formative processes contributing to the evolution of the Karakoram landscape.

The Karakoram glaciers are among the largest outside the polar regions. They are glaciologically complex with thick and steep glaciers of high activity Alpine type. Large quantities of debris are supplied to the surface of the ice by avalanching, with the result that the supraglacial debris path is dominant. Glacial deposits are thus deposited mainly by melt out with an important input from supraglacial sliding. The basal debris zone is relatively thin, and observed lodgement tills rarely exceed a few metres in thickness. Two main types of glaciers can be differentiated based on the landforms in their lower reaches:

1. Ghulkin type, dominated by ice-contact fan landforms;
2. Pasu type, dominated by hummocky moraines and glaciofluvial outwash plains.

Ancient examples of the glacial sediments and landforms and the sedimentary characteristics of these deposits are described. The sedimentary characteristics are used to compare the different types of tills and to compare sediments deposited during the Pleistocene with those of the Holocene.

O/50. Owen, L.A., Derbyshire, E., White, B.J. & Rendell, H., 1992. Loessic silt deposits in the western Himalayas: their sedimentology, genesis and age. *Catena*, 19: 493-509

Loess is abundant in the foreland basins of the Himalayas. However, it is poorly developed within the intermontane basins of the western Himalayas and Karakoram. Selected sections were studied from the Swat Himalaya and the Karakoram Mountains. Fieldwork and sedimentological analysis including grain size, mineralogy and microfabric showed that the loessic sediments have been reworked and some have undergone weak pedogeneses. These silts are not true loess, rather a "loessic colluvium". Thermoluminescence (TL) dates from the loessic sediments in sections from the Swat valley provided younger ages than earlier workers had suggested. This is consistent with reworking of the loess in these areas. It is concluded that care must be taken when using loessic silts for TL in similar mountainous terranes.

O/51. Owen, L.A., Finkel, R.C., Caffee, M.W. & Gualtieri, L., 2001. Timing of multiple late Quaternary glaciations in the Hunza Valley, Karakoram Mountains, northern Pakistan: Defined by cosmogenic radionuclide dating of moraines. *Geological Society of America Bulletin* 114(5), 593-604.

Moraines and associated landforms in the upper Hunza Valley, Karakoram Mountains, northern Pakistan, provide an excellent record of multiple glaciations. During the late Quaternary, glaciers advanced at least eight times. By using ^{10}Be and ^{26}Al surface-exposure dating on moraine boulders and scoured bedrock, we determined the timing of glaciation for four of these glacial advances: ca. 54.7–43.2 ka (Borit Jheel glacial stage), ca. 25.7–21.8 ka (Ghulkin I glacial stage), ca. 18.4–15.3 ka (Ghulkin II glacial stage), and ca. 10.8–9.0 ka (Batura glacial stage). For two of the older advances, the Yunz and Shanoz glacial stages, our data set a limit of >60 ka. Although, at present, the uncertainties in dating make it impossible to describe unequivocally the climate processes controlling glaciations in the Hunza Valley, the results suggest that precipitation changes related to oscillations in the southwest Asian monsoonal system combine with cooling that is broadly associated with Heinrich events to cause glacial advances in this region.

The Indus River is one of the large river systems draining the Himalaya. We report in this paper the major-ion chemistry, Sr and U isotope systematics of the Indus system, particularly its headwaters. The results show that: (1) on an average about a third of the cations in the waters can be from silicate weathering; however, most of the (Ca + Mg) is likely to be from the weathering of carbonates and evaporites; (2) the $^{87}\text{Sr}/^{86}\text{Sr}$ of the waters ranges between 0.7085 and 0.7595, the higher values (> 0.72) are typical of the tributaries draining the Precambrian granite/gneissic terrains. The $^{87}\text{Sr}/^{86}\text{Sr}$ of the Indus main channel, throughout its entire stretch, shows only minor variations, 0.7104–0.7116. The Indus transports $\sim 8.8 \cdot 10^6$ mol Sr to the Arabian Sea annually with a $^{87}\text{Sr}/^{86}\text{Sr}$ of 0.7111 if our results of Sr concentration and $^{87}\text{Sr}/^{86}\text{Sr}$ measured at Thatta can be considered typical of the Indus throughout the year; and (3) the U concentration in the Indus and its tributaries is generally high, 0.37–10.3 $\mu\text{g l}^{-1}$. The source for the high uranium can be the weathering of granites, zones of uranium mineralisation and black shales.

The Indus results when compared with our earlier data on the Ganga-Brahmaputra show that in all these three river systems carbonate weathering is the dominant source of (Ca + Mg) and HCO_3^- and that U concentrations are high. In the case of $^{87}\text{Sr}/^{86}\text{Sr}$, the Indus waters are less radiogenic; however, its tributaries draining the Precambrian granites/gneisses have $^{87}\text{Sr}/^{86}\text{Sr}$ in excess of 0.72, similar to that in the rivers of the Ganga system. The low $^{87}\text{Sr}/^{86}\text{Sr}$ of the Indus, 0.7111, suggests that its contribution to the Sr isotope evolution of oceans since the Cenozoic is less significant than that of the Ganga-Brahmaputra.

A magnetotelluric survey in northern Pakistan contains effects from both 2D and 3D structure. Identification of the effects of the sediments along the Indus River valley using 3D modeling permitted the selection of modes that could be accurately inverted with 2D inversions. The resulting 2D model reveals generally resistive ($> 500 \text{ km}$) upper crust (0–8 km), a more conductive (30–50 km) middle to lower crust (8–40 km), and a resistive ($> 300 \text{ km}$) upper mantle. Shallow crustal ($< 10 \text{ km}$) conductors correlate with a hydrothermally altered fault zone and/or carbonaceous metamorphic rocks near the Raikot fault. A prominent midcrustal conductor located beneath Nanga Parbat is required to fit the data, but its depth, dimensions, and conductivity are poorly constrained by existing data.

P/16. Park, S.K. & Mackie, R.L., 1998. Lack of crustal fluids beneath Nanga Parbat, northern Pakistan: Results from magnetotelluric soundings. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 146.

The Nanga Parbat-Haramosh Massif (NPHM) in the Himalaya of northern Pakistan is a finger of Indian crust extending northward into the Kohistan-Ladakh island arc. Collision between Kohistan and the Indian plate about 55 Ma along the Main Mantle Thrust (MMT) placed plutonic and high-grade metamorphic rocks of Kohistan above the Indian plate. In the past 10 M.y., differential erosion of NPHM has exposed the underlying Indian crust. Recent and rapid denudation has provided a unique glimpse into modern reworking of old continental lithosphere by metamorphic processes and partial melting. As part of a multidisciplinary study of NPHM, a magnetotelluric (MT) study was conducted to determine the distribution of fluids and partial melt in the crust. Mafic partial melts, water-saturated silicic melts, brines and metamorphic or igneous waters, metallic solid phases, and graphite are all capable of increasing the conductivity of the crust and upper mantle.

This MT study was interpreted with both 2-D and 3-D models to account for the complex geology and physiography. North of Nanga Parbat in Kohistan, the upper crust (0-8 km) is generally resistive ($> 500 \text{ ohm-m}$), the middle to lower crust (8-40 km) is generally conductive (30-50 ohm-m), and the upper mantle is again resistive ($> 300 \text{ ohm-m}$). This structure is reminiscent of the typical continental crust in which the generally conductive middle layer reflects fluids trapped in the ductile region of the crust and is similar to the structure seen on the INDEPTH profile of Tibet. Immediately north of Nanga Parbat, the Raikot fault is imaged to depths of 8-10 km as a vertical, tabular conductive body. The high conductivity of the fault is attributed to fluids migrating along the fault zone and to hydrothermal alteration. South of Nanga Parbat, the MT data show a moderately conductive region at midcrustal levels which appears to match a shear zone mapped by geologists. The shear zone is likely conductive because it offers a more porous conduit for fluid migration; hydrothermal alteration is seen in the zone in the eastern end of Rupal Valley.

There is no evidence of conductive bodies beneath the Nanga Parbat peak between Fairy Meadows and Rupal Valley to depths of at least 50 km. The data are matched instead by very high resistivities ($> 5000 \text{ ohm-m}$) indicative of igneous and/or high-grade metamorphic rocks. If magma is present beneath Nanga Parbat, then it must be the result of water-unsaturated partial melting of continental crust (which would result in high resistivities). The simpler interpretation is that magma is not present, however.

Key word: Magnetotelluric studies, structure, MMT, Nanga Parbat, Himalaya.

P/17. Park, S.K. & Mackie, R.L., 2000. Resistive (dry?) lower crust in an active orogen, Nanga Parbat, northern Pakistan. *Tectonophysics* 316, 359-380.

Conductivity models beneath the Nanga Parbat Haramosh Massif (NPHM) derived from magnetotelluric soundings reveal that there is no widespread, interconnected, conductive aqueous fluid to minimum depths of 40 km below sea level. Given the continuing tectonic denudation, young granitic and migmatic bodies indicating partial melt at shallow crustal depths, and active seismicity, this result is surprising in light of similar studies in active tectonic regimes elsewhere. Away from the NPHM, models reveal the usual conductive lower crust. We propose that deep magmatic and metamorphic fluids are produced beneath NPHM in isolated zones but that the active deformation permits their escape through the brittle-ductile transition. A magnetotelluric survey in an area as complicated as Nanga Parbat required the development of methodologies for utilizing standard two-dimensional inversions in a three-dimensional environment. We show here how to identify which parts of the magnetotelluric responses are adequately represented with two-dimensional approximations. Unlike previous efforts, we do not attempt to create a set of generic rules that may be applicable to all geologic environments. Instead, a procedure is outlined that can be tailored to each interpretation. One important result of this work is that magnetotelluric data along a profile can be used to constrain structure off the ends of the profile.

P/18. Parker, N.A., 1968. Lightweight aggregate as a potential industry for Pakistan. US Geological Survey/Geological Survey of Pakistan, (IR) PK-48, 11p.

A common characteristic of growing economics throughout the world is the ever increasing demand for all kinds of construction materials, at which sand, gravel, and crushed stone play a most important part. Increasing sophistication in building, and structural designs, in turn demands more exacting specifications in aggregate (sand, gravel, and crushed stone mixtures) requirements for concrete; furthermore in the construction of large buildings, reduction in weight, through the use of light-weight but strong aggregate, becomes important.

In East Pakistan the topography and geology is such that rock suitable for concrete aggregates is in limited supply. In such areas where the natural material or aggregate are lacking but where clay, shale, and slate are present the development of a light weight (synthetic) aggregate industry offers a mean of supplying much of the demand.

In 1971, a chemist by the name of Hayde found that by heating certain clays, shales and slates to incipient fusion he was able to produce an extremely light weight material of high strength and excellent insulation properties. By reason of patent held by Mr. Hayed, only seven plants were licensed under the "Haydite" patent, and the industry did not develop extensively until the expiration of basic license.

The Baltoro granite is a major late- to post-tectonic plutonic phase of the Karakoram batholith of the northwest Himalaya in northern Pakistan. U-Pb zircon analyses indicate both emplacement at 21.0 ± 0.5 Ma and significant Precambrian zircon inheritance. Dates on monazite are 17-19 Ma and are interpreted to have remained near their closure temperature of about 700 °C for several million years after emplacement, resulting in Pb loss by diffusion. We suggest that the granite was emplaced into rocks which were at high temperature and that they remained so until late Miocene northeast-tilting, rapid uplift and/or tectonic denudation, and cooling.

P/26. Pascoe, E.H., 1919. The early history of the Indus. Brahmaputra and Ganga. *Quarterly Journal of the Geological Society of London* 75, 138-157.

The ideas expressed in this paper are the outcome of a study of the Punjab oil-belt. The principal hypothesis proposed has been advanced simultaneously by Dr. H. G. E. Pilgrim. F.G.S., in a paper still in manuscript, to explain the formation of the Siwalik boulder-conglomerates. That paper will, I hope, soon be published, but I have taken the liberty of following up an interesting point to which Dr. Pilgrim has drawn attention: namely, the frequent V-shaped course of the north-bank tributaries of the Ganges where they leave the belt of Siwalik deposits.

Briefly, the hypotheses that I desire to bring forward may be summarized as follows:—

(i) That in Eocene times a gulf extended from Sind northwards as far as Afghanistan, and thence curved eastwards and south-eastwards through Kohat and the Punjab to the neighbourhood of Naini Tal.

(ii) That this gulf gave place to a great river, the head-waters of which consisted of the portion of the Brahmaputra flowing through Assam. This river flowed westwards and north-westwards along the foot of the Himalaya as far as the North-West Punjab, where it turned southwards along a line not very different from that of the modern Indus, and emptied itself into the Arabian Sea. In other words, the Assam Brahmaputra was once the head- waters of the Indus.

(iii) That two separate rivers or two branches of the same river, debouching into the Bay of Bengal, cut back and beheaded this old Indus, the

P/32. Pascoe, E.H., 1964. A manual of the Geology of India and Burma. Volume 3, 1345-2130. Government of India Press, Calcutta.

Pascoe presented in three comprehensive volumes all the information available on the geology, stratigraphy, structure, mineral deposits and other geological aspects of sub-continental India and Burma. This is the most comprehensive compilation of the geological account of the region and a very important contribution to our knowledge. The book is a must for all libraries interested in the geology of the sub-continent. vol. 1 deals with the Pre-Cambrian rocks, vol. ii with the Palaeozoic and Mesozoic, vol. iii with the Deccan Traps, the Tertiary, the Pleistocene, and Recent deposits, and vol. iv will contain geographical and general indexes. The preface to the first volume is given in the following, and sets up the format and contents of the three volumes published. The fourth was not published.

This is the first volume of an important work which, when completed, will take first place as a standard book of reference on the geology of India and Burma. The complete *Manual* will consist of four volumes : vol. 1 deals with the Pre-Cambrian rocks, vol. ii with the Palaeozoic and Mesozoic, vol. iii with the Deccan Traps, the Tertiary, the Pleistocene, and Recent deposits, and vol. iv will contain geographical and general indexes. The second edition, revised by R. D. Oldham, was published in 1893, and when the late Sir Edwin Pascoe began the work of preparing a new edition in 1933, he was faced with a formidable task. The first three volumes were ready for the printers in 1939, and more than half the book had been set up in type when Japan entered the war. Owing to the extreme shortage of paper in India at that time, it was impossible to print off even the first volume, and the type, weighing 2 tons, was broken up and melted for munitions. Thus faced with a long delay in publication, the author once more revised the text of volumes i and ii, and was still engaged on volume iii when he was taken seriously ill in 1949. The first two chapters give an admirable summary of the physical geography and geological history of India and Burma, which every student of regional geology could read with profit. Throughout this account the reader cannot fail to be impressed by the contrast between the rapidity of recent geological changes in the mountains and the almost ageless

permanence of the main features in the peninsula. Thus we read of violent movements in the front ranges of the Himalaya during Pleistocene times, and of the probability that important river captures have taken place during historical times. In contrast with this we are told that the Aravalli range (folded and uplifted before the end of the Pre-Cambrian) is in fact a remnant of one of the most important watersheds of Peninsular India; it may well have been from this watershed, for instance, that some of the rivers flowed in which the rich coal deposits accumulated. The remaining eleven chapters are devoted to the Pre-Cambrian rocks, which are divided into two major groups, separated by a profound unconformity. The author wisely makes no attempt to extend smaller divisions to the whole of India, but describes in full detail the sequences found locally in the various parts of his territory, and then gives his opinions on their correlation. It would be futile to attempt to review the wealth of information contained in these chapters, whose value can only be appreciated when they are appealed to for reference. Nevertheless, a few subjects of outstanding interest deserve special mention. There is an excellent description of the remarkable manganiferous schists of the Dharwar System, with their valuable ore-bodies in the Central Provinces, and the discussion of the banded iron ores also contains much of general interest, particularly in the comparison with similar rocks in the Pre-Cambrian of other continents. The author has taken great pains to present a logical and well-argued account of the post-Dharwar intrusions, and to give a strictly impartial and balanced discussion of the charnockites and their associated problems. The attempt to sort out the complicated relationships of the various masses of gneiss, both to each other and to the adjacent schists, clears away a good deal of confusion and misconception about the chronology of the pre-Purana rocks of Peninsular India.

In the absence of Cambrian fossils, it is not easy to determine the age of some of the unaltered but unfossiliferous sediments in relation to the beginning of the Palaeozoic era. There is reason for regarding the bulk of the Purana group, which includes the Cuddapah and Delhi systems, as being Pre-Palaeozoic in age, and this conclusion is supported by such evidence as is available from radioactive minerals. The Vindhyan System, on the other hand, contains rocks unlike any known before the Cambrian either in India or elsewhere, and the author removes the Vindhyan from the Purana and refers it, with some doubt, to the earliest Palaeozoic. In his preface the author points out that the *Manual* is to be regarded as a work of reference rather than as a students' textbook, and the treatment of the Pre-Cambrian rocks in this volume is fully in keeping with this purpose. The information is so detailed, indeed, that the book may well prove to be of considerable service to local geologists in India, as the author intended. It is pleasantly written, and notwithstanding the wealth of local detail, is far from being heavy reading; but without its index it is by no means easy to use, and we must hope that the appearance of volume iv will not be unduly delayed. The price is extremely reasonable when compared with that of books of a similar calibre which have been published recently. It is perhaps a pity that a work of such scholarship and distinction, destined to face many years of constant use, could not have been given a more attractive format and a more robust binding; most of the copies seen by the reviewer had already suffered damage before reaching their destination in this country. But these are trifling matters: it is a cause of great satisfaction that Sir Edwin Pascoe's edition of the *Manual* is at last being published. For many years to come it will remain as a fitting memorial not only to the author himself, but also to the whole staff of the Geological Survey of India, with their long record of devoted service and distinguished achievement during the period which has now come to an end.

The second edition of this well-known and useful book has been considerably revised and improved. While the author keeps, for the most part, to the well-tried methods given in the previous edition, he is careful to point out improvements or alternative methods which have been devised during the past twelve years. In the chapter on Normal Methods for Silicate Rocks more attention is given to methods of determining ferrous iron, lithium, chromium, and vanadium, while new sections on phosphate rocks and on the determination of free and combined silica appear in the Notes on Technological Applications. The chapter on Special Methods has much enlarged sections on determination of ferrous iron in refractory silicates, and of manganese, with new sections on the direct determination of sodium or potassium, the determination of minute quantities of nickel, and on micro- and semi-micro- methods of analysis. It is a pity that no mention is made of the polarograph or of the flame photometer as these are likely to be increasingly used in silicate analysis in the future. The chapter on Errors is enlarged and made more valuable, and the final chapters on Occurrence of the Various Elements and on Computations as a Check on the Accuracy of Chemical Analyses have been virtually rewritten. Incidentally, the statement on page 258 that Al occurs surrounded by four oxygens in the structures of minerals is very misleading. In calculating the structural formulae of minerals, the author advocates the use of molecular weights to two places of decimals and five-figure logarithms, so that the results are accurate to three places of decimals. It is doubtful if the average chemical analysis of a mineral is of a high enough degree of accuracy to give a structural formula accurate to more than two places of decimals. Errors occur in the valency checks given in Tables X (p. 314) and XI (p. 316). In Table X, Si^{+4} should be 7.868, Al^{+3} should be 0.240, Li is shown with two positive charges. In Table XI, Al^{+3} should be 8.292, Ti^{+4} should be 0.356, Mg^{+2} should be 6.216, and Mn^{+2} should be 0.030. The author points out that the kind of valency

check used by him is no check on the accuracy of the chemical analysis of a mineral. But valency checks balancing excess negative charges caused by substitution of metal ions of lower valency than that proper to a group, with excess positive

P/34. Patriat, P. & Attache, J., 1984. India-Eurasia collision chronology and its implications for crustal shortening and driving mechanism of plates. *Nature* 311, 615-621.

The motion of the Indian plate is determined in an absolute frame of reference and compared with the position of the southern margin of Eurasia deduced from palaeomagnetic data in Tibet. The 2,600±900 km of continental crust shortening observed is shown to have occurred in three different episodes: subduction of continental crust, intracontinental thrusting and internal deformation, and lateral extrusion. The detailed chronology of the collision and plate reorganizations in the Indian and Pacific oceans supports the hypothesis that slab-pull is a dominant driving mechanism of plate tectonics.

P/35. Pêcher, A., Giuliani, G., Kausar, A.B., Malik, R.M. & Muntaz, H.R., 2001. Geology of Nanga-Parbat Himalaya in Nangimali ruby deposit area (Azad Kashmir, Pakistan). *Journal of Asian Earth Sciences* 19, p.50.

The Nangimali ruby deposit in the southern part of the Nanga Parbat Himalaya has been investigated through field work, geochemistry, stable and radiogenic isotopes. It outcrops in the Shontar valley in a large north-vergent syncline consisting of high-grade metamorphic gneisses capped by a metasedimentary series dominated by marbles and amphibolites. The ore-body is stratiform. Ruby is found within 0.1 - 2 cm thick shear-veinlets and gash veins cutting dolomitic marbles and carbonate-bearing bands.

The marbles of the Nangimali Formation display restricted ranges in $\delta^{18}\text{O}$ (from 23.6 to 27.6 ‰ relative to SMOW) and in $\delta^{13}\text{C}$ (from - 1.9 to 2.6 ‰ relative to PDB). Fluid infiltration along the shear-zone in the marble has no effect on the isotopic signatures of the carbonates. Fluids are metamorphic and CO_2 is derived from the decarbonation of marbles.

Mass-balance and geochemical analyses suggest that the mobilisation by the fluids of aluminium and chromium in the marbles is sufficient to enable the formation of ruby in the shear-zone. Rubies have been indirectly dated using a stepwise ^{40}Ar - ^{39}Ar laser heating technique on syngenetic phlogopites. The Miocene age records a Neogene cooling in the South of the Nanga Parbat massif and a minimum formation age for ruby of 16 Ma.

P/36. Pêcher, A. & Le Fort, P., 1996. Is Nanga Parbat an active indenter or a passive dome? Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 113-114.

1 – Tectonic interpretation around the Himalaya-Karakoram boundary has consider the present structure, clearly revealed by the geological map (Figure):

Nanga Parbat has the shape of an indenter in the heart of the Himalayan western syntaxis, bending out the “Indus-Tsangpo suture”, i.e. the accepted limit between the Himalaya and the Ladakh-Kohistan island arc; the rectilinear pattern of the southern Karakoram and “Shyok suture”, the traditional limit between the Karakoram and the Ladakh to Kohistan island arc, forms a strong contrast with the Indus-Tsangpo suture; between the two, the green belt of the island arc, made up of the Greenstone complex to the north and the Askore amphibolite to the south, continues without interruption from Ladakh to Kohistan; the two, “sutures” are clearly recent tectonic boundaries that crosscut all previous deformation.

2 – In both the Karakoram and the Himalaya the ductile syn-metamorphic deformation displays recumbent isoclinal folding in amphibolite grade metamorphism as the major structural event.

In the Karakoram, this deformation involves granitoid bodies and marble levels in plurikilometric folds; In the Himalaya, similar structures can be observed although they may be less conspicuous due to the abundance of basement gneissic material. In places, marble horizons draw large scale (kilometric) isoclinal folds; In the Karakoram-Ladakh contact zone, this same style of deformation persists, but the lithological contrast is less obvious. Polygenic conglomerates, with pebbles originating in both units, are highly affected by the syn-metamorphic deformation in greenschist metamorphic grade. The major difference between the Karakoram, north, and Ladakh-Kohistan, south, lies in the rapid, though continuous, decrease in metamorphic grade.

The Himalaya-Kohistan contact is known to be a brittle reverse fault, the Raikot fault (Lawrence et al., 1983; Madin et al., 1989). To the north, this fault dies out in the upper Darchan valley, and does not join the E-W strip of the Greenstone complex. The Himalaya-Ladakh contact is well exposed in the upper Turmik valley and is marked by a ductile shear zone with right-lateral strike-slip, clearly indicated by rotation at map scale of the syn-metamorphic folds (Pognante et al., 1993). This shear-zone in the same Greenstone complex strip. On the right bank of the Chogo Lungma glacier, the northern contact shows no evidence of normal faulting, but, in some places, thrusting of the greenstone complex over the Himalayan gneisses can be observed. Locally, in the Remendok valley, the northern contact is overprinted by a slightly deformed leucotrochilitic body.

3 – Taking into account all the previous observations, it appears that: during the main metamorphic stage, all three units have behaved as a single and continuous crustal piece. The ductile structures are post collisional. These structures do not result from indenting by a Himalayan indenter. In addition, the linearity of the main structures of southern Karakoram cannot be explained without a significantly more extensive Himalayan basement, that is not restricted to Nanga-Parbat indenter, but which probably also underlies Ladakh and Kohistan.

If the present geometry of Nanga-Parbat does not represent that of an indenter, it must result from other mechanisms. One such mechanism is doming in a NW-SE compressive regime with a strong transcurrent component, instead of a frontal collision. Nanga-Parbat from this perspective would correspond to a gneissic dome at crustal scale. Further analysis of its western side may tell whether the dominant regime has more recently rotated to that of transcurrent shortening.

Key words: Tectonics, structure, Nanga Parbat, Himalaya.

P/37. Pêcher, A. & Le Fort, P., 1998. Is the Dobani-Dasu ultramafic lineament an internal suture for Ladakh and Kohistan? Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 147-149.

In Ladakh, the contact between the Greenstone complex and the Askor amphibolite is underlined by a series of isolated pods and masses of serpentinised ultramafics, one of the major ones cutting the Turmik valley at Dasu. The Dasu lineament has been followed eastward into the Komara valley where a kilometer-thick body of metaperidotite is wrapped in a shell of foliated serpentinite, interlayered with chlorite-talc-magnesite schist and albite epidote-tremolite-chlorite rodingite. Westward we have encountered blocks of serpentine in the valley north of Skoyo. Further to the north-west, besides ultrabasic rocks and calc-silicate fels that occur in lower Remendok valley, in a similar structural position, boulders of serpentinized material occur now and then.

In Kohistan, almost exactly symmetrical to the Dasu lenticular stripe across the Himalayan spur, squeezed against the northern end of the Raikot fault, we have discovered a similar stripe of serpentinised ultramafics: the Dobani lineament. Twenty-five kilometers long, it rises from the village of Khaltaro, follows the right (west) bank of the Darchan river, crosses to the north of the Dobani peak (or Bilchar Dobani, 6134 m) in the upper part of the Gutumi glacier, forms a large kilometeric band on the northern side of the Bilchar valley, and finally thins out on the right bank of the Bagrot river between the villages of Datucho and Sinakkar. Further to the west, it does not cross as such the Dyor and Hunza valleys, but leads into the tectonic lineament, that follows the edge of the Bilchar meta-volcano-sedimentary formation. There the two intricated formations could form a tectonic melange.

In Ladakh the metaperidotites are usually antigoritic serpentinites with cumulitic textures, and two generations of olivine (magmatic and metamorphic). In Kohistan the serpentinised peridotites are accompanied by pyroxenites. The Dobani-Dasu ultrabasic lineament separates the island-arc into two units. It is possible to consider these serpentinites as a part of the ophiolitic sole of the island arc as described near Dras (Ladakh, NW India). Thus, the Chalt-Turmik volcanics, with the MKT lineament to the north and the Dasu-Dobani ultramafics to the south, compare well with the Dras volcanics that have tectonic melanges on their northern and southern sides. In our view,

it could mark the limit between the volcano-sedimentary back-arc basin and the island-arc itself that includes peraluminous crustal material of Katchura Gilgit type.

The ultramafics that divide Kohistan and Ladakh in two sub-units are a good marker of the global deformation of the arc. Parallel to the general structural trend, away from the NPHM, they are bent when getting closer to the contact with the Himalayan gneisses. To the east, the bending of the lineament marks and supports the right-lateral movement also evidenced in the Greenstone complex. To the west, the curvature of the Bilchar-Dobani ultramafics would also indicate a right-lateral movement, whereas the movement observed in the mylonitic Himalayan gneiss of the upper Darchan valley, is left-lateral and obviously not of the same age. The two dextral shear zones could represent a meridian vertical slicing of the Himalayan crust that has driven the NPHM doming and the Raikot fault.

Key word: Ultramafics, structure, Dasu, Ladakh, Kohistan, Himalaya.

P/38. Pêcher, A. & Le Fort, P., 1999. Late Miocene tectonic evolution of the Karakoram-Nanga Parbat contact zone (northern Pakistan). In: Macfarlane, A., Sorkhabi, R.B. & Quade, J., (Eds.), Himalaya and Tibet: Mountain root to mountain tops. Geological Society of America, Special Papers 328, 145-158.

In northern Pakistan, the northwestern syntaxis of the Himalaya is marked by the spur of the Nanga Parbat-Haramosh massif, bounded by the Arc formation of Ladakh and Kohistan, and located south of the Karakoram range. The three units are separated by two major tectonic features, corresponding to late reactivation of the southern Indus-Tsangpo suture and northern Shyok suture. Field mapping in the as-yet poorly known Nanga Parbat-Haramosh massif-Karakoram contact zone, together with structural, metamorphic, and geochronological data, has led to new constraints on the interpretation of this key zone, viz.: (1) the backarc belt continues without interruption from Ladakh to Kohistan; (2) the southern Karakoram, the Arc, and the northernmost part of the Nanga Parbat-Haramosh massif display the same recumbent isoclinal folds and related metamorphic schistosity as the major structural event; (3) ductile deformation ended after 6 or 7 Ma; (4) in front of the Nanga Parbat spur, there is no evidence of normal-type faulting, or of Karakoram indentation, either considering the lithological boundaries or the metamorphic fabric; (5) on both sides of the spur, the right-lateral and left-lateral cartographic displacements mainly reflect the late doming of the initial arc-massif contact, a south-directed shear zone. Thus, the three units, east of the Raikot fault, define an east-west-trending broad zone that has thermally and tectonically behaved as a single crustal piece. The northern part of the Nanga Parbat-Haramosh massif can be considered to be a large dome in the westward extension of the Karakoram domes, a line of domes that developed east of the Raikot fault and possibly initiated as a crustal-scale fold system, induced by broad and diffuse northwest-southeast dextral shearing in transpressive regime.

P/39. Peltzer, G. & Tapponnier, P., 1988. Formation and evolution of strike-slip faults, rifts and basins during the India-Asia collision: An experimental approach. *Journal of Geophysical Research* 93, 15085-15117.

The processes which have governed the formation and evolution of large tertiary strike-slip faults during the penetration of India into eastern Asia are investigated by plane strain indentation experiments on layered plasticine models. The results show the influence of boundary conditions as well as that of the internal structure of the plasticine model on the faulting sequence. The ubiquity of strain softening in experimental deformation of a variety of rocks, as well as the widespread occurrence of shear zones in nature, suggest that long-term deformation of the continental lithosphere may also be primarily influenced by the geometry of large faults which rapidly develop with increasing strain. The deformation and faulting sequence observed in the plasticine indentation experiments may thus be compared to collision-induced strike-slip faulting in Asia, particularly to total offsets and rates of movements on the faults. The experiments also illustrate mechanisms for the formation of extension basins near active continental margins.

P/41. Pennington, W.D., 1979. A summary of the field and seismic observations of the Pattan Earthquake, 28th December, 1974. In: Farah, A. & DeJong, K.A. (Eds.), *Geodynamics of Pakistan*. Geological Survey of Pakistan, Quetta, 143-144.

The Pattan earthquake, magnitude 6.0, caused considerable loss of life and damage to property, resulting both from severe ground shaking and from rockfalls. This earthquake is the largest yet observed in the Indus-Kohistan Seismic Zone, west of the western Himalayan syntaxis, where the Himalayan arc terminates. The focal mechanism and aftershock distribution indicate thrusting in a NNE-SSW direction, similar to that which is expected for Himalayan thrusting, but not what would be expected from surface geologic mapping.

P/42. Pennock, E.S., 1988. Structural interpretation of seismic reflection data from the eastern Salt Range and Potwar Plateau, Pakistan. M.S. Thesis, Oregon State University, Corvallis, 55p.

Approximately 1600 km of seismic reflection profiles from the eastern Salt Range and Potwar Plateau (SR/PP) of Pakistan are integrated with available magnetostratigraphic, surface geologic and well data, to categorize structural styles, determine the timing of deformation and estimate the amount of telescoping of the sedimentary cover. The eastern SR/PP is similar to other fold-and-thrust belts underlain by evaporites in that: 1) it is part of a zone of overthrusting that extends considerably farther over the Himalayan foreland than adjacent areas not underlain by evaporites; 2) the overall thrust wedge has a narrow cross-sectional taper; 3) structures verge toward the hinterland as well as toward the foreland; and, 4) fold trends are long and continuous, consisting of tight, salt-cored anticlines separated by broad synclines. Disharmonic folding of the sedimentary section relative to the underlying basement is due to effective decoupling along the intervening salt layer. Subsurface mapping on top of a strongly reflective package of Cambrian to Eocene strata reveals that many surface folds are cored by both foreland- and hinterland-dipping, blind thrusts, and some are fault propagation folds. In some cases, intersecting thrusts result in local triangle zones; other surface folds have a pop-up geometry. The dip of the basement towards the inner part of the fold-and-thrust belt is relatively gentle in the eastern SR/PP (1° - 1.5°) compared to the central SR/PP (2° - 3°). Mechanical considerations demonstrate that, unlike the relatively undeformed central SR/PP, a broad deformational zone has developed in the eastern SR/PP to provide a surface topographic slope necessary to maintain a critical taper of the thrust wedge. Furthermore, previous paleomagnetic studies indicate that deformation across much of the eastern PP preceded tectonic rotation. This implies that individual structural trends developed perpendicular to the transport direction and were then rotated into their current NE-SW alignment in response to ramping over a basement buttress in the central SR/PP. Cross-section balancing indicates that approximately 23.1 km of shortening has occurred across the foreland in the eastern SR/PP since 5.5 Ma, 17.8 km in the last 2.5 Ma. The shortening rate of 7 mm/yr for that time interval is roughly 15% of the 40-50 mm/yr convergence rate between the Indian and Eurasian plates.

P/45. Pervez, M.K., 1987. Geology of a part of Attock-Cherat and Kalachitta Ranges in the vicinity of Nizampur, Pakistan. M.Phil. Thesis, University of Peshawar, 120p.

Rocks of the Attock-Cherat and Kalachitta Range are thoroughly mapped and studied to work-out their structural patterns. The two Ranges are separated by a well-defined Hissartang Thrust. The rocks of the Attock-Cherat Range, of Precambrian to Paleozoic age, consist of sedimentary and meta-sedimentary sequences. Lying unconformably on these are Mesozoic and Tertiary strata. Rocks of the Kalachitta Range in the study area range in age from Jurassic to recent. These are mostly limestone, shales and sandstones. Three main thrust faults (oriented E-W) divide the area into four blocks. The Khairabad thrust mars-off the northern block, the cherat thrust limits the central block and the Hissartang thrust separates the southern block from the Kalachitta range. These thrusts are the splay faults of the MBT, which runs south of the Kalachitta range. The push from north on these thrusts have been the major cause of the deformation of these Ranges. The big synclinalorium in the Kalachitta rocks north of the Indus River is resulted because of the movement on Hissartang thrust. A model is proposed to explain the structural relationship of the rocks of the Attock-Cherat Range, east of Indus River. During the movement along the Hissartang fault a splay fault was cutoff in this area producing a low angle Hissartang back thrust. The rootless patches of Jurassic limestone on Palaeozoic sequence, east of the Indus River, indicate that the Mesozoic strata are thrust over the Paleozoic rocks. Previously, the Hissartang thrust was considered to exist beneath the alluvium of Nizampur and Campbellpur Basins (Yeats and Hussain, 1986). As a result of present work it is relocated just at the southern foot of the Attock-Cherat Range. Similarly, the structural style of the central and southern blocks does not display a homocline system as was suggested by Yeats and Hussain (1986), but is dominantly a south verging overturned folded system.

P/46. Pervez, S., 1985-87. Geology and petrography of Luat-Thod Area, Neelum valley (A.K.) with special emphasis on granites. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 77p.

The project area is a part of Middle Himalayas and covers about 350 sq. km. located between Doarian and Thod in Neelum Valley (Azad Kashmir) at the scale 1: 25,000 of topographic sheet No. 43 F/13, 43 F/14 and 43 J/2 of survey of Pakistan. The studied area comprises of broader lithology of Salkhala formation containing predominantly metapelites, psammites and calcareous material. Various granitic and basic bodies are also outcropping the area. Basic bodies are present as dykes and sills. All the quartzofeldspathic rocks (Granites) of the area are the products of metasomatism (Granitization) and these are possibly the part of Nanga Parbat Haramosh massif. The area is rich in economic rocks and mineral deposits are discussed briefly.

P/51. Petterson, M.G., 1984. The structure, petrology and geochemistry of the Kohistan batholith, Gilgit, Kashmir, N. Pakistan. Ph.D. thesis, Leicester University.

This is perhaps the most detailed study of the Kohistan batholith. In addition to geochemistry and petrology, several phases of magmatism were identified. Careful mapping around Gilgit shows that the batholith there is made up of repeated pulses of granitic plutons. Details of the work are represented in a series of papers in the following.

P/52. Petterson, M.G., Crawford, M.B. & Humayun, M., 1992. Sr, Nd and O Isotope Data from the Kohistan Batholith, N Pakistan: Constraints on the evolution of the Kohistan mantle and crust from 102 Ma to 30 Ma. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, p.70.

The 102 Ma-30 Ma Kohistan batholith forms a major part of the Kohistan arc terrane, N Pakistan. It intruded in three distinct stages which correlate with the existence of Kohistan; (i) as an island arc (102 Ma-85 Ma), (ii) as an Andean-type margin (85 Ma-40 Ma) and (iii) as a collisional zone trapped between the colliding Indian and Eurasian plates. Sr and Nd isotope data are now available for five granitoid plutons from the batholith: the Matum Das (102 Ma), Gilgit (54 Ma), Shirot (40 Ma) plutons and two acid sheet units (Parri and Indus Confluence) dated at 30 Ma. The range of isotope values for these units are: $^{87}\text{Sr}/^{86}\text{Sr}$ 0.7039-0.7052, E^{Sr} -6.8 to 10.36, $^{143}\text{Nd}/^{144}\text{Nd}$ 0.512861-0.512723, E^{Nd} 6.91 to 2.04.

The E^{Sr} and E^{Nd} data for the Matum Das, Gilgit and Shirot plutons plot within the mantle (upper left) quadrant on an $E^{\text{Sr}}-E^{\text{Nd}}$ diagram. The Indus Confluence, and most notably, the Parri acid sheets plot in the upper right quadrant on an $E^{\text{Sr}}-E^{\text{Nd}}$ diagram as they have both positive E^{Nd} and E^{Sr} values. The full data set follows a temporal evolutionary trend: E^{Sr} increases and E^{Nd} decreases with time. These data imply a mantle or primitive arc crust origin for the Matum Das, Gilgit and Shirot granitoids, with contamination of mantle derived magmas by immature Kohistan crust becoming more important with time. The Parri acid sheets are probably the result of upper crustal anatexis; possibly being melt derivatives of a thick meta-sedimentary sequence which crops out between Gilgit and Jaglot.

O18 data have recently been produced for a wide range of plutonic units including three of the above (Gilgit, Shirot and Parri). O18 values vary between 6‰ and 9.2‰; the leucogranites having O18 values >8‰; the bulk of the gabbro-diorites have O18 values between 6.5‰ and 7.7‰, whilst three gabbro-diorites have O^{18} values of 6-6.5‰. The high O18 for the leucogranites is consistent with a crustal melt origin. Munir Humayun interprets the O^{18} values of 6.8‰-7.7‰ for granitoids as indicating a primitive arc crustal melt origin, with the Nd and Sr isotope compositions being inherited from their precursor mantle source. MGP and MBC feel that the granitoid data could also be explained by subduction zone fluids ± subducted sediment elevating the O^{18} of a mantle source, followed by limited assimilation of high O^{18} crust.

P/53. Petterson, M.G., Crawford, M.B. & Windley, B.F., 1993. Petrogenetic implications of neodymium isotope data from the Kohistan batholith, North Pakistan. *Journal of the Geological Society of London* 150, 125-129.

Neodymium data are presented for five granitoid (trondhjemite, granite and leucogranite) plutonic units from the Kohistan batholith aged 102 Ma to 29 Ma. These have present day $^{143}\text{Nd}/^{144}\text{Nd}$ ratios of between 0.512980 and 0.512734, calculated initial $^{143}\text{Nd}/^{144}\text{Nd}$ ratios of between 0.512861 and 0.512705 and Nd values of between 6.91 and 2.04. There is a decrease in ϵNd with time which is inversely correlative with a similar increase in ϵSr .

Three plutonic units (Matum Das, Gilgit and Shirot) formed from a source enriched in Sm and depleted in Rb or radiogenic Sr relative to bulk earth, whilst a fourth unit (the Indus Confluence acid sheets), is only slightly enriched in radiogenic Sr. These four units define a temporal trend from the least evolved Matum Das pluton to the most evolved Indus Confluence acid sheets. This trend was produced as a result of subducting oceanic sediment or seawater-altered oceanic crust which melted or dehydrated and increasingly modified the isotopic composition of an original mantle protolith situated above the subducting plate. The data preclude any significant input to the magmatism from ancient crust. New data presented here, together with other published data, indicate an immature metavolcanic crustal source for the Matum Das pluton, and a plutonic basement crustal source for the Indus Confluence acid sheets. These crustally derived units retain a mantle isotopic signature indicating that the geochemical signature of Kohistan evolved by remobilization of recently formed arc crust in addition to new inputs of mantle-derived magma.

A fifth plutonic unit (the Parri acid sheets) shows a clear compositional break from the other units, being significantly enriched in radiogenic Sr and Nd with respect to bulk earth. The source to the Parri acid sheets is interpreted as metasedimentary rocks with a high Rb/Sr ratio and a crustal residence time of c. 70 Ma.

P/54. Petterson, M.G. & Windley, B.F., 1985. Rb-Sr dating of the Kohistan arc-batholith in the Trans-Himalaya of N. Pakistan, and tectonic implications. *Earth and Planetary Science Letters* 74, 45-57.

The Kohistan arc-batholith in northern Pakistan is situated between the Indus Suture and the Northern Suture. It belongs to the Trans-Himalayan belt which continues eastwards as the Ladakh arc-batholith in northwest India and the Gangdese batholith in southern Tibet. In Kohistan the island arc consists (upward sequence) of the Chilas stratiform complex of norites, noritic gabbros and chromite-layered dunites which formed in the sub-arc magma chamber, plutons of tonalite and diorite, one of which has a Rb-Sr isochron age of 102 ± 12 Ma, the Chalt volcanics of basaltic tholeiites succeeded by andesites to rhyolites, and the Yasin Group sediments which formed in overlying intra-arc basins and which contain Albian-Aptian faunas. All these rocks were deformed by major fold structures which are correlated with the formation of the Northern Suture. NE-SW trending basic Jutal-Nomal dykes (north of Gilgit) cross-cut all the above structures and have a $^{39}\text{Ar}/^{40}\text{Ar}$ hornblende age of 75 Ma. Thus the Northern Suture must have formed in the period 102 ± 12 to 75 Ma. With the island arc attached to the Eurasian plate, further northward subduction of the Tethyan plate gave rise to an Andean-type batholith, two plutons of which have Rb-Sr isochron ages of 54 ± 4 Ma and 40 ± 6 Ma. The Dir-Utror Group of calc-alkaline lavas (and sediments with Eocene fossils) are remnants of the volcanic cover of the Andean-type batholith. We suggest that late Cretaceous blueschists formed during subduction under the active continental margin, and that continental collision and formation of the Indus Suture was in the Eocene. The batholith was intruded by layered aplite-pegmatite sheets at 34 ± 14 Ma and 29 ± 8 Ma (Rb-Sr ages) in post-collisional times. The $^{87}\text{Sr}/^{86}\text{Sr}$ initial ratios of all the dated rocks range between 0.7039 and 0.7052.

P/55. Petterson, M.G. & Windley, B.F., 1986. Petrology and geochemical evolution of the Kohistan-arc batholith, Gilgit, North Pakistan. *Geological Bulletin Peshawar University*, 19, 121-149.

The Kohistan batholith is the most north-westerly part of the Trans-Himalayan batholith which extend some 2700 kms from near Lhasa in the east to Pakistan in the west. Detailed framework of an area of 2500 km², centered on the town of Gilgit, had shown that the batholith had evolved in the three distinct stages:

An early bi-modal sequence of high-K gabbroic diorites and high SiO₂, low K tonalites, which have been deformed and folded, together with associated meta-volcanic and -sedimentary country rocks around a major syncline (the Jaglot Syncline). These early plutonics, which comprise 1/3 of the batholith, have a penetrative, gneissose fabric

which is orientated parallel to the major structural trends of the area. These rocks formed in an island arc environment. An undeformed sequence of basic dykes, gabbros, diorites, granodiorites and granites which cut the structure associated with the Jaglot Syncline. These rocks formed in an Andean-type continental margin.

Extensive swarms of layered aplite-pegmatite sheets, which formed after the terminal collision between India and Eurasia. Some of these rocks formed by crustal melting. Five rock units have yielded Rb-Sr whole rock isochron ages. These are 102 ± 12 Ma for an early, deformed tonalite, 54 ± 4 Ma and 40 ± 6 Ma for two second stage granitoids, and 34 ± 14 Ma and 29 ± 8 Ma for two late leucogranitic sheets.

Even the least evolved gabbros of stages 1 and 2 are enriched in Rb, K Ba, Sr, P and LREE relative to Nb, Zr, Ti, Y and HREE. With fractionation LFS/HFS, K/Na and LREE/HREE element ratios increase and the batholith displays a calc-alkaline trend with respect to Mg, Fe, Na and K. The main magmatic trend of the batholith can be explained by the fractionation of amphibole-plagioclase-magnetite $\pm$ clinopyroxene in the basic-intermediate rocks and plagioclase-K-feldspar-biotite and magnetite in the acid rocks. Zircon, apatite, and sphene were important accessory minerals. Low $^{87}\text{Sr}/^{86}\text{Sr}$ initial ratios (0.7039-0.7052) suggest that the ultimate source for the majority of the plutonics was the upper mantle. However the stage 1 tonalite and some of the stage 3 leucogranites were formed by partial melting.

P/56. Petterson, M.G. & Windley, B.F., 1991. Changing source region of magmas and crustal growth in the Trans-Himalayas: evidence from the Chalt volcanics and Kohistan Batholith, Kohistan, northern Pakistan. *Earth and Planetary Science Letters* 102, 326-341.

The Kohistan batholith and Chalt volcanics form a major part of the Kohistan island arc terrane in northern Pakistan. They record some 70–80 Ma of magmatism within the northwestern Himalayan orogen; the Chalt volcanics are Albian-Aptian (mid-Cretaceous), and currently available Rb-Sr age data for the batholith indicate an intrusive age span of 102 to 30 Ma. The volcanics are composed of medium-K, calc-alkaline andesites and low-K, high-Mg, tholeiites, some of which have boninitic and basaltic komatiitic chemistry. Three intrusive stages are recognised in the batholith: (1) (110–90 Ma) comprises low-K trondhjemitic and medium-high-K calc-alkaline gabbro-diorites with associated hornblende cumulates; (2) (85–40 Ma) comprises low-high-K, calc-alkaline gabbro-diorites (with hornblende cumulates, granodiorites and granites; and (3) (circa 30 Ma) comprises biotite $\pm$ muscovite $\pm$ garnet leucogranites. $^{87}\text{Sr}/^{86}\text{Sr}$ for the batholith range between 0.7039 and 0.7052.

Four magmatic source regions (Sce 1–Sce 4) have been identified. Sce 1 is a variably metasomatised mantle wedge situated above an active subduction zone during stages 1 and 2. Sce 2 is a harzburgite depleted with respect to major elements and incompatibles, whilst retaining “subduction-related” trace element ratios. Sce 2 melted during stage 1 within a fore-arc position during the subduction of young, hot oceanic crust to provide the necessary extra thermal input for harzburgite anatexis. Melts from Sce 2 produced the high-Mg tholeiitic volcanics. Sce 3 melted during stage 1 to produce the low-K trondhjemitic, and it is envisaged as incompatible element-depleted primitive arc crust with a similar composition to the depleted Chalt volcanics. Sce 4 melted at 30 Ma during stage 3 as India underthrust Eurasia: frictional heating and dehydration of the Indian plate caused crustal anatexis within the deep Kohistan arc and these melts formed the stage 3 leucogranites. The low $^{87}\text{Sr}/^{86}\text{Sr}$ initial ratios for the great bulk (> 95%) of the batholith indicate that it represents a major juvenile addition to the continental crust. This conclusion has important implications for crustal growth theories of island arc accretion and batholith underplating.

Key word: Magmatism, orogeny, crustal growth, Chalt volcanics, Kohistan batholith.

P/57. Petterson, M.G. & Windley, B.F., 1992. Field relations, geochemistry and petrogenesis of the Cretaceous basaltic Jutal dykes, Kohistan, northern Pakistan. *Journal of the Geological Society of London* 149, 107-114.

A 75 Ma Cretaceous suite of low-medium-K basalt to basaltic andesite dykes intrudes the Kohistan terrane between Jutal and Chalt, Gilgit area, northern Pakistan. Orientational data suggest they intruded in response to NW–SE to N–S tension. The dykes cut the Albian–Aptian Chalt Volcanic Group and the 102 Ma Matum Das trondhjemitic pluton. They cut the fold structures and penetrative fabrics associated with the collision between Kohistan and Eurasia and thus constrain the age of formation of the Northern Suture. The dykes define two groups on the basis of trace element geochemistry and geochemical trends. A depleted D-type group has low concentrations of incompatible elements (2–8 x primordial mantle) and (Ce/Yb)_N ratios <1. An enriched E-type group is relatively enriched in both

low field strength and light Rare Earth elements and exhibits increasing incompatible element concentrations with increasing Zr. Trace element and field data suggest that the dykes are genetically linked and formed by partial melting of a mantle source which has been metasomatized by subduction-related processes. Models involving (i) different degrees of partial melting (ii) two-stage partial melting and (iii) partial melting of a heterogeneous source are considered.

Key word: Geochemistry, petrogenesis, basalt dykes, Cretaceous, Kohistan.

P/58. Petterson, M.G., Windley, B.F. & Luff, I.W., 1991. The Chalt volcanics, Kohistan, Pakistan, high-Mg tholeiitic and low-Mg calc-alkaline volcanism in a Cretaceous Island Arc. *Physics and Chemistry of the Earth* 17, 19-30.

The Chalt Volcanic Group, together with the Drosh volcanics form a thin, arcuate, 300 km long, linear belt cropping out to the south of the Northern Suture, Kohistan, N Pakistan. The upper volcanics are interbedded with sediments which have yielded fossils of Albian-Aptian age. Contemporaneous volcanics occur to the south of the Shyok Suture in Ladakh (the Dras volcanics). The Chalt volcanics comprise a sequence of lavas and volcanoclastics which vary in composition from high-Mg basalt and andesite to low-Mg basalt, andesite and rhyolite. They have undergone greenschist to lower amphibolite grade metamorphism. Geochemically the volcanics are divisible into two groups: (1) High-Mg basalts and andesites, some of which approximate basaltic komatiite and boninite in composition. This group has high MgO, Ni and Cr contents, low concentrations of incompatible trace elements such as Ce, Y, Zr, Ti, Rb and K, and it displays tholeiitic trends with fractionation; the closest modern analogues are boninites and low-K tholeiites. (2) Basalts, andesites and rhyolites which exhibit typical calc-alkaline trends with fractionation. These are enriched in low field strength elements (e.g. Rb, Ba, Sr, K) and LREE (e.g. Ce) relative to high field strength elements and HREE (e.g. Zr, Ti, Y). Concentrations of incompatible elements increase with fractionation; their closest modern analogues are medium-K calc-alkaline andesites. These two magma groups have separate mantle sources, an MgO-rich incompatible element depleted residual harzburgite type source for the high-Mg volcanics, and a mantle source enriched in LFS elements relative to HFS elements for the calc-alkaline volcanics. Evidence from the volcanics indicates lateral variations in magmatism and source composition along the Cretaceous Kohistan island arc. The arc was situated between the Indian and Eurasian plates, and it was produced as a consequence of north-directed subduction of Tethys.

Key word: Volcanism, Chalt volcanics, Kohistan, Himalaya.

P/59. Petterson, M.G., Windley, B.F. & Sullivan, M., 1990. A petrological, chronological, structural and geochemical review of Kohistan batholith and its relationship to regional tectonics. *Physics and Chemistry of the Earth* 17, 47-70.

The Kohistan batholith located west of Nanga Parbat, is situated entirely within the Kohistan terrane between the Northern and Indus sutures and is the most northwesterly component of the Trans-Himalayan batholith. It is an ENE-SSW elongate 300 km x 60 km body consisting of many plutons which intrude Chalt volcanics to the north and a meta-sedimentary sequence to the south. The batholith can be subdivided into three stages on the basis of field relations, petrology and geochronology: stage-I; an early bi-modal sequence of deformed gabbro-diorites and trondhjemitic, stage-II; gabbro-diorites, granodiorites and granites, with the magmatism becoming more acidic with time, and stage-III; dense swarms of leucogranitic sheets. Two magmatic types are recognised in stage-I and the early part of stage-II which are a low-K tholeiitic and a medium high-K calc-alkaline, respectively. Only the latter continued throughout the later part of stage-II and stage-III. Radiometric ages constrain the three magmatic stages to the following periods; stage-I, pre-Northern Suture which formed between 102 and 85 Ma; stage-II, post-Northern Suture and 40 Ma with most basic magmatism at 85-60 Ma and acid magmatism at 60-40 Ma; stage-III, ca. 30 Ma.

The three magmatic stages of the batholith correlate with the tectonic development of Kohistan arc, i.e. stage-I plutons formed in an island arc, stage-II plutons formed at an Andean-type margin, and late stage II plutons and stage-III plutons during syn- to post-Himalayan collision times (Kohistan collided with India at ca. 45 Ma). Sr isotope data suggest that stage-I and II plutons are mantle-derived, and that stage-III plutons are possible melts of the Kohistan crust. K-Ar and Ar-Ar mineral ages show that uplift rates in Kohistan are greatest within the Nanga Parbat syntaxis and that the Kohistan crust to the north and west of Gilgit cooled through the blocking temperature for biotite (330 °C) at about 60-40 Ma.

P/60. Phillips, W.M., Quade, J., Shroder, J.F. Jr. & Poths, J., 1996. Cosmogenic ^3He in garnet, Raikot valley, Nanga Parbat, Northwestern Himalaya, Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 116.

Garnet is common in gneisses and leucogranites exposed in the Raikot Valley where previous workers have documented high-grade metamorphism, partial melting, high strain, and rapid denudation during the Quaternary. With the ultimate goal of quantifying Nanga Parbat denudation rates and glacial histories, we are evaluating garnet for ^3He surface exposure dating. For successful ^3He work, garnet must a) retain cosmogenic ^3He ; b) possess low concentrations of ^3He inherited from pre-metamorphic surface exposure or mantle sources; and c) contain low Li, U, and Th in order for nucleogenic ^3He and radiogenic ^3He to be minimized.

Preliminary results from a road cut with $\sim 3\text{m}$ shielding from cosmic rays and from a weathered erratic are promising. Helium inherited during garnet growth (crush data) has radiogenic $^3\text{He}/^4\text{He}$ ratios, and variable but low ^3He and ^4He concentrations. Nucleogenic and/or muonic ^3He (shielded sample fusion data) is $<2\%$ of cosmogenic ^3He gained during long exposure (erratic fusion data). Using estimates of the ^3He production rate⁴ in $\text{Al}_{76}\text{Py}_{15}\text{Sp}_{5}\text{Gr}_4$, the glacial erratic sample has an exposure age of $55.1 \pm 4.1 \text{ ka}$. This is a minimum age due to shielding by heavy winter snow and possible (probably minor) erosion of the boulder.

P/62. Picard, C., Kausar, A.B., Amossê, J., & Rahim, S., 1998. The Kohistan arc, northern Pakistan: an example of PGE and PGM distribution in convergence zones. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 149-151.

Latest studies on the distribution of PGE indicate that the highest absolute abundances of PGE concentrations are generally associated with chromitite and nickel sulphide occurrences in large ultramafic-mafic layered intrusions (Stillwater and Bushveld) or in greenstone belts of komatiitic affinity. Most of them are related to distensive tectonic regime or mantle plume activity. The Kohistan arc, northern Pakistan has several discontinuous and elongated ultramafic and mafic bodies that formed at the base of an immature intra-oceanic island arc in response to northward-directed subduction of neo-Tethys ocean lithosphere during Late Jurassic and Cretaceous. Each-either contain or have the potential for PGE mineralization.

Massive chromitite occurs in lenses and pods in dunite of Jijal complex and reach 2 to 3 meters thickness and 50 meters strike length. No chromite assemblages of large concentrations (1-2 vol.%) are known in ultramafic-mafic rocks from Thak Gah and Sapat areas. In the last two complexes, chromitite and Cr-rich spinel is the most common accessory phase which occur as low-grade disseminations (dunite and pyroxenite) as well as in layers (mm scale) in dunite. Jijal complex has also primary pyrrhotite, chalcopyrite, pentlandite, bornite and pyrite and they are sparsely distributed in the different cyclic units of this complex. Surprisingly, no megascopically visible sulphide phase has been found in Thak Gah and Sapat complexes.

The whole-rock abundance PGE + Au data from Cr-rich, Cr-poor, sulphide-rich and silicate rocks of Thak Gah ultramafic-mafic complex, Chilas; Sapat ultramafic-mafic complex, Kaghan valley; and Jijal ultramafic-mafic complex were determined to know the primary distribution of PGE in these arc-related rocks and their behaviour during normal igneous processes. Thak Gah complex mostly composed of layered dunite, pyroxenite, anorthosite, troctolite and gabbro covers an area as large as 5 sq. km, east of Chilas. The complex, interpreted as intruded in the Chilas gabbro-dioritic complex (Khan et al., 1989), displays restricted range of total PGE contents (7.71 to 33.54 ppb) and exhibits positive slope ($\text{Pd}/\text{Ir}=3.95$ to 50.33). The abundances of total PGE range from 13.13 to 33.54 ppb

in dunites; 7.71 to 13.10 ppb in pyroxenites; 6.44 to 15.74 ppb in layered gabbro and 9.04 to 20.45 ppb in gabbro norite. No PGE enrichment zone has been found in this complex.

The Sapat complex along with Jijal complex form a closely spaced group to the south of Kohistan arc and extends NE-SW immediately to the north of MMT. The complex occupies over 13 km² and has ultramafic sequence at the base and gabbro sequence at the top. Dunite (total PGE= 13.72 to 31.02 ppb) shows a strong Ir (1.93 to 4.06 ppb), Ru (4.12 to 8.29 ppb) enrichment and slight impoverishment in Rh, Pd and Pt resulting flat to slightly negative Pd/Ir ratio (1.31 to 0.36). Clinopyroxenite shows abundant concentration of PGE, ranging from 48.95 to 57.87 ppb, and exhibits extremely steep positive patterns (Pd/Ir=12.46 to 146.76). Layered gabbro has low total PGE concentration of 12.66 ppb and less steep positive pattern (Pd/Ir=10.13) as compared to clinopyroxenite. These data suggest that silicate melt feeding Thak Gah and Sapat complexes were carrying appreciable levels of PGE and Au.

The Jijal complex, northern Pakistan, is a 150 km² body of dunites, olivine clinopyroxenites, websterites, garnet websterites and garnet gabbro, resting tectonically over the gneissic basement of the Indian plate. Both the ultramafic and mafic phases contain minor amounts of base metal sulphides and chromites with which the platinum group elements (PGE) are associated. The abundances of PGE range from 9 to 86 ppb in olivine clinopyroxenites; 13 to 54 ppb in websterites; 17 to 54 ppb in dunites; 9 to 41 ppb in garnet clinopyroxenites and 9 to 27 ppb in garnet gabbro. Several PGE enriched horizons occurred through the series: 1) chromite- rich levels (1a to 1d) moderately enriched in Ir+Ru+Rh in lower dunites; 2) two disseminated sulphide bearing pyroxenites levels (2a and 2b) with strong concentrations of Ir-Rh-Ru-Pd-Pt, Cu and Ni (Σ Y.PGE = 345 and 1417 ppb); and 3) one disseminated sulphide bearing garnet gabbro horizon (3) with moderate Pt-Pd concentrations (Σ PGE 196 ppb) in upper part of the complex. The mineralogy of Pd- and Pt-bearing platinum group minerals (PGM) appears to be commonly associated with sulphide-bearing as intercumulus sulphides. The PGM's include merenskyite, temagamite and melonite. In addition Miller et al. (1991) have reported atheneite, tetraauricupride, electrum and hessite from the same complex. No PGE bearing phase was recognized in the chromite bearing levels.

Mantle normalized PGE profiles from the chromite-rich dunite present a sawtooth appearance with low Pt - Pd and high Ir, Ru, Rh which may be related to early ferrochromite crystallization correlative with high oxygen fugacity (Amoss & Allibert, 1993). However, most of the ultramafic and mafic samples show fractionated mantle normalized PGE patterns with relatively high (Pd/Ir)_n. These ratios mainly result from melt and fractionation processes. Pt and Pd were extracted during partial melting, and concentrated in the silicate melt whereas Ir and Ru were remained in the residual mantle. Crystallization of chromite and, to a lesser extent, olivine will further deplete the Ir and Ru in melt and any rock that subsequently forms from this fractionated magma will have more steeper positive slopes than the original liquids (i. e. higher Pd/Ir ratio).

P/63. Picard, C., Rolland, Y. & Pêcher, A., 1998. The Masherbrum greenstone unit: transported arc or ophiolitic suture? Geological Bulletin, University of Peshawar 31. Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 151-153.

During summer 1997, field work has been conducted in Hushe, Thalle, and Skoro valleys (NE Pakistan). Main aim of this campaign was the study of volcanic rocks throughout the suture zone. In the northern part of this zone, a narrow strip of basic rocks, the Panmah ultramafic unit, has been interpreted as an ophiolite in an intra - Karakoram Mesozoic suture (Searle et al., 1989). Thus, it seems important to compare these basic rocks with the Shyok suture zone volcanic rocks. Our observations of this unit, on both sides of the Masherbrum glacier (see Figure 1B) have shown numerous imbricated scales, viz: ultrabasites of harzburgitic composition (cartoon 3, Figure 1B), gabbros locally flaserised and doleritic dykes (1). Lavas and greywackes (2). These lithological associations suggest some ophiolitic affinities compatible with the interpretation of an oceanic crust relict.

Structurally, the basic rocks are separated from crinoid bearing limestones (5, Fig. 1A-B) by a folded tectonic contact (4, Fig. 1B). Both the basic and the sedimentary units are metamorphosed in the greenschist facies and lie on the Hushe gneiss unit, metamorphosed in the amphibolite facies. This metamorphic contrast and the structural relations show that the basic + metasedimentary units form a klippe on the Hushe gneiss. Preliminary geochemical data (major elements, REE) suggest an arc signature. The basic rocks of the Masherbrum area could possibly be related to the Kohistan-Ladakh volcanics, located 30 km southwestwards, on the south side of the MKT.

P/76. Pilbeam, D., Behrensmeyer, A.K., Barry, J. & Shah, S.M.I., 1979. Miocene sediments and faunas of Pakistan. *Postilla* 179, 1-45.

Five field seasons of work on the Siwalik sediments of Northern Pakistan have greatly expanded the knowledge of these Miocene sediments and their vertebrate faunas. Six long stratigraphic sections on the north limb of the Soan synclinerium near the town of Khaur were measured. These columns, the longest of which is over 3000 m provide the stratigraphic framework for the paleontological studies and give a detailed description of the lithological sequences in the Khaur region. The formational units of previous workers are poorly defined and of little practical value for biostratigraphy or chronostratigraphy. Three major lithological facies are recognized: a blue-gray sand facies; a buff sand facies; and a silt/clay facies. Intensive paleomagnetic sampling allows a provisional correlation to the La Brecque magnetic time scale. The paleomagnetic sampling also defined a series of isochrons, 1 of which was followed laterally along a 30 km-long belt of outcrop. Certain lithological horizons also may be reliable chronostratigraphic markers. Fossils are usually found only in the buff sands or their laterally equivalent fine-grained floodplain and levee deposits. Three types of fossil localities are recognized based on the characters of the fossil assemblages and the sediments. Localities in channel-related deposits were formed as composite events averaged over time and space, and therefore provide information suitable for paleoecological reconstructions. On the basis of appearances of key species a series of 11 biostratigraphic zones are provisionally defined. These span the sequence from the Lower Siwaliks to the base of the Upper Siwaliks. The faunas of the 3 lowest zones show similarities to the Asteracian faunas of Europe and to the East African middle Miocene faunas. Zones 4-8 appear to be a period of faunal endemism although there are some resemblances to European and Asian faunas.

As this account does not have an abstract, the first few paras are taken for ready reference.

Mr. W. K. Edwards, Keeper of the Geological department of the British Museum, and Dr. A. T. Hopwood have very kindly invited me to study a small collection of vertebrate fossils which was presented to the Museum by Mr. E.S. Pinfold, of the Attock Oil Company. They were originally discovered by him in the Lower Khirthar series, south of Fort Munro in Dera Ghazi Khan district, on the right bank of the Indus. Better preserved specimens were collected by Mr. T. G. B. Davies and other geologists in three sites on the southern edge of the kala Chitta Range, in the Attock district of the Punjab, which runs almost from Rawal Pindi to the Indus River. These last lie near the top of the Lower Charat series, at a horizon which is believed to be identical with that of the first-named locally. The Lower Chharat series is now correlated, on the basis both of the stratigraphy and of the foraminiferal fauna, on the one hand with the Lower Khirthar series of Sind, Baluchistan, and the North-West Frontier Province, and on the other hand with the Lower Lutetian stage of the Eocene of Europe. Although remains are extremely fragmented, and, indeed for the most part generally indeterminable, yet an interest attaches to them beyond what such fragment would ordinarily possess, because, they include the first land mammals of Eocene age which have been found in India proper, and are of an even earlier age than those which for several years have been known to occur in the Pongaung series (probably Ludian) of Pakokku, Burma.

The fossils were collected from the following localities. A brief list of the specimens which each has yielded is added, while full descriptions of such of them as merit it will be found in the body of the paper.

1. Lammidhan, north west of Basal and 1-1/2 miles due west of Ganda kas village (lat. 33 38' 15"; long. 72 11' 20") on India topographical survey sheet no. 43 c/2, from the Planorbis Freshwater Beds of the Lower chharat stage, which is considered by Nuttall 1926, p.121), Lt. Col. L.M. Davies, and E.S. Pinfold to be the equivalent of the Lower Khirthar stage of other parts of India, and probably of Lower Lutetian age, contrary to the opinion formerly expressed by L.M. Davies (1926, 1927) and by Cotter (1933, pp 74, 95).

P/94. Pinet, C. & Jaupart, C., 1987. A thermal model for the distribution in space and time of the Himalayan granites. *Earth and Planetary Science Letters* 84, 87-99.

In southern Tibet, crustal thickening due to the India-Asia collision has led to the formation of two granite belts. One is located at the southern edge of the accretionary wedge of Tethyan sedimentary rocks, close to the contact with basement gneisses of the Tibetan slab. The other is found within the wedge itself, close to the Kangmar thrust trace. Available ages suggest that the granites appeared first in the southern belt and then in the Kangmar belt. This sequence seems to violate the chronology of thrusting. Another feature of the Himalayas is that melting started only about 20 Ma after the onset of thickening, which is much less than the thermal time constant of thick crust. We give a thermal model, based on the assumption of conductive heat transfer, which explains these features. The model relies on the geometry of a sedimentary accretionary wedge bounded by low-angle thrust faults and on the existence of a thermal conductivity contrast between old basement and young sedimentary rocks. The wedge of sedimentary rocks acts as an insulating cap and its southern edge heats up along the contact with basement rocks. On a horizontal cross-section, there is a temperature maximum along this southern edge, which explains why melting starts there. The early thermal evolution is sensitive to local conditions and granites first appear in the vicinity of the most radiogenic parts of the basement. The distribution of granites in space and time is seemingly random, reflecting different melting events in different radiogenic environments in the heterogeneous basement. This model predicts a relationship between radioactivity and age which is compatible with available data. The results emphasize that there are large horizontal temperature variations across a thickened region and that granite ages are not related simply to the timing of tectonic phases.

P/96. Pinfold, E.S., 1918b. Conditions governing the occurrence of oil in the Punjab. *Journal of the Asiatic Society of Bengal, New Series* 14, 173-184.

The oil-springs of the Punjab are so numerous and prolific that they must have been known and used from very early times. A bibliography of the references to them up to 1891 is given as an appendix to a paper by Holland in the *Records of the Geological Survey of India*, volume xxiv, page 96. As far back as 1869 the Punjab Government made its first attempt to drill for oil, and a boring was put down by Fenner, of the P.W.D., at Jafar about five miles west of Fatehjang. There are no oil springs at Jafar and the geological evidence is unfavorable. The boring proved a failure, but this did not discourage the oil authorities and in the early seventies an expert, F. W. Lyman, was commissioned to examine and report on all the then known oil localities. His results and recommendations were published in a long report dated 1879. I have been unable to find any record of what borings were put down on Lyman's recommendations; some wells were drilled at Chharat, five miles northwest of Fatehjang, and others, possibly at Jaba in the Salt Range. The Chharat bores yielded some oil, but the venture was a failure commercially.

In 1890 a more ambitious attempt to develop the oil localities was made by a syndicate in which the Townsend brothers had the main interest. Wells were drilled by Canadians at Sudkal, near Fatehjang, at Jaba, and at Alugud in the Trans-Indus Salt Range. Some of these wells were carried down to over 700 feet; small quantities of oil were obtained at each locality, but the project was eventually abandoned. Still another failure has to be recorded. In 1912 Indolex Syndicate imported a Swiss geologist, Professor Preisswerk, under the direction of the Austrian oil authority, professor Zuber of Lemberg. A well was drilled on a closely compressed limestone anticline near Golra junction during cold season of 1913-14. The well was carried to about 1000 feet but obtained only a few gallons of oil.

P/105. Pirzada, A.A., Azhar, A.M. & Nasimuddin, 1997. Lithofacies variations in Nagri Formation across southwest Potwar Plateau. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, 31-33.

Numerous surface radioactive anomalies at different stratigraphic levels in sandstones of Nagri Formation of Southwestern Potwar Plateau, along with other favorable factors for its uranium potential i.e. source, mobilization and trapping, was the prime motive behind the present study. To achieve this objective, four geological sections covering the whole thickness of Nagri Formation were studied. From NW to SE, these sections are Daud Khel,

Dhok Zamah, Dhok Miani and Thatla, 57 number of sandstone, clay/siltstone samples were got analyzed to ascertain petrographic composition.

Nagri Formation, an important and extensively outcropping formation of middle Siwaliks of Potwar Plateau has been traditionally presented as a thick sequence of multistoried sandstones of bluish grey color intervened by dull red mudstones and siltstones. However, during the course of present study, significant departures from the stratotype descriptions have been noted in South West Potwar Plateau (SWIPP). These variations are in thickness, geometry, grain size, sand-clay ratio, provenance etc. Nagri formation of south west Potwar represent comparatively finer facies which is evidenced from sand-clay ratio, relatively finer grain size of sandstones, and dominance of clay clast over other types.

Highly variable thickness of total Nagri was observed within a strike distance of about 80 km. From NW to SE, its thickness is 1050 m at Daud Khel, 441m at Dhok Zamah, 593 m at Dhok Miam and 750 m at Jhatla. If no tectonic thinning or thickening is involved (which has not been evidenced), then thickness variations are due to basin configuration of the Potwar foredeep during Nagri time.

Sandstones of Nagri Formation, from bottom to top and from NW to SE, are dominantly lithic arenites with the exception of Dhok Zamah where one sample from Middle Nagri and one sample from Lower Nagri show arkosic composition. The composition of rock fragments indicate that the source rocks of Nagri Formation are predominantly low-grade metamorphics and sedimentary, whereas contribution from igneous and volcanic rocks is very subordinate.

P/106. Pirzada, A.A., Din, N., Rashid, C.M. & Majid, A.A., 1995. Tectonic setting of the Potwar Plateau. Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, 23-24.

Potwar Plateau (PP) is a part of the Sub-Himalayan tectonic zone. It shows partial, differential salt induced decoupling which causes its lesser northward movement than its immediate surroundings. As a result of this underlying salt, PP is not only over spilling southwards but also westwards, onto the Kalabagh thrust, due to uplift and room available.

It is a composite tectonic unit which North Potwar Deformed Zone (NPDZ) and Southeast (SEPP) corner representing independent blocks. There is an interplay of basement and cover tectonics in which, generally, the basement reaction is in the form of faulting and cover reaction is in the form of folding. PP is bounded on three sides by thrusts and on eastern side by strike slip fault. All the boundaries are tectonically controlled.

NPDZ structures are not true thrusts but are shear boundaries between isoclinal folds along which thrusting took place due to continued stress. Soan Syncline is a result of thrusting on Northern and Southern sides of the PP. In East PP the anticlines have resulted from Salt build-up, mainly along basement normal faults, while synclines are undeformed areas between two anticlines, SEPP Corner is a triangular block formed due to transfer of stress, from Salt Range Thrust (SRT), onto Donmli-Diljabba Thrust. Southwest PP is much less deformed than rest of the PP where faulting predominates over folding in extant distribution and intensity.

P/107. Pivnik, D.A., 1988. Magnetostratigraphy and sedimentology of the Hazara intermontane basin, Pakistan. Geological Bulletin, University of Peshawar 21, 85-104.

The Hazara Intermotane Basin (named herein) is nestled within the Hazara Hill Ranges located on the hanging wall of the Main Boundary Thrust. The Havelian Group represents the fill of this basin and consists of unconsolidated silts, sands and gravels. Paleomagnetic investigations of the silts consisted of both thermal and alternating-field demagnetization experiments for nearly all of the sites of the two measured and sampled stratigraphic sections sampled. All sites are normally polarized and correlated with the Brunhes Chron (0.73Ma to present). Sedimentological analysis shows that the Havelian Group was deposited as a sandure, a large, silt-laden plain of glacio-fluvial sediments consisting of fluvial gravels, sands and windblown loess. It is interpreted that this sandur emerged from valleys of the Hills Ranges which contained Alpine-type glaciers in their upstream reaches. Minimum sedimentation rates determined for the Havelain Group range from 0.07 to 0.27 mm/yr, and are remarkably similar to those determined for the Potwar loess (Rendell, 1988). No evidence was found to suggest that the Havelian Group was deposited as a result of tectonic activity in the foredeep.

P/108. Pivnik, D.A. & Johnson, G.D., 1995. Depositional response to Pliocene-Pleistocene foreland partitioning in northwest Pakistan. *Geological Society of America Bulletin* 107, 895-922.

Pliocene–Pleistocene synorogenic deposits of the Upper Siwalik Group in the northwest Pakistan foreland record changes in dispersal patterns, provenance, and sedimentary facies in response to Himalayan contraction. Three depocenters in the northern Pakistan foreland have been studied: the Peshawar and Campbellpore Basins, situated north of the ranges associated with the Main Boundary fault; and the Soan syncline depocenter, situated in the northern Potwar Plateau, south of the Main Boundary fault. In the Peshawar Basin, an early generation of northward-prograding alluvial fans and gravelly braided streams deposited at ca. 3.0 Ma was folded by en echelon pressure ridges bounded by high-angle reverse faults between 1.7 and 1.4 Ma. The alluvial fan and fluvial deposits were entrenched and infilled by a second generation of northward-flowing braid plain deposits. In the Campbellpore Basin, southwestward-directed fluvial and alluvial-fan deposition in response to uplift of the Kawa Ghar hills began at ca. 1.8 Ma. In the Soan syncline depocenter, deposition occurred at ca. 2.0 Ma as southeastward-flowing braided streams emanating from the Khair-i-Murat uplift, and a southwestward-flowing, gravelly, meandering river derived from highlands to the northeast.

Previous stratigraphic and structural interpretations of this part of the Himalayan foreland have included north-dipping, imbricated thrust faults and duplex structures to characterize the deformation patterns in the region. Recently acquired seismic and other geophysical and surficial structural data from the western part of the foreland indicate that the foreland has experienced strike-slip as well as contractile deformation. The structures that controlled depositional patterns of the Upper Siwalik Group are localized uplifts bounded by high-angle reverse faults and not regional thrust faults. The pattern of Pliocene–Pleistocene uplift and resultant deposition across the foreland does not indicate a progression of deformation in either the foreland or hinterland directions, typical of fold-and-thrust belts.

Key word: Depositional environments, Pliocene, Pleistocene, Siwaliks.

P/109. Pivnik, D.A. & Khan, M.J., 1996. Transition from foreland- to piggyback-basin deposition, Plio-Pleistocene Upper Siwalik Group, Shinghar Range, NW Pakistan. *Sedimentology* 43, 631-646.

Plio-Pleistocene synorogenic deposits of the Upper Siwalik Group in the Shinghar Range (Trans-Indus Salt Ranges) of north-western Pakistan record the transition from foreland-basin to piggyback-basin deposition on the hangingwall of the Salt Range thrust. The Siwalik and Upper Siwalik Groups are over 4 km thick in the Shinghar Range. The lower 3 km consists of the Miocene Siwalik Group, which was deposited by a south-flowing foreland trunk stream, the palaeo-Indus River. The upper 1.5 km consists of the Upper Siwalik Group, which is herein divided into three members. The lowest member includes deposits of the south-flowing palaeo-Indus River and is distinguished from the underlying Siwalik Group by the first appearance of conglomerate. The transition from the lower member to the middle member is interpreted as recording uplift on the Salt Range thrust. As the Salt Range thrust was active, the palaeo-Indus River was bifurcated to the east and west around the embryonic Shinghar Range and overbank and lacustrine deposition occurred, represented by the middle member. When the Shinghar Range achieved significant topography, the upper member was deposited by streams transporting gravel and sand that flowed north and west out of the range and into a piggyback basin that formed on the hangingwall of the Salt Range thrust. New and previously published palaeomagnetic stratigraphy and fission-track ages from volcanoclastic deposits within the Upper Siwalik Group provide tight constraints on the chronology of sedimentary-facies transitions and timing of uplift of the Shinghar Range. The integration of sedimentological and geochronological data indicates that motion on the Salt Range thrust and repositioning of the Indus River began at 1.0 Ma.

P/110. Pivnik, D.A., Qayyum, M., Lawrence, R.D. & Beck, R.A., 1997. The edges of the Himalayan Suture, western Pakistan and Myanmar. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 189-190.

The western and eastern edges of the Himalayan suture, located in western Pakistan and western Myanmar respectively, are complexly deformed zones that have experienced multiple phases and styles of deformation and sedimentation. These include ophiolite emplacement, subduction, strike-slip faulting, compressional faulting, and flysch- and molasse-type deposition. The two edges of the suture are in many ways geological mirror images, but also have contrasting histories and resultant structural geometries. Western Myanmar has not experienced the intense collisional deformation that western Pakistan has, thus may serve as an analogue for the depositional and tectonic evolution of the western edge of the suture.

The western edge of the Himalayan suture, in western Pakistan and eastern Afghanistan, consists of, from hinterland to foreland: a plate bounding strike-slip fault (Chaman Fault); a deformed Tertiary sedimentary basin (Katawaz Basin); ophiolites; a belt of intensely deformed “melange” deposited in a foredeep (Kahi Melange); a major transpressional fault (Zhob Fault); telescoped Indian continental-margin deposits (Sulaiman Range); and an undeformed foreland basin (Indus Plain). The most recent interpretations of the structural and depositional history of the western edge of the suture involve Late Cretaceous obduction of ophiolites, Paleocene collision of India with Asia (Beck and others, in press), and Miocene to Quaternary compressional and transpressional deformation (Pivnik, 1995). During the Eocene, the Kohat Basin formed as a restricted marine evaporite basin on the formerly stable Indian continental shelf (Pivnik and Wells, 1996). The Katawaz Basin was formed by Eocene-Oligocene transtension, and hosted fluvio-deltaic and marine deposition that took place on transitional crust between the colliding landmasses. The sedimentary rocks in the basin record southward progradation of the paleo-Indus fan and river system, which presumably flowed south from the Himalayas (Qayyum and others, 1996). The course of the Indus shifted eastward to its present position during the Miocene, when northwest India moved past the Kabul block and the Katawaz Basin was crushed.

The eastern edge of the Himalayan suture, in western Myanmar, consists of, from hinterland to foreland; a plate bounding strike-slip fault (Sagaing Fault); a mildly deformed Tertiary sedimentary basin (Central Basin); ophiolites; a belt of “melange” deposited in a foredeep (Indo-Burman Ranges); an oblique subduction zone (Andaman Trench); and an undeformed foredeep basin (Bengal Fan). Although interpretations vary, it is generally recognized that a north-south striking subduction zone was established by the end of the Cretaceous, and that ophiolite obduction took place during the Eocene (Bhattacharjee, 1991; Brunnschweiler, 1966; Duarah and others, 1983; Mitchell, 1993; Sengupta and others, 1990; Srivastava and others, 1978). This, and subsequent deformation, is most likely related to collision of the northeastern edge of the India Plate with the Burma Plate. The Central Basin has hosted fluvio-deltaic and marine deposition throughout the Tertiary, recording southward progradation of the Irrawaddy deltaic and fluvial system. The basin has not been sutured closed, thus the present-day Irrawaddy Delta represents the recent expression in a continuum of deposition. Phases of deformation were distinct in the Central Basin, with extensional deformation occurring in the Miocene and compressional deformation occurring in the Plio-Pleistocene (Pivnik and others, in press).

The main difference between the two edges of the Himalayan suture is that the western edge has experienced intense collisional deformation, and the eastern edge has experienced a combination of collisional deformation, dominant in the north, and extensional deformation, dominant in the south. This has influenced the development and preservation of sedimentary basins and controlled the position of Tertiary volcanic arcs.

Key word: Tectonics, sedimentation, suture, Himalaya, Pakistan, Burma.

P/111. Pivnik, D.A. & Sercombe, W.J., 1992. Out-of-sequence, evaporite-controlled faulting and folding in the Kohat Plateau, NW Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, p.71.

Detailed surface mapping and recently acquired subsurface data in the Kohat Plateau of northwestern Pakistan show complex structural styles created by the overprinting of transpersonal structures on pre-existing compressional structures and the presence of a mid-level shale and evaporate decollement horizon. The Kohat Plateau is roughly divided into two regions; a northwest region (NW) and a southeast region (SE). Surface structural styles in the NW region include doubly-overturned anticlines (shishtaray structures) and synclines involving a lower Eocene through Pleistocene stratigraphic succession. Intensely folded (and locally overturned) with the stratigraphy of the NW region is a relict, southward-verging thrust belt, the Mir Khweli Sar I Thrust Belt (MKSTB), that involves mostly middle Eocene to Miocene aged rocks. What were originally low-angle thrust faults of the MKSTB can be traced for 10's of kms along the limbs of folds with lateral ramps exposed in numerous locations. The SE region of the plateau also contains shishtaray structures, however, many of these have had either their southern or northern limbs faulted

out along a lower Eocene shale and gypsum decollement, presumably in the latest stages of fault-propagation folding. Recent structural models of fault-propagation folds with boundary layers similar to gypsum have produced structures very much like those seen in the SE region. The MKSTB is not present in the SE region, and evaporate-floored thrusts are not present in the NW region. The absence of gypsum in the NW region is believed to have limited the propagation of faults, leaving unfaulted detachment folds exposed at the surface.

Newly acquired subsurface data from the Kohat Plateau indicate that previous models of duplex formation and typical foreland thrusting applied to adjacent areas do not apply to this section of the foreland. Instead, steeply dipping strata at depths of over 10,000 ft, steeply dipping faults that become shallow near the surface forming flower structures, and large vertical I displacements across faults suggest transpressional rather than purely compressional deformation. The near-surface, shallow thrusts form flats in lower Eocene shales resulting in detachment folds in the NW region. Localized ramps in lower Eocene gypsum and limestone allow the faults to surface in the SE region. Since low-angle thrusts of the MKSTB have been folded with the rest of the structures in the Kohat Plateau, an out-of-phase sequence of deformation is proposed, which involves the formation of a thrust belt (MKSTB) and subsequent deformation of this thrust belt by younger transpression-related folding and faulting. Based upon sedimentary-facies changes, compositional changes and unconformities within chronologically-constrained molasse deposits in and adjacent to the Kohat Plateau, it is believed that the transpressional phase of deformation occurred from approximately 2.6 to 1.8Mya, while the earlier formation of the MKSTB probably occurred between 3 and 8Mya.

P/113. Pivnik, D.A. & Wells, N.A., 1996. The transition from Tethys to the Himalaya as recorded in northwest Pakistan. *Geological Society of America Bulletin* 108, 1295-1313.

Early Cenozoic sedimentary rocks exposed in the Kohat Plateau of northwestern Pakistan record tectonic closure of the Tethys sea and development of a restricted marine basin that formed during Himalayan collision between India, Asia, and a series of microplates. In the Paleocene, initial subsidence of the basin was caused by the downward deflection of the Indian plate in response to loading of the Asian plate. The western margin of the early Eocene basin was dominated by deposition of shale, sandstone, and conglomerate derived from microplates located to the north and west of the Indian continental margin. The eastern margin of the basin was a carbonate shelf and sabkha flat. Salt deposition occurred subaqueously in the central parts of the basin. In the late early Eocene, redbeds derived from the northwest were deposited by a fluvial and/or deltaic system. This influx of clastic sediments marks the earliest record of terrestrial foreland-basin deposition in northwest Pakistan. During the middle Eocene, the basin was reflooded and a carbonate shelf developed. Relative sea-level rise may reflect subsidence of the Indian plate in response to continued crustal loading in the Himalayan suture zone. Uplift and erosion occurred between the late Eocene and Miocene, possibly related to a peripheral bulge south of the Himalayan suture zone. The main phase of Himalayan foreland-basin fluvial deposition began in the Miocene. Renewed uplift related to final collision of India and Afghanistan during the Pliocene is recorded by a thick sequence of conglomerate in the western Kohat Plateau. Correlation with Eocene sedimentary rocks from southern Pakistan to northern India delineates the depositional systems that developed as the Tethys sea closed during Himalayan convergence.

P/114. Pognante, U., 1991. Different P-T-t paths along the High Himalayan Crystallines: constraints on the formation and distribution of Miocene leucogranites. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Auris, France, 65-66.

On the ground of previous studies of the P-T metamorphic conditions and of new data emerged recently on the High Himalayan Crystalline (HHC), this paper suggest that different P-T-t paths exist not only in N-S cross sections, as

usually described, but also along the belt from western to eastern Himalayas. In the Kaghan nappe of northern Pakistan, the P-T-t path with an early (M1) eclogite-facies metamorphism ($P > 13$ kbar, $T = 650 \pm 50^\circ\text{C}$; Pognante and Spencer, in prep.) and a later exhumation at decreasing temperatures (Greco, 1989), are typical of subducted and collided tectonic sheets with low initial heat supply which were uplifted very rapidly and/or were imbricated with other nappes. In northern Pakistan the minerals give prevalent pre-Miocene cooling ages (Treloar et al. 1989).

East of Pakistan, occasional granulites formed during stage M1 (Burg et al. 1987. Pognante and Lombardo, 1989) instead of eclogites and relatively slow uplift rates are suggested by the prevalent Miocene cooling ages of minerals. The decompression path occurred at uniform or increasing temperatures which produced anatexis and formation of leucogranitic melts during stage M2 (e.g. Caby et al., 1983; Staubli, 1989; Pognante et al., 1990;) $P = 4-7$ kbar, $T = 600-750^\circ\text{C}$). This is typical of rocks involved in a continental event and derived from crust with normal or high initial heat supply (Thompson and England, 1984). The stage M3 produced an incipient retrograde recrystallization in Zaskar. In contrast, anatexis continued during stage M3 in Buthan and Nepal where leucogranite melts were produced also in the cordierite-andalusite field (Brunel and Kienast, 1986; personal observations in the Everest-Makalu area;) $P = 3-5$ Kbar, $T = 600-650^\circ\text{C}$). From the available data along the HHC also emerges that close relations exists between P-T-t paths and distribution and characters of the Miocene crustally derived leucogranites.

Intrusive leucogranite bodies are subordinate in western Himalayas. In the Khagan nappe, the lack of a heating stage during uplift and the crossing of the granite melting field only at medium-/high pressures, all should be responsible for the formation of small amounts of melt.

In Zaskar, extensive anatexis occurred during stage M2 (in the sillimanite $\pm$ kyanite field) but relatively small amounts of melt were produced. In the middle structural levels, collection and ascent may have been partly inhibited by high, viscosity of the dispersed melt which chiefly freezed "insitu" as migmatites and anatectic leucogranites (Pognante, in prep.). In Buthan and Nepal, anatexis continued after stage M2 with the production of more significant amounts of melt. In fact relatively low amounts of H₂O (or micas in case of dehydration melting) are required to produce a granitic melt at the low-pressure conditions of stage M3. Large portions of this melt were extracted and intruded to high structural levels (Le Fort et al., 1987) where they coalesced to form large lens-shaped leucogranite bodies.

P/115. Pognante, U., Benna, P. & Le Fort, P., 1992. High-Pressure metamorphism in the High Himalayan Crystallines of the Stak Valley (North-Eastern Nanga Parbat-Haramosh Syntaxis, Pakistan). Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, p.120.

After the pioneering work of Zanettin (1964), the NE termination of the High Himalayan Crystallines (HHC) in the Haramosh syntaxis has been studied during a geological expedition in the Stak and Turmik valleys (NW Skardu, Pakistan). The eastern boundary of the HHC with the overlying low-grade sedimentary, metabasic and minor ultrabasic rocks of the Ladakh Unit (Le Fort et al., this vol.) is defined by a shear zone dipping toward east.

The HHC consists of paragneiss, orthogneiss, metabasic rocks derived from original dykes and rare calc-silicate rocks and marbles. Leucogranitic dykes are lacking or very rare, while deformed pegmatitic dykes are common at the uppermost structural levels. The rocks of the HHC show rather homogeneous metamorphic assemblages: Qtz-Pl-Or-Bt-Ms-Grt-Ky in the gneisses and Grt-Aug(Xrd < 0.14)-Pl-Rt-Qtz in the metabasic rocks. Except for the later growth of amphiboles (hornblende and actinolite) and biotite in the metabasites, apparently related to H₂O-infiltration along discrete fractures, evidence of decompressional re-equilibrations are rare. Only in the uppermost levels (a few tens of meters below the shear zone) an obvious metamorphic zonation and a pervasive greenschist-facies re-equilibration have been observed. Green amphiboles, albite, clinozoisite porphyroblasts and chlorite are widespread near the upper shear zone.

Grt-Cpx geothermometer and Grt-Pl-Cpx geobarometer in the Grt-granulites of the middle structural levels indicate $T = 700 \pm 50^\circ\text{C}$ at $P = 8-10$ kbar and $T = 600 \pm 80^\circ\text{C}$ at $P = 7-8$ kbar for cores and rims, respectively. Grt-Bt geothermometer and Grt-Pl-Ky geobarometer in the associated gneiss give comparable estimates with $T = 650 \pm 30^\circ\text{C}$ at $P = 9-12$ kbar and $T = 590 \pm 30^\circ\text{C}$ at $P = 7-8$ kbar for cores and rims, respectively. An incipient migmatization with formation of Ky-bearing leucosomes has been observed at these structural levels. In the gneiss of the upper levels, Grt-Bt geothermometry and Grt-Pl-Ky geobarometry give $T = 580 \pm 30^\circ\text{C}$ and $P = 6-9$ kbar.

The lack of a pervasive low-P re-equilibration of the high-P assemblages, the thermobarometric data and the study of garnet zoning profiles, all suggests that exhumation of the HHC occurred at decreasing T and, perhaps, at high rates. The metamorphic zonation with upward I decrease and the pervasive low-T recrystallization near the

extensional shear zone were probably induced by conductive cooling and shearing along the boundary with the “cold” Ladakh Unit.

These data are consistent with the evolution proposed for the eclogitic rocks recently found in the HHC of the upper Kaghan valley (SW Nanga Parbat-Haramosh syntaxis). For the Kaghan eclogites, petrological and geochronological data suggest rapid cooling and exhumation after the eclogitic peak (Tonarini et al., this vol.). In contrast, exhumation paths at increasing T and extensive anatexis with formation of leucogranite plutons characterize the HHC in eastern Himalayas (e.g. Pognante and Benna, this vol.).

P/116. Pognante, U., Benna, P. & Le Fort, P., 1993. High-pressure metamorphism in the High-Himalayan crystalines of the Stak valley, northeastern Nanga Parbat-Haramosh syntaxis, Pakistan Himalaya. In: Treloar, P.J. & Searle, M.P. (Eds.), *Himalayan Tectonics*. Geological Society, London, Special Publications 74, 161-172.

The High Himalayan Crystallines (HHC) from the little-known NE termination of the Nanga Parbat-Haramosh syntaxis (Stak and upper Turmik valleys, Pakistan) consist of kyanite-bearing gneiss with minor garnet-granulite and garnet-amphibolite. The HHC underwent a Himalayan metamorphism with a peak at high pressure (8–13 kbar) and high temperature (650–700° C). During exhumation the HHC rocks followed a rapid exhumation path at high temperature with little or no medium to low pressure re-equilibration. These lines of evidence, combined with geochronological and petrological data from Eocene eclogites recently found in the Kaghan nappe, indicate that, after subduction and high to very high pressure metamorphism, part of the HHC from northern Pakistan underwent very rapid cooling and exhumation. By contrast, exhumation along paths of increasing temperature are recorded by the HHC from regions located east of Pakistan (e.g. Nepal). These differences along strike in the HHC suggest that, during the Eocene collision between India and Eurasia, subduction and exhumation occurred at higher rates in northwestern than in central-eastern Himalaya. Additional information can be obtained in the preceding account.

P/118. Pogue, K.R., DiPietro, J.A., Hughes, S.S., Dilles, J.H., Rahim, S. & Lawrence, R.D., 1992. Late Paleozoic rifting in northern Pakistan. *Tectonics* 11, 871-883.

Late Paleozoic rifting in northern Pakistan was investigated using stratigraphic, structural, geochemical and radiometric analyses of samples and sites in the area. Derived clasts from Jafar Kandao is indicative of extensional tectonics that took place in the Early Carboniferous. The area underwent uplift during the early Permian and Carboniferous periods accompanied by magmatism. The tectonic history in the north parallels that of central Pakistan indicating continuity of the two areas before the Neo-Tethys opened up.

P/119. Pogue, K.R., DiPietro, J.A. & Khattak, W., 1996. Precambrian stratigraphy and the Foreland-Hinterland transition in the Himalayan thrust belt of Northern Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona, USA, 118-119.

Recent investigation in the Indus syntaxis between Tarbela Lake and Besham have revealed critical relationships that permit the reconstruction of the pre-Himalayan configuration of the Precambrian of northern Pakistan which, in general, consists of Proterozoic and Archean (?) crystalline basement rocks overlain by a Proterozoic sedimentary and metasedimentary cover sequence. Both the thickness and metamorphic grade of the cover sequence increase to the north. South of the Main Mantle Thrust (MBT) Upper Proterozoic evaporites (the Salt Range Formation) unconformably overlie Proterozoic gneiss and granite (Gee, 1989). Between the MBT and the Panjal-Khairabad thrust (PKT), the Proterozoic sedimentary cover is represented by siltstone, argillite, slate and limestone of the Hazara Formation and its western equivalent, the Dakhner Formation. Gypsum intervals in the Hazara Formation imply that the Hazara and Salt Range Formations are lateral equivalents. The crystalline basement for the Hazara and Dakhner Formations is not exposed. Between the PKT and Tarbela Lake, the oldest exposed Precambrian rocks are slate and phyllite of the Manki Formation, which are interpreted as the metamorphosed equivalent of the Hazara/Dakhner Formation. The Manki Formation is overlain by stromatolitic limestone of the Shahkot, Utch Khattak, and Shekhai Formations. These limestones thin northward to be replaced by quartzite and argillite of the Tanawal Formation. Near Tarbela Lake, the Tanawal Formation overlies marble and graphitic schist of the Gandaf Formation, which is interpreted as a higher-grade equivalent of the Manki Formation. Northwest of Tarbela Lake, in Swat, higher-grade equivalents of the Tanawal Formation are mapped as the Manglaur Formation. The Gandaf Formation thickens northward in the Indus syntaxis and the deeper levels expose intervals of gneiss and sheared monzonite interpreted as a Proterozoic intrusive complex (the Kotla complex). North of Tarbela Lake, Gandaf Formation lithologies are included in the Karora Formation. In the northern part of the Indus syntaxis, the Karora Formation overlies the Besham Complex. The Besham Complex consists of gneisses that record early Proterozoic metamorphism (Baig, 1990; Baig and Snee, 1989; Treloar and Rex, 1990) that are intruded by granitic rocks and mafic dikes of Proterozoic and Paleozoic age. Near Besham, the unconformity of the Karora Formation with underlying early Proterozoic gneiss of the Besham Complex is marked by a conglomerate. However, at other locations, granitic rocks of the Besham complex intrude the basal part of the Karora Formation, obscuring this unconformity. The entire Precambrian sequence north of Tarbela Lake is extensively intruded by Cambrian granodiorite (the Mansehra and Swat Granites), Late Paleozoic alkaline granitoids (the Ambela intrusive complex), and Permian mafic dikes and sills. Precambrian rocks exposed north of Besham in the Nanga Parbat area are divided between the Iskere Gneiss, Shengus Gneiss, and Haramosh Schist (Madin, 1986). Radiometric dating implies that these units are equivalents of the Besham Complex, Mansehra-type granites, and the Karora Formation (Zeitler and others, 1989).

The relationships outlined above indicate that while the demarcation between basement and cover within the Precambrian can be defined in the southern part of the Pakistan Himalaya, it is obscure to the north. North of the PKT, much of the Precambrian sections were subjected to pre-Himalayan metamorphism and north of Tarbela Lake the entire section is extensively intruded by granitic plutons. Mechanically, these rocks would behave as basement, not as cover. Exposures of Proterozoic gneisses in the Indus syntaxis indicate that the Himalayan basal decollement must have stepped downward into crystalline basement south of Tarbela Lake. Involvement of the basement in thrusting probably first occurs at the PKT, which forms the southern limit of exposures of extensively metamorphosed rocks. The PKT thus forms the boundary between the foreland and hinterland in the Himalayas of Pakistan.

P/121. Pogue, K.R., Hylland, M.D. & Yeats, R.S., 1993. Stratigraphic and structural framework of Himalayan foothills, Northern Pakistan. Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, p.73.

The integration of new paleontological, stratigraphic, and structural data permit analysis of the pre-Himalayan configuration of the Indian plate passive margin in northern Pakistan. Thick sections of Paleozoic metasediments exposed in the Peshawar basin were preserved in half grabens created during Late Paleozoic rifting. Rift highlands

were largely stripped of Paleozoic cover in Swat where Permian metabasalts overlie the Proterozoic Manglaur Formation and in the Attock-Cherat Range where Jurassic and Cretaceous rocks overlie the Proterozoic(?) Dakhner Formation. In the absence of a fossiliferous Paleozoic section, lithologic correlation of Proterozoic units is crucial to retro deformation and estimates of Himalayan shortening. The Proterozoic Salt Range Formation, Hazara (Dakhner) Formation, Manki Formation, Gandaf (Salkhala) Formation, and Karora Group are interpreted as a formerly continuous northward-deepening sequence.

The Khairabad and Nathia Gali-Hissartang faults divide the foothills region into three stratigraphically distinct structural blocks. The northern block consists of the Proterozoic Gandaf and Manki Formations overlain by younger Proterozoic (?) formations and fossiliferous Paleozoic and Mesozoic strata. The metamorphic grade in the northern block gradually increases northward from lower greenschist facies near the Khairabad fault to upper amphibolite facies in central Swat. The central block consists of weakly metamorphosed Proterozoic Hazara (Dakhner) Formation and locally Cambrian and younger Paleozoic(?) strata overlain by Cretaceous and Paleogene marine strata. The southern block consists of unmetamorphosed fossiliferous strata of Triassic to Eocene age. Proterozoic rocks in the subsurface of the southern block are probably transitional between the evaporite dominated Salt Range Formation and the shallow marine clastics of the Hazara (Dakhner) Formation.

P/122. Pogue, K.R., Hylland, M.D., Yeast, R.S., Khattak, W.U. & Hussain, A., 1999. Stratigraphic and structural framework of Himalayan foothills, northern Pakistan. In: Macfarlane, A., Sorkhabi, R.B. & Quade, J. (eds.), *Himalaya and Tibet: Mountain root to mountain tops*. Geological Society of America, Special Papers 328, 257-274.

We present a geological synthesis of northern Pakistan between the Main Boundary and Main Mantle thrusts based on new stratigraphic and structural information. The Hazara (Dakhner) Formation and its metamorphosed equivalents form the basal Proterozoic sedimentary sequence in the Himalayan foothills of northern Pakistan. These units were deformed and metamorphosed prior to the deposition of the overlying Phanerozoic section. The Paleozoic section of the Peshawar basin was preserved in a half graben created during late Paleozoic rifting. Paleozoic rocks were mostly removed from elongate northeast-trending highlands bounding the half graben on the north and south. Whereas the northern highland was submerged by the Late Triassic, large parts of the southern highland remained subaerial until the Middle Jurassic.

The Hissartang fault of the Attock-Cherat Range is interpreted as being continuous with the Nathia Gali fault of Hazara. Both are the first faults north of the Salt Range thrust to expose Proterozoic rocks in their hanging walls. The Panjal fault of Hazara and Khairabad fault of the Attock-Cherat Range are also interpreted to be single continuous faults. The Panjal-Khairabad fault forms the southern limit of rocks that were metamorphosed by the Himalayan collision. Between the Panjal-Khairabad fault and Main Mantle thrust, there is now evidence for a Himalayan fault comparable to the Main Central Thrust of the central Himalaya of India and Nepal. The absence in Pakistan of a Main Central Thrust analog as well as other stratigraphic and structural contrasts precludes the extrapolation of central Himalayan tectonic subdivisions to northern Pakistan.

P/123. Pogue, K.R., Quade, J., Hussain, A., Hinz, N. & Wright, H., 1999. Isotopic constraints on the age of metasedimentary rocks of the Peshawar basin, Pakistan. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 117-118.

The ages of many of the metasedimentary formations exposed in the Himalayan foothills that surround the Peshawar Basin have long been the subject of debate. The Manki, Shahkot, Utch Khattak, Shekhai, Dakhner, Darwaza, and Hissartang Formations and Inzari Limestone of the Attock-Cherat and Gandghar Ranges, the Khyber Limestone and Ali Masjid Formation of the Khyber region, and the Ambar, Tanawal, and Gandaf Formations of the northern Peshawar Basin (fig. 1) have been assigned inferred ages based largely on lithologic correlation. Early workers correlated these rocks with unmetamorphosed Paleozoic and Mesozoic rocks of similar lithology exposed to the south (e.g. Calkins et al., 1975). However, they were not aware of the significance of the intervening Panjal-Khairabad fault, a thrust fault with large displacement that is largely concealed beneath Cenozoic basin fill. Later studies (e.g. Pogue et al., 1992) described stratigraphic contrasts across this fault that are similar to those observed on either side of the Main Central Thrust (MCT) of India and Nepal.

An upper age limit of Early Ordovician on the Ambar Formation and stratigraphically lower units was established through the discovery of fossils in the overlying Misri Banda Quartzite (Pogue et al., 1992) and radiometric dating of the Mansehra Granite (Le Fort et al., 1980) which intrudes the Tanawal Formation. Rocks of the Attock-Cherat and Gandghar Range have been considered to be older than these units by most workers even though stratigraphic relationships are obscured by faulting and basin fill. Most recent workers infer a Proterozoic age for the majority of the rocks of the Gandghar and Attock-Cherat Ranges based on the presence of pronounced unconformities at the base of dated Paleozoic rocks and Late Proterozoic whole rock Rb-Sr model age dates on the Hazara Formation near Abbottabad (Crawford and Davies, 1975). These dates were interpreted by Baig et al., (1988) to represent the provenance age of Hazara Formation clastic material. Outcrops of the Hazara Formation however, are confined to the south side of the Panjal-Khairabad thrust and are never in depositional contact with the inferred Proterozoic rocks of the Gandghar or Attock-Cherat Ranges.

Until recently, it has not been possible to further constrain the ages of the undated Peshawar Basin formations. The only associated igneous rocks are ubiquitous diabase dikes of Permian age and the only fossils reported have been stromatolites. Since many of the undated units are carbonates, we concluded that it might be possible to collect samples suitable for stable strontium isotope analysis. Initial seawater ratios are best preserved in unmetamorphosed pure limestone from each undated formation at its southernmost exposure. All of the sampled formations lie in the hanging wall of the Panjal-Khairabad thrust. The metamorphic grade of rocks within this tectonic block increases dramatically northward.

As expected, many of the samples appeared to have acquired excess ^{87}Sr from silicates during metamorphism and were thus too altered to permit correlation with published seawater curves. However, five samples from the Attock-Cherat and Gandghar Ranges have $^{87}\text{Sr}/^{86}\text{Sr}$ ratios below 0.7065 indicating a minimum age of approximately 750 Ma. A ratio of 0.7074 for one sample from the Inzari Limestone in the southern tectonic block of the Attock-Cherat Range rules out the correlation of this unit with Paleozoic rocks exposed near Nowshera proposed by Pogue et al. (1999). This ratio gives an ambiguous age as it is shared by Late Proterozoic, Late Permian, and Mesozoic age for the Inzari Limestone based on the absence of fossils which are generally common in the Permian and Mesozoic carbonates of northern Pakistan. Samples of the Khyber limestone from near the Khyber Pass road yielded ratios as low as 0.7064 which indicates an unambiguous Proterozoic age.

These new data have important implications for the stratigraphy of northern Pakistan. All rocks stratigraphy below the Shekhai Formation, including the widely exposed Manki Formation, are at least 750 Ma in age. A Proterozoic age is also confirmed for the thick Khyber Limestone which crops out extensively in the Khyber region. Similarities in both age and lithology strongly imply a direct correlation between the Khyber Limestone and the Shahkot, Utch Khattak, and Shekhai Formation of the Attock-Cherat Range. Based on these constraints, the Precambrian/Cambrian boundary must lie somewhere between the Shekhai Formation and the Misri Banda Quartzite within the stratigraphic interval represented by the Ambar and Tanawal formations. The Proterozoic rocks of the Peshawar Basin region are probable correlatives with the upper part of the Vindhyan Supergroup of Peninsular India. The new age information also indicates a correlation of the Peshawar Basin Proterozoic section with recently dated protoliths for the Greater Himalayan sequence exposed in the hanging wall of the MCT in Nepal (Parrish and Hodges, 1996).

P/124. Pogue, K.R., Sak, P.B. & Khattak, W.U., 1995. A Geological Reconnaissance of the Indus Syntaxis, Northern Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

The Indus syntaxis is an elongate north-striking faulted anticlinorium centered in the valley of the Indus River between the northern Gandghar Range and the Besham area. At its southern extremity near Tarbela dam, northeast-striking rocks in the Gandghar Range are separated from northwest-striking rocks across the river by a complex fault zone marked by pervasively sheared and mineralized graphitic schist (figure 1). Calkins (1975) mapped this fault zone as the Darband fault. Recent activity along the Darband fault is indicated by offset Indus River gravels in drill cores and tilted terraces near the dam site (Yeats and Hussain, 1989). The Gandghar Range southeast of the dam site is composed of low-grade Proterozoic metasediments in two structural blocks separated by the Baghdarra fault. The southeastern block exposes the slates and phyllites of the Manki Formation overlain by a thick limestone interval that is divided between the Shahkot, Utch Khattak, and Shekhai Formations. A relatively thin section of Tanawal Formation quartzite overlies the limestone. The oldest rocks in the northwestern block are graphitic schist and minor marble exposed along the Baghdarra fault. The schist has a gradational contact with the overlying Manki Formation. A thick interval of Tanawal Formation quartzite is separated from the underlying Manki Formation by limestone of

the discontinuous Tobrah Formation. North of the Indus River, the oldest rocks are graphitic schist and marble that were mapped by Calkins (1975) as Salkhala Formation. Due to the ambiguity of the term "Salkhala" with regard to lithologic content, unit boundaries, and type section in Kashmir, these rocks will be referred to as Gandaf Formation in this study. The Gandaf Formation is overlain unconformably by the Tanawal Formation. A relatively complete Paleozoic and Mesozoic section overlies the Tanawal Formation in the Peshawar Basin to the west.

North of Tarbela Dam, the strike of rocks on either side of the syntaxis abruptly swings from east-west to north-south near Tarbela Lake. Rocks in the core of the syntaxis exposed along the lake shore consist of quartzofeldspathic gneiss intruded by granite bearing characteristic blue-gray microcline. The upper part of the gneiss contains discontinuous intervals of marble. At many localities the basal gneiss unit and granite is pervasively sheared. Based on its stratigraphic position, grade of metamorphism, and lithologic similarity, the basal unit is correlated with Indian plate basement rocks of the Besham Group. The gneiss passes gradationally into a northward-thinning interval of Gandaf Formation schist and marble. The Gandaf Formation is overlain by an enormous thickness of quartzite and quartz-mica schist of the Tanawal Formation. On the east side of the syntaxis, the Tanawal is intruded by porphyritic granodiorite of the Mansehra Granite. On the west side of the syntaxis, similar rocks belonging to the Ambela Granitic Complex intrude the Tanawal. The belt of granitic rocks on the west side of the syntaxis narrows and becomes increasingly mylonitized to the north. Where the belt crosses the Barundu River it is a 2 km-wide mylonitic gneiss. It is presumed that this narrow belt of granitic rock continues northward to join the Choga granitic gneiss. East of Tarbela Lake, the Tanawal Formation is unconformably overlain by lower Paleozoic dolomite and quartzite in the Sherwan synclinorium. The youngest rocks of the synclinorium are burrowed feldspathic quartzites similar to the Ordovician Misri Banda Quartzite of the Peshawar Basin. West of Tarbela Lake, the Tanawal Formation is overlain by a thick sequence of marble with interbedded amphibolite that may correlate with parts of the Peshawar Basin Paleozoic section.

P/125. Pogue, K.R., Wardlaw, B.R., Harris, A.G. & Hussain, A., 1992. Paleozoic and Mesozoic stratigraphy of the Peshawar basin, Pakistan: Correlations and implications. *Geological Society of America Bulletin* 104, 915-927.

The most complete Paleozoic sequence described from Pakistan is exposed in bedrock inliers and in ranges fringing the eastern Peshawar basin. Interbedded quartzite and argillite of the Precambrian and Cambrian Tanawal Formation is overlain unconformably by the Cambrian(?) Ambar Formation. The Misri Banda Quartzite unconformably overlies the Ambar and contains Ordovician Cruziana ichnofossils. New conodont discoveries restrict the ages of overlying formations as follows: Panjpir Formation, Llandoveryan to Pridolian; Nowshera Formation, Lochkovian to Frasnian; and Jafar Kandao Formation, Kinderhookian to Westphalian. The Karapa Greenschist, consisting of metamorphosed lava flows, separates the Jafar Kandao from Upper Triassic (Carnian) marbles of the Kashala Formation. The Upper Triassic and Jurassic(?) Nikanai Ghar Formation forms the top of the section.

Correlatives to the Peshawar basin stratigraphy are present locally in the Sherwan synclinorium of Hazara and in the Khyber Pass region. The sequence contrasts markedly with the Paleozoic and Mesozoic section exposed south of the Khairabad thrust in the Attock-Cherat Range. This thrust and its northeastern continuation in Hazara north of Abbottabad thus form the boundary in Pakistan between the Lesser Himalayan and Tethyan Himalayan sections, a function performed by the Main Central thrust (MCT) in the central Himalaya of India and Nepal.

The newly dated Carboniferous to Triassic horizons provide the first firm age constraints on the protoliths of the high-grade Swat metasediments. The dating of the metasediments has, in turn, provided age constraints on pre-Himalayan tectonism and associated intrusions. Two major tectonic episodes during the Late(?) Cambrian and Carboniferous produced positive areas north of the Peshawar basin that provided coarse detritus to the Misri Banda Quartzite and Jafar Kandao Formation.

P/127. Porter, S.C., 1970. Quaternary glacial record in Swat Kohistan, West Pakistan. *Geological Society of America Bulletin* 81, 1421-1446.

During three Pleistocene glaciations, large valley glaciers originating at altitudes of 12,000 ft or more occupied the northern part of the Swat River drainage basin and terminated at altitudes as low as 5800 ft. Discrimination and subdivision of the three principal drift sheets is based on various relative-age criteria, including moraine and terrace morphology, weathering characteristics of surface stones, and degree of soil development. The areal and altitudinal distribution of the three drifts, which are designated Laikot (oldest), Gabral, and Kalam, indicates a less extensive glacier cover during each successive glacial age (510 mi², 473 mi², and 430 mi², respectively). Laikot Drift is poorly preserved, strongly weathered, and retains little or no depositional morphology. Moraines and outwash terraces built during the Gabral and Kalam advances are well preserved in two intermont valleys at Kalam and Utror and permit subdivision of the two younger drifts into two and three units, respectively, of lesser stratigraphic rank. Moraines of Gabral age tend to be broad and smooth and have few surface stones, whereas those of Kalam age are bouldery and sharp-crested.

The altitude of the equilibrium-line (ELA) for existing glaciers in Swat Kohistan ranges from 13,000 to 14,000 ft. Assuming accumulation-area ratios of 0.6 ± 0.1 for Pleistocene glaciers in this region, steady-state ELA's during former glaciations are estimated to have been some 3000 to 3600 ft below their present levels.

P/128. Potts, G.J., Treloar, P.J. & Wheeler, J., 1992. Faulting history of the Nanga Parbat Syntaxis, Northern Pakistan; Constraints from modern earthquake data. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, p.73.

Faults and fault rocks have been examined along a 40 km traverse of the Indus gorge through the Nanga Parbat syntaxis of Northern Pakistan. Using field evidence the direction and sense of displacement have been determined for many of these. From this analysis hypothetical fault plane solutions have been derived and compared with published solutions obtained from modern earthquakes. The comparison shows that, of the faults observed in the field, only those, which display reverse oblique-slip displacement, have counterparts that are seismically active. The remaining faults must be considered either aseismic or inactive. Without geodetic information there is no way to test if the faults are moving aseismically and therefore the second possibility is considered in greater detail. Geometrically the "inactive" faults can be grouped into two sets of normal faults (with associated strike-slip faults). Thus it is necessary to consider the possibility that a period of normal faulting preceded the current regime of thrusting in the Nanga Parbat region and that the exhumation of this portion of the Himalayas was achieved by a combination of normal faulting and erosion.

P/130. Powell, C.McA., 1979. A speculative tectonic history of Pakistan and surroundings: Some constraints from the Indian Ocean, In: Farah, A. & DeJong, K.A. (eds.), *Geodynamics of Pakistan*. Geological Survey of Pakistan, Quetta, 5-24.

The position of India relative to Africa since the mid-Cretaceous, recently determined from ocean-floor magnetic-anomaly patterns between India and Madagascar, is traced from 80 my to the present. Three stages can be identified: I) Rapid northward flight of India from Late Cretaceous to Early Eocene; II) Small counterclockwise rotation of India about a close pole during the Eocene, and III) Slower northward movement from the Oligocene to the present. Using geological arguments, the various tectonic elements of the Late Mesozoic and Cenozoic fold belts

from Iran to western Tibet are positioned palinspastically relative to India and Africa at 70, 55, 40 and 20 m.y. before the present. From these reconstructions the history of the major tectonic elements is then traced from the Late Cretaceous to the present.

The tectonic history of the region is modelled in terms of two major convergence zones; a-northern one, the Albon-Hindu Kush convergence zone bordering the southern edge of the stable Eurasian plate, and a southern one, the Zagros Chitral convergence zone, lying at the southern edge of a complex of microcontinents, island arc and ocean-floored basins which is preserved at present as a wide orogenic belt in Iran and Afghanistan. The Eocene counterclockwise rotation of India, following its probable Late Cretaceous or Palaeocene collision with the Zagros-Chitral convergence zone, initiated the north-northeastward trend of the Pakistani fold belt. Continued convergence choked the Zagros-Chitral convergence zone, and a new intra-continental convergence zone on which the Himalayas grew was developed during the Oligocene and Miocene. The Pakistan fold belt is not a simple oroclinal bend of Himalayan structure, but has evolved as a consequence of the shape of the northwestern corner of India. The Salt Range, Tram-Indus Salt Range and Sulaiman fold-festoon structures may all be currently moving on shallow decollements as the Indo - Pakistani shield continues its northward convergence with Eurasia.

P/131. Powell, C.McA. & Coneghan, P.J., 1973. Plate Tectonics and the Himalayas. *Earth and Planetary Science Letters* 20, 1-12.

The Himalayas, commonly taken as the type example of continent-continent collision, have developed in two stages. The first stage involves convergence of the northward-drifting Indian subcontinent with a proto-Tibetan landmass during Late Cretaceous and Palaeocene, with collision before Middle Eocene. The second stage involves formation of a fundamental crustal fracture within the Indian block during Late Eocene and Oligocene, and underthrusting of the Indian subcontinent along this fracture from Miocene to Recent. The present elevated Himalayan mountain chain is not a direct result of the continent-continent collision, but of uplift during underthrusting along the deep crustal fracture.

P/132. Powell, C.McA. & Vernon, R.H., 1979. Growth and rotation history of garnet porphyroblasts with inclusion spirals in a Karakorum schist. *Tectonophysics* 54, 25-43.

Idioblastic garnet porphyroblasts in the metapelitic layers of a Cenozoic garnet-staurolite-biotite-muscovite-plagioclase schist from the Hunza valley, Karakoram Mountains, Pakistan, contain both quartz and graphite inclusion spirals. Growth-zones within the crystals enable reconstruction of the growth and rotation history of each porphyroblast. All the observed microstructural features are adequately accounted for by the model of Schoneveld (1977), which involves growth of the porphyroblast during rotation relative to the matrix. Apparent rotation angles up to 540° have been found. In contrast, xenoblastic to sub-idioblastic garnet porphyroblasts in adjacent metapsammitic layers have only slightly curved inclusion trails.

The quartz spirals appear to have developed by the garnet overgrowing quartz concentrated in "pressure-shadow" domains around the growing porphyroblasts. However, none of the quartz spirals reach the margins of the final crystal outline, and the present "pressure-shadow" domains contain little or no quartz. Furthermore, microprobe analyses of growth-zones within the garnet crystals show a relatively abrupt change in the concentrations of MnO, MgO and FeO across a boundary coinciding approximately with the disappearance of quartz from the inclusion spirals. These changes may be related to a change in metamorphic reactions during garnet growth.

P/138. Priest, J.E., 1962. Snow surveys in West Pakistan. *Pakistan Geographical Review* 17, 43-49.

The ultimate development of water resources in an area requires that all factors of the hydrologic cycle be investigated and evaluated. The Indus Waters Treaty of 1960 envisages the construction of two large dams on the Indus River System. These dams, which are a big step towards the full utilization of the waters of the Indus Basin, will provide storage to assure irrigation and power supplies at all times of the year. The water which will enter these reservoirs comes from two sources: the melting of snow and ice and monsoon rainfall. Melt supplies are most important the first half of each year, and rainfall assumes most importance from the beginning of July. Therefore the irrigation water supply necessary for maturing the rabi crop and for planting the kharif crop is derived from melt water. It is important to determine the comparative magnitude of this melt runoff.

The Jhelum River upstream of the proposed Mangla Dam (See figure 1), in which catchment snow studies have begun, is a good example. Its melt runoff derives primarily from snow fields as opposed to the huge ice fields which feed the Upper Indus River. The snow field in the Jhelum catchment represents at any one time during the spring, a reservoir of about five million acre feet. This is the equivalent of the Mangla first stage storage capacity. To manage intelligently the Mangla reservoir, it is obviously desirable to have knowledge of snow conditions prior to the melt season. By using techniques developed in other snowy regions it may be possible to predict subsequent runoff by knowing the winter and spring snow conditions.

P/139. Prior, D.J., 1985. Uplift evolution of the Hunza valley metasediments. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

In the Hunza Valley, N Pakistan, a suite of metasediments outcrops between the Northern Suture and the Karakoram Batholith. The metasediments sub-divided into two units: a phyllitic melange and a group of interbedded schists and

marbles. Metamorphic grade increases from south to north. The structure is dominated by one pervasive foliation. Parallels to this foliation are numerous shear zones and thrusts.

Porphyroblast textures indicate that the main period of metamorphic growth occurred during foliation development. Development of foliation ceased shortly after or coincidentally with the end of the metamorphic episode. Deformation of the main foliation is rare, except in the shear zones where complex progressive crenulations are developed. Porphyroblasts become deformed without retrogression in the shear zones and syntectonic garnets are sometimes present.

Across one shear zone, staurolite-garnet schists contact metamorphosed chlorite-garnet schists to an andalusite-biotite hornfels. This shear zone juxtaposed material of differing metamorphic grade whilst still close to peak metamorphic conditions. The hornfels assemblage indicates that uplift occurred at this time. This uplift is interpreted as the result of shear zone/thrust movement in lower grade rocks to the south.

Differential uplift, caused by shear zone movement, over the whole belt of metasediments is responsible for the present distribution of metamorphic assemblages. Younger K/Ar ages (4-5 Ma: Rex pers comm) in higher grade rocks result from their excavation from deeper hotter levels than their low grade equivalents which yield ages of c.30Ma (op cit).

Fission track ages (1-2Ma: Zeitler, 1985) of high and low grade rocks are comparable suggesting that there was little differential uplift across the metasediments at this stage. Considerable homogenous uplift recorded by combining zircon, apatite and sphene fission track ages (op cit) was probably all accommodated by movement on the Northern Suture. Uplift evolution is dominated by a complex interaction of deformation and metamorphism. Movement on shear zones and faults is the most important uplift mechanism. Tectonic uplift is an important control on the thermal evolution of this belt.

P/140. Prior, D.J., 1987. Syntectonic porphyroblast growth in phyllites: textures and processes. *Journal of Metamorphic Geology*, 5, 27-39.

Porphyroblast textures in a Karakoram phyllite reveal that porphyroblast growth was syntectonic with respect to a cleavage forming deformation. During and after porphyroblast growth it partitions the deformation such that zones of intensified cleavage are developed which wrap around the porphyroblast whilst the porphyroblast and its strain shadow undergo little deformation. Porphyroblast strain shadows comprise quartz, calcite and feldspar with little mica, and are probably formed by solution transfer during deformation. Unless the deformation is so strongly partitioned that no deformation of the porphyroblasts and their immediate surrounds occurs, inequidimensional porphyroblasts will rotate. Porphyroblasts undergo some dissolution after they have finished growing.

P/144. Pudsey, C.J., 1986. The Northern Suture, Pakistan: Margin of a Cretaceous island arc. *Geological Magazine* 123, 405-423.

The Northern Suture is a fault separating the Cretaceous Kohistan island arc terrain (northwest Himalayas) from Palaeozoic sediments of the Asian Plate to the north. The Kohistan arc includes volcanic and sedimentary rocks (andesitic lavas, tuffs, volcanoclastics, slates and limestones), metamorphosed to greenschist facies and intruded by the two-phase Kohistan Batholith. Asian continental margin sediments are mainly of shelf type, are variably metamorphosed and intruded by the Karakoram Batholith. The Northern Suture is a zone of melange from 150 m to 4 km wide, and contains blocks of volcanic greenstone, limestone, red shale, conglomerate, quartzite and serpentinite in a slate matrix. It has a strong planar fabric; but in many places bedding is preserved in blocks and matrix, and depositional rather than tectonic contacts are seen between the two. The melange is inferred to be an olistostrom largely derived from the Kohistan arc, formed in a small back-arc basin between Kohistan and Asia. Limestone blocks in the melange are dated as Aptian–Albian; post-tectonic intrusions yield radiometric ages from 111 to 62 Ma. The Northern Suture therefore probably formed in the early Late Cretaceous during closure of the back-arc basin. The Tethys ocean lay south of Kohistan, where the Main Mantle Thrust represents the westward continuation of the Indus - Tsangpo Suture.

P/147. Pudsey, C.J. & Maguire, P.K.H., 1986. Magnetic profiles across the northern suture, Kohistan, NW Pakistan. *Geological Bulletin, University of Peshawar* 19, 47-60.

The northern boundary fault (Northern Suture) of the Kohistan island arc terrain separates Cretaceous arc sediments and volcanics from Palaeozoic shelf sediments of the Asian plate. Arc rocks are more magnetised than Asian plate rocks, and ultramafics along the suture are very strongly magnetised. Four magnetic profiles across the suture show the following features:

A gradual north to south decrease in total field of about 15 nT/km. Asian plate sediments are magnetically quiet and in only one profile does the Northern Suture have a magnetic anomaly. Within the arc sequence, anomalies are associated with the sediment / volcanic boundary and large anomalies occur over granodioritic plutons. We have modelled the best-defined anomaly across the arc sediment / volcanic boundary using a cartoon structure consistent with the surface geology.

About 130 sq. km Doarian, Dudhnial, Khoja-Seri area a part of Neelum valley (Azad Kashmir) has been mapped at a scale of 1:50,000. The area is characterized by high relief and v-shaped valleys. The rocks of the area are metamorphic of lower Pre-Cambrian, injected by later intrusions of igneous bodies, granites with some basics. Regional metamorphism and accompanying penetrative deformation post-dates the granite intrusions, because the granite itself is involved in the deformation. Field evidences and laboratory studies favour magnetic origin for the granitic bodies. The area is tectonically highly disturbed being involved in Himalayan orogeny. For petrographic analysis thirty thin sections were studied. Petrogenesis of the rocks of the area is interpreted. Major and minor structures of the area are described. Geological history of the Project area is worked out in comparison with adjoining areas of Punjab Himalayas and northern peninsular India. Economic minerals found in the area are listed.

Q/4. Qadri, S.A.A., 1990. Shallow seismic reflection studies in Latambar area District Bannu (NWFP) to map the weathered and sub-weathered zones and to establish a velocity-lithology relationship. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan.

The object of the survey carried out in Latambar area was to map the low velocity zone in the project area and to establish a velocity-lithology relationship. Seven seismic cross profiles were shot, adopting a reverse shooting technique. In all 27 refraction spreads each with spread length 270m were observed. Time distance graphs were prepared for obtaining true velocities, depths and dip. The results so obtained have been tabulated and presented in the form of Isovelocity and Isopach maps. Integrating the available geological information with the interpreted velocity depth models, a possible relationship between the velocity and lithology has been established. The velocity in the weathered layer ranging from 300- 950 m/sec, indicates the Alluvium/loose weathered material composed of sand, silt and clay. Its thickness varies from 1 -8 meters. The velocity range of sub-weathered layer from 1000- 2400 m/sec exhibits the presence of sandstone with varying amount of clay and degree of compactness. Its thickness ranges from 11- 38 meters. The velocity below the sub-weathered layer picked at some locations ranging from 2400-3800 m/sec shows the presence of Sandstone/Limestone with varying percentage of clay which is relatively more compact.

Q/5. Qaiser, M.A., Akhtar, S.M. & Khan, A.H., 1970. Rodingite from Naranji Sar, Dargai ultramafic complex, West Pakistan. Mineralogical Magazine 37, 735-738.

The rodingite described here (which has been sold locally as 'jade') occurs at Naranji Sar (71° 46' E., 34° 28' N.), a hill south of the village of Mena, about 20 miles west of Dargai (with which it is connected by a jeep road), Malakand. The hill forms part of the northern edge of the Dargai ultramafic complex, consisting

mainly of peridotites such as harzburgite and dunite, the latter enveloping bodies of chromite. In addition, gabbroic rocks are found in places along the northern and eastern contacts with the metasediments (northward dipping phyllites, chlorite schists and, on the north side, talc schists), into which the ultramafic rocks are intruded. Within both the peridotites and gabbros intense serpentinization or chloritization or both is found locally. The rodingite occurs in strings of ovoid lenses, individually up to 2.5 m long and 0.7 m wide, in the altered gabbroic areas, at Naranji Sar trending nearly east-west, to the north and Musa Mena on the east.

Key words: Ultramafics, metasediments, rodingite, metasomatism, Naranji sar, Dargai.

Q/6. Qaiser, M.A., Akhtar, S.M. & Khan, A.H., 1972. Rodingite near Musa Mena, Malakand, West Pakistan. *Journal of Earth Sciences, Leeds* 8, 197-204.

Petrography and geochemistry of a rodingite are given. The rock comprises grossular, idocrase, serpentine, and some altered orthopyroxene.

Key words: Rodingite, ultramafics, metasomatism, Dargai, Malakand.

Q/7. Qaiser, M.A., Alauddin, M., Akhtar, S.M. & Khan, A.H., 1980. Talc-chlorite rocks in Attock slates. *Pakistan Journal of Scientific and Industrial Research* 23, 53-57.

Dark grey to whitish rocks from Attock Cherat, previously described as low grade soapstone, were found to contain talc with a subordinate amount of chlorite (penninite). Other impurities are quartz, calcite, dolomite, magnesite and pyrite. The mineral assemblage has in all probability resulted from magnesium containing solution of hydrothermal origin acting on illite of the slate.

Key words: Talc, clay, slates, Attock-Cherat.

Q/8. Qaiser, M.A., Alauddin, M., Chaudhry, M.A. & Khan, A.H., 1982. Mica from Mego Katz, Loe Shilman, Khyber Agency, North West Frontier Province. *Pakistan Journal of Scientific and Industrial Research* 25, 59-60.

Chemical, X-ray, and differential thermal analysis data are presented for Mica from Mego Katz, Loi Shilman, Khyber Agency. This mica has been identified as phlogopite with subordinate amounts of calcite and quartz. Its application for the manufacture of fire - resistance board, high temperature heat insulation bricks and decorative tiles were also studied.

Key words: Minerals, mica, Loe Shilman, Khyber Agency.

Q/9. Qaiser, M.A., Ali, M.K. & Khan, A.H., 1967. Mineralogy of some asbestos from Northwest Pakistan. *Pakistan Journal of Scientific and Industrial Research* 10, 116-120.

Chemical, X-ray, differential thermal analysis and thermogravimetric data are presented for asbestos from Charsadda Tehsil, Khyber and Mohmand Agencies. Asbestos from Charsadda area was identified to be chrysotile, Khyber and Mohmand minerals were tentatively grouped with tremolite-anthophyllite asbestos. Poor strength of fibers limits their commercial utilisation.

Key words: Mineralogy, asbestos, Charsadda, Khyber Agency, Mohmand Agency.

Q/10. Qaiser, M.A., Ali, M.K. & Khan, A.H., 1968. Study of some indigenous mineral by DTA. *Pakistan Journal of Scientific and Industrial Research* 11, 23-25.

Thermal characteristics of clays, asbestos, talc, bauxite, calcite, magnesite, and dolomite have been presented.

Key words: Minerals, clay, asbestos, magnesite.

Q/11. Qaiser, M.A., Ali, M.K. & Khan, A.H., 1970. Mineralogy of clay deposits near Bagh (33° 45' 30" N, 72° 11' 40" E), Campbellpur District, Rawalpindi Division. Pakistan Journal of Scientific and Industrial Research 12, 483-487.

X-ray, DTA, thermobalance and chemical analyses data have shown that Bagh clays are composed of kaolinite with subordinate amounts of diaspore, haematite and rutile (or anatase). The leaching of alkaline earths from ferruginous carbonate rocks resulted in the formation of brown laterites. Further weathering of laterites under restricted conditions gave rise to bleached clays.

Q/17. Qasim, M., 1990-91. Structure, stratigraphy and petrography of the western limb of the Hazara-Kashmir syntaxis, Garhi Habibullah-Shinkari area, Northern Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 105p.

The Garhi Habibullah-Shinkari area lies along the western limb of the major northwest plunging antiformal structure known as the Hazara-Kashmir syntaxis. The 293 Km² area has been mapped in this study. The western limb of the Hazara-Kashmir syntaxis has been divided into four fault-bounded tectonostratigraphic zones. These are named as the Muzaffarabad-Balakot zone, the Garhi Habibullah-Abbottabad zone, the Panjal zone and the Mansehra zone. These zones belong to different tectonic and stratigraphic provinces which have been juxtaposed during the Himalayan thrusting.

The Muzaffarabad-Balakot zone lies to the east of Main boundary fault. This zone constitutes late Proterozoic to Cenozoic sequence. This sequence is involved in the Muzaffarabad-Balakot southwestward overturned anticline. The late Proterozoic Dogra formation forms the core of the Muzaffarabad-Balakot

anticline. The Dogra formation is unconformably overlain by the early Cambrian Muzaffarabad formation. The Ordovician (?) Yadgar formation disconformably overlies the Muzaffarabad formation. The Yadgar formation is unconformably overlain by the Paleocene-Eocene sequence which includes the Hangu Formation, Lockhart Formation, Patala Formation and Margala Hill Limestone. This was followed by the late Eocene Kuldana and Miocene Murree molasses. The most of the Paleocene to Miocene sequence along the overturned limb of the Muzaffarabad-Balakot anticline is faulted.

The Garhi Habibullah-Abbottabad zone lies between the Main boundary fault and Garhi Habibullah fault. This zone is involved in the Garhi Habibullah syncline. The Cambrian Abbottabad group lies in the core and Hazara formation along the limbs of the anticline. In the Garhi Habibullah syncline, the late Proterozoic Hazara formation is unconformably overlain by the Cambrian Abbottabad group of rocks. The Jurassic sequence has been eroded from the core of the syncline due to later Himalayan uplift.

The Panjal zone lies between the Garhi Habibullah fault and Panjal fault. The Panjal zone includes the late Proterozoic to Triassic rocks which are involved in the Tarkot anticline and Doga syncline. In this zone the Carboniferous Chushal formation unconformably overlies the late Proterozoic Hazara formation and grades into the Permo-Triassic Panjal formation. These rocks are metamorphosed up to lower green schist facies metamorphism. The Mansehra zone lies west of Panjal fault. It includes the late Proterozoic Hazara and Tanol formations and intrusive Cambrian Mansehra granite. The grade of metamorphism varies from chlorite-grade in the south to staurolite-grade in the north. The Panjal and Mansehra zones are intruded by Permian mafic dikes and sills of basalts and dolerites. These basalts and dolerites are fresh but at places show weak Himalayan metamorphic effects. The sedimentary, metamorphic and igneous rocks of these zones are classified by petrographic studies. The rocks of these zones have been affected by multiple pre-Himalayan and Himalayan deformational events. Four deformational events have been recognized as D1, D2, D3 and D4 deformations. D1 Hazara deformation is restricted to the late Proterozoic sequence. D2 deformation produced a barrovian type metamorphism which produced lower-green schist to amphibolite facies metamorphism in the Panjal and Mansehra zones. The effect of D2 deformation is weak or absent in Garhi Habibullah and Muzaffarabad-Balakot zones. D3 deformational event produced southeast-directed folds and thrusts in Mansehra, Panjal and Garhi Habibullah zones. Whereas D3 deformational event in the Muzaffarabad-Balakot zone produced southeast-directed folds and thrusts. The backsteepening and late extensional folding in all of the four zones occurred in the later phase of D3 deformation. However, the D4 deformational event is related to the northwest plunging antiformal and synformal structures which are related to the formation of the Hazara-Kashmir syntaxis.

Q/18. Qasim, M., 1999-2000. Structure, stratigraphy and petrography of Aghar, Gulpur and Nar areas, District Kotli, Azad Jammu & Kashmir, Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 134p.

The geological and the structural mapping of Aghar, Gulpur and Nar areas of about 200 square kilometers was carried on the scale 1: 50,000 using the Toposheet No.43 G/15 of Survey of Pakistan. Then it was enlarged to the present scale 1: 18750. The lithostratigraphic units exposed in the area are mainly sedimentary in nature and range in age from Upper Miocene to Pliocene. These units are the Nagri Formation (Upper Miocene) and the Dhok Pathan Formation (Pliocene) of Siwalik Group of rocks. The Siwaliks are the molasse sediments which were derived from the upthrust mountain ranges of the Himalayas and adjoining foredeep area. The rocks of the area have been deformed during the two phases of deformation named as D1 and D2. D1 deformational event is related to F1 folds. F1 folds are the major anticlines and synclines of the area. These are Barali Anticline, Gulpur Syncline and Nar Anticline. F2 folds are formed during the second phase of deformation D2 due to change in plunge of F1 folds. About fifty rock samples were collected from different localities of the project area out of which twenty samples were selected for the petrographic studies. Tectonically, the Siwaliks lie in Sub-Himalayas and the project area is situated on the southern side of the Himalayan region, where the Siwaliks are deposited in the foreland basin. This foreland basin was formed in association with the collision of the Indian and Eurasian plates.

Q/21. Qayyum, M. & Lawrence, R.D., 1998. Leading edge of the Himalayan thin-skinned thrust system in Pakistan: the Salt Range. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 154-155.

The 180 km, ENE trending Salt Range is the leading edge of the progressive, south migrating Himalayan thrust front. The presence of a basal salt layer is manifested by the very narrow cross-sectional taper (<10°) and great width (150 km N-S) of the overthrust wedge. Integration of approximately 450 km of seismic reflection data with available surface geologic, magnetostratigraphic, and exploration well data delineate different tectonic features in the Salt Range. These data reveal a concealed duplex structure under the roof sequence, help to determine the footwall and hangingwall geometries of the leading edge at successive evolutionary stages, estimate the lateral extent of a basement normal fault, constrain the ages of different structural features, and define lateral variations in the deformational style within the leading edge. We suggest an out-of-sequence evolutionary model of the Salt Range.

The newly interpreted, concealed duplex structure is the earliest structure of the Salt Range formed during 9-7 Ma. It evolved along a décollement that first ramps within the Salt Range Formation and then across the platform sequence to follow shady horizons of the overlying Murree Formation. The northern ramp is localized in the central Salt Range due to the development of the basement normal fault, around 7 Ma, in the north of concealed duplex structure. It is offset 15 km farther south along a lateral ramp in the western Salt Range, and is entirely within the sedimentary sequence. In the eastern Salt Range, however, it continues within the sedimentary sequence beyond the end of the basement normal fault and then changes into an oblique ramp. The development of basement normal fault interrupted the southward progradation of the thrust wedge. A thick salt pad, formed between 5-6 Ma on the down-thrown side, allowed the thrust wedge to ramp over the northern ramp at about 5 Ma. The topography, newly built by the ramping, resisted the southwards progradation of the thrust wedge and caused further out-of-sequence thrusting in the north. This was followed by the major horizontal translation of the thrust wedge over the roof sequence flat started about 2 Ma. A 130° of counter clockwise rotation has occurred along the northern ramp and the concealed duplex structures.

Q/26. Quade, J. & Cerling, T.E., 1995. Expansion of C4 grasses in the late Miocene of northern Pakistan: evidence from stable isotopes in paleosols. *Palaeogeography, Palaeoclimatology, Palaeoecology*, 155, 91-116.

Stable-isotopic, clay-mineralogic, and bulk-chemical analyses were conducted on paleosols of the Neogene Siwalik sections in northern Pakistan in order to reconstruct floodplain environments over the past ~ 17 Ma. The stable carbon isotopic composition of soil carbonate (mean $\delta^{13}\text{C}$ (PDB) = -10.2‰) and associated organic matter (mean $\delta^{13}\text{C}$ (PDB) = -24.1‰) in paleosols representing 17– $\sim$ 7.3 Ma reveal that floodplain vegetation was dominated by C3 plants. At 7.3 Ma, a shift toward more positive carbon isotopic values began, signaling the gradual expansion of C4 grasses onto the floodplain. From 6 Ma to present, carbon isotopic values for paleosol carbonate (mean $\delta^{13}\text{C}$ (PDB) = +0.6‰) and organic matter (mean $\delta^{13}\text{C}$ (PDB) = -14.4‰) are uniformly enriched in ^{13}C , indicating the presence of nearly pure C4 grassland.
