The scarcity of kaolinite and abundance of smectite and pedogenic carbonate in most paleosols suggest that rainfall in the region remained 1.0–1.25 m/yr or less for the entire 17 Ma of record. Paleosols in the lower portion of the section lack organic A horizons but have reddish B horizons often containing secondary iron-oxide nodules. Leaching depths of soil carbonate in these older paleosols are typically greater than those in the Plio-Pleistocene part of the section, where organic A horizons are common, and B horizons are markedly more yellow. The combined evidence suggests that the mature paleosols in the pre-7.3 Ma part of the record are dominantly calcareous Alfisols or Mollisols that once underlay nearly pure C3 vegetation, perhaps trees and shrubs, while calcareous Mollisols underlying C4 grassland dominate the upper part of the record.

The carbon- and oxygen-isotopic trends in the paleosol record in Pakistan are also evident in the diet of fossil mammals, and in paleosols from Nepal, thus demonstrating that these paleoenvironmental changes in floodplain vegetation may be continent-wide. Local effects, such as the development or intensification of the Asian Monsoon driven by uplift of the Tibetan Plateau, may have led to the expansion of C4 grasses. If, however, the expansion of C4 grasses proves globally synchronous, then a larger scale cause, such as a marked decrease in CO_2 , may be the driving mechanism.

Key words: Stable-isotope, clay, mineralogy, Siwalik, Floodplain, Miocene.

Q/27. Quade, J., Cerling, T.E., Barry, J.C., Morgan, M.E., Pilbeam, D.R., Chivas, A.R., Lee-Thorp, J.A. & Van der Merwe, M.J., 1992. A 16 Ma record of paleodiet using carbon and oxygen isotopes in fossil teeth from Pakistan. *Chemical Geology* 94(3), 183-192.

The Siwalik Sequence of northern Pakistan contains a 16-Ma record of paleosol carbonate and fossil teeth from which a record of paleovegetation can potentially be reconstructed and compared. The carbon isotopic composition of paleosol carbonate and organic matter from Siwalik strata reflects a major paleoecological change on the floodplains of major rivers beginning $\sim$ 7.3 Ma ago. By 6 Ma C3-dominated plant communities, probably composed of mostly trees and shrubs, were displaced by nearly continuous C4

grassland. We find that the carbon isotopic ratios in herbivore tooth enamel reflect this dramatic ecologic shift. Carbonate in enamel older than 7 Ma averages -11‰ in $\delta^{13}\text{CPDB}$, consistent with a largely C3 diet. Enamel from the Plio-Pleistocene averages $+1.9\text{‰}$ in $\delta^{13}\text{C}$, similar to the value displayed by modern C4 grazers. Analysis of post-burial carbonate cements, and the concordance with isotopic evidence from paleosols argues strongly against major isotopic alteration of the enamel, while coexisting bone may have been altered early in burial. This study confirms that enamel apatite is useful for paleodietary reconstruction much further back in the geologic record than was previously thought.

Key words: Carbon isotopes, paleosole, fossil teeth, Siwaliks, Himalaya.

Q/28. Quade, J., Cerling, T.E. & Bowman, J.R., 1989. Development of Asian monsoon revealed by marked ecological shift during the latest Miocene in northern Pakistan. *Nature* 342, 163-166.

Carbon isotopes from soil carbonate¹⁻⁴ and soil organic matter^{5,6} yield palaeoecological information because the carbon in the soil carbonate forms in isotopic equilibrium with local soil CO₂ (refs 1, 7), the isotopic composition of which is in turn determined by local plant cover. Siwalik Group sediments in northern Pakistan contain a well exposed palaeosol record spanning the past 18 Myr. Here we report on stable-carbon-isotope results from associated pedogenic carbonate which indicate a dramatic ecological shift from C3- to C4-dominated floodplain biomass beginning 7.4–7.0 Myr ago. The earlier C3 floodplain biomasses were probably mainly composed of trees and shrubs, whereas C4 grasslands dominated in the Plio-Pleistocene. Oxygen isotopes also exhibit a shift in the latest Miocene, probably corresponding to a major climate change which may have induced the forest-to-grassland transition. This dramatic ecological shift in the latest Miocene may mark the inception or a marked strengthening of the Asian monsoon system.

Key words: Paleoecology, monsoon, Miocene.

Q/29. Quade, J., Roe, L., DeCelles, P.G. & Ojha, T.P., 1997. The late Neogene $^{87}\text{Sr}/^{86}\text{Sr}$ record of lowland Himalayan rivers. *Science* 276, 1828-1831.

Fossil shells and paleosol carbonate from ancestral Himalayan river deposits provide a $^{87}\text{Sr}/^{86}\text{Sr}$ record of lowland Himalayan river water during the late Neogene. Reconstructed $^{87}\text{Sr}/^{86}\text{Sr}$ river values increased sharply in the late Miocene, probably marking the beginning of exhumation of high- $^{87}\text{Sr}/^{86}\text{Sr}$ metalimestones, more in the central than in the western Himalayas. These results imply that the marine $^{87}\text{Sr}/^{86}\text{Sr}$ record may not be a proxy for silicate weathering or consumption of atmospheric CO₂ resulting from that weathering.

Key words: Himalayan rivers, Hydro geochemistry, $^{87}\text{Sr}/^{86}\text{Sr}$, isotopes, Uplift.

Q/30. Quintavalle, M., Tongiorgi, M. & Gaetani, M., 2000. Lower to Middle Ordovician acritarchs and chitinozoans from northern Karakorum mountains, Pakistan. *Rivista Italiana de Paleontologia e Stratigrafia* 106, 3-18.

The lower Vidiakot section (Chitral, Pakistan) comprises the lower part (Yarkhun Formation and base of the Vidiakot Formation) of the terrigenous complex transgressively overlying the crystalline basement of Northern Karakorum. From this section, 8 of 15 samples contain moderately abundant and poorly preserved acritarchs and rare, badly preserved chitinozoans. Three different palynological assemblages have been distinguished which are referable to the chronological interval early Arenig-earliest Llanvirn.

The presence of *Arbusculidium*, *Coryphidium*, and *Striatotheca* in most samples confirms the palaeogeographic attribution of the Northern Karakorum Terrane to the northern Gondwana margin (Lower to Middle Ordovician Mediterranean acritarch Palaeo- province). Refined correlation with other areas and with the previously studied Ishkarwaz section (upper Yarkhun Valley, Chitral) enables the authors the Yarkhun Formation to be dated as early Arenig (British lower nitidus graptolite Zone) to latest Arenig (uppermost graptolite hirundo Zone). The base of the overlying Vidiakot Formation is here correlated with the uppermost hirundo-lowermost artus graptolite Zones (latest Arenig-earliest Llanvirn).

Key words: Palaeontology, Ordovician, Karakoram.

Q/31. Quittmeyer, R.C., Farah, A. & Jacob, K.H., 1979. The seismicity of Pakistan and the relation to surface faults. In: Farah, A. & DeJong, K.A. (Eds.), *Geodynamics of Pakistan*, Geological Survey of Pakistan, Quetta, 271-284.

The historical and modern seismicity of Pakistan and its vicinity is examined in terms of its relation to mapped surface faults. There are found to be three categories into which the seismicity may be classified: 1) earthquakes with large source dimensions that are associated with faults on the basis of either surface rupture of a mapped fault or aftershock area or focal mechanism that defines a trend that is consistent with a mapped fault; 2) narrow, elongate zones of earthquakes that may be related to movement along a single, continuous fault or a group of similarly oriented smaller faults; 3) diffuse activity that is not clearly related to any individual fault. The seismicity of this last category may in some places be the result of the scatter of epicentral locations of earthquakes occurring along shallow-dipping thrust faults. The seismic activity also defines portions of the Indus basin as seismically active even though no surface faults are mapped there.

Care must be employed when using only documented seismic activity to evaluate seismic hazards within Pakistan. The seismic record may be short when compared to recurrence interval for large earthquakes. Geologic evidence of recent fault movement, and geodetic measurements, will help alleviate this deficiency of the seismic record.

Q/33. Quraishi, A.A. & Imam, S.A. 1960. Report on manganese showings of Galdanian, Hazara District, West Pakistan. *Geological Survey of Pakistan Information Release* 15.

Ferruginous rock containing very little manganese is present in the Galdanian Valley, situated about ten miles northeast of Abbottabad. The iron-manganese rock extends discontinuously over two miles with an average thickness of ten feet. The iron mineral is haematite, and in the weathered portion there is a local abundance of limonite. Manganese is found in the oxide form. Neither iron nor manganese is in suitable concentration for economic exploitation.

Key words: Manganese, Abbottabad, Hazara.

Q/34. Qureshi, A., 1981-83. Lithostructural mapping of Mansehra Susal and Matial Area District Mansehra with special reference to structural studies. M.Sc. Thesis, Punjab University, Lahore, 109p.

Lithostructural mapping with preliminary structural studies have been made of Mansehra, Khaki, Rihar area district Mansehra at a scale, of 1:1000. An attempt has been made to delineate the boundaries of igneous and metamorphic rocks precisely. Physiographic/Stratigraphic studies and various structural contour diagrams have been drawn to determine axis of minor folds. Orientation of joints has been determined with the help of Rose diagram. Thin sections have been studied to determine different phases of deformation. Attempt has been made to analyse the strain with Flinn's and Ramsay's plots.

On the basis of microscopic and mesoscopic analysis it has been tried to interpret the structure and macroscopic scale. On the basis of Kinematic Studies, structure of the area is interpreted.

Key words: Lithostructure, mapping, Mansehra.

Q/35. Qureshi, A.A. & Abdullah, S.K.M., 1960. Report on manganese-iron deposit of Churagali, Hazara District, West Pakistan. Geological Survey of Pakistan, Information Release 19, 6p.

Q/36. Qureshi, A.A., Bangash, M.A., Khattak, N.U. & Akram, M., 1996. Study of radioactive minerals from Loe Shilman Carbonatite Complex. The Nucleus, Special volume on Radioactivity, 3(4), 71–74.

The Loe Shilman Carbonatite Complex is the western extremity of a 200 km long Alkaline Belt which extends from Mansehra to Pak-Afghan border in an arcuate fashion around Peshawar valley. The complex is mainly composed of carbonatites with subordinate amount of related alkaline rocks with uranium, niobium and rare earths in ppm range and apatite in % age range. The techniques of alpha-autoradiography, XRD and XRF have been used to locate and identify the radioactive minerals in the Carbonatite. The radioactive mineral has been identified as betafite of primary origin which occurs as small black grains having somewhat parallel alignment; in addition a minor phase of pyrochlore has also been identified.

Key words: Radioactive minerals, Loe Shalman, Khyber Agency.

Q/37. Qureshi, A.A., Butt, K.A. & Khan, H.A., 1990. Fission track dating of carbonatite complexes of Pakistan. Abstracts, 2nd Pakistan Geological Congress, Peshawar, p.44.

Fission track dating on the zircon and apatite from Loe Shilman and Sillai Patti carbonatite have revealed that the carbonatite activity in this area took place in the Mid Tertiary (≈ 30 Ma). The younger fission track age of 19.09 ± 0.19 Ma on apatite from Loe Shilman 21.8 ± 0.4 Ma on apatite from Sillai Patti represent the time of a later thermal episode.

Key words: Carbonatites, fission track dating, Pakistan.

Q/38. Qureshi, A.A., Butt, K.A. & Khan, H.A., 1991. Emplacement time of Silai Patai carbonatite, Malakand, Pakistan, from fission track dating of Zircon and apatite. Nuclear track Radiation Measurement 18, 315-319.

Based on fission track dating of zircon and apatite, the emplacement history of Silai Patai carbonatite has been traced. It has been estimated that the carbonatite was emplaced along the thrust plane associated with the Indian-Eurasian plate collision during the Oligocene period followed by some thermal/tectonic episode during Early Miocene. This negates the previous proposal that all carbonatites found in Pakistan are a part of a 200 km long alkaline province associated with the rifting of Peshawar Valley during Late Cretaceous or Early Tertiary.

Key words: Carbonatite, Silai Patai, Collision, Oligocene, Malakand.

Q/39. Qureshi, A.A. & Jan, M.Q., 1977a. The ultramafic and high-grade metamorphic rocks near Jijal, Indus Valley, Swat. 24th Pakistan Science Conference, Islamabad, H1-H2.

Briefly describe the ultramafic rocks and high-grade mafic rocks from Jijal area. Further information is given in the following.

Key words: Ultramafics, metamorphism, petrology, Jijal, Indus Kohistan.

Q/40. Qureshi, A.A. & Jan, M.Q., 1977b. The ultramafic and high grade metamorphic rocks near Jijal, Indus Kohistan, Northwest Pakistan. Accademy Nazionale Lincei, Series VIII, 63, 259-268.

The Jijal area is occupied by ultramafic and mafic rocks metamorphosed in the granulite facies conditions. These rocks occur in the hanging wall of the Indus suture. The paper gives details of petrography, optical data for clinopyroxenes, and major element analyses of eight samples. The ultramafic rocks comprise diopsidite, websterite, peridotites, and dunite. The mafic consist of garnet-clinopyroxene-plagioclase-quartz granulites, but there also are large bodies of garnet-rich rocks (garnetites) and hornblendites (commonly garnetiferous).

Key words: Ultramafics, granulites, petrology, Jijal, Indus Kohistan.

Q/41. Qureshi, A.A. & Khan, H.A., 1992. Emplacement history and genetic relationship of various carbonatite complexes of Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.32.

In Pakistan, carbonatites are exposed at Naranji Kandao, Sillai Patti, Loe-Shilman, Jambil, Tarbela, Jawar and Jandai. The Loe Shilman, Jawar, Sillai Patti, Jandai and Jambil carbonatites represent Tertiary Alkaline silicate carbonatite magmatism in the Peshawar Plain Alkaline Igneous Belt. The Naranji-Kandao and Tarbela carbonatites belong to Late Paleozoic carbonatite magmatic activity.

The carbonatites are associated with distinct alkaline silicate magma associations. The Loe-Shilman potassic silicate suite comprise of biotite-rich alkali lamprophyres, gabbros and syenites. The Sillai Patti carbonatites are associated with alkaline ultramafic-mafic rocks. In Loe Shilman the evolution of carbonatites follows the general trend of differentiation of the order of crystal fractionation from calcite to dolomite and siderite. Loe-Shilman and Sillai Patti carbonatites as well as many of the African Rift carbonatites have a similar Sr-Nd isotope patterns (Tilton et. al., 1998). The lithospheric source for the carbonatites was probably transported within the Indo-Pakistan Plate after the breakup of Gondwanaland to the Himalayan collision zone.

Key words: Carbonatite, Silai Patai, collision, Oligocene, Malakand.

Q/42. Qureshi, A.A. & Khan, I.H., 1971-72. The ultramafics and highgrade metamorphic rocks near Jijal, Indus Kohistan, Swat. Part 1: Geology and Petrography. M.Sc. Thesis, University of Peshawar, 1-72.

An area of 28 sq. miles near Jijal in Indus Kohistan (Swat) has been mapped and detailed petrography is presented. It is occupied by ultramafic rocks in the south and metamorphic rocks in the north. The former mainly consist of clinopyroxenites with local patches of dunite and peridotites. The latter are represented by the garnet gneisses and related rocks, and are at the southeastern fringe of the upper swat hornblendic groups. The clinopyroxenites are mainly composed of diopside with minor serpentine, enstatite and olivine. Peridotites and dunites also contain clinopyroxene and serpentine, in some up to 50%. Some dunites are free of pyroxene. The rocks show widespread selective serpentinization.

The garnet gneisses contain epidotized plagioclase, garnet, hornblende and/or pyroxene, with muscovite their major constituents. Towards the south near the contact with ultramafics, these come poor in feldspar and very rich in garnet and pyroxene or hornblende. Such rocks are non-gneissose granoblastic. The rocks show amphibolite grade of metamorphism, however, hornblende granulite facies conditions are locally indicated by the presence of hypersthene.

Detailed studies of clinopyroxene and garnet in the ultramafics and gneisses, and their structural relationship suggest that they may not be genetically related. The ultramafics are apparently emplaced along a faulted contact between the gneisses and the schistose group. No contact metamorphic effects noted in the schists suggest that the emplaced ultramafic mass had lower temperature. The area investigated does not have much economical potential, however, garnet and building stone is of some importance.

See further information in the following.

Key words: Ultramafic-mafic rocks, high grade metamorphism, petrology, Jijal, Indus Kohistan.

Q/43. Qureshi, A.A. & Khan, I.H., 1971-72. The ultramafics and high-grade metamorphic rocks near Jijal, Indus Kohistan, Swat. Part 2: Chemistry and Pathogenesis. M.Sc. Thesis, Peshawar University, 72-107.

This thesis presents a preliminary geological map of the Jijal-Duber-Pattan area of the Indus Kohistan. The principal lithologies can be divided into a southern ultramafic part (peridotites and pyroxenites) and a northern high-grade part (metagabbros, ultramafic lenses). Petrographic details have been given for various rocks, along with (in Part 2) chemical analyses of the major elements in some rocks.

Q/44. Qureshi, A.A., Khattak, N.U., Chaudhry, M.N. & Khan, H.A., 1999. Thermo tectonic history of Loe Shilman carbonatite complex, NW Pakistan, based on fission tract dating of apatite and other radiometric ages. Geological Bulletin, Punjab University 33 & 34, 105-110.

The Peshawar Plain Alkaline Igneous Province (PAIP) consisting of alkaline granites, syenites, gabbros, albitites, carbonatites etc., occurs in the north of Peshawar Plain in an arcuate fashion. It stretches from Loe Shilman near Pakistan-Afghanistan border up to Tarbela through Warsak, Sillai Patti, Shewa-Shabazgarhi, Koga and Ambela. The Loe Shilman Carbonatite Complex comprises of sill like bodies emplaced along thrust plain of an east-west trending and northerly dipping fault zone in Paleozoic to Pre-Cambrian metasedimentary rocks. This paper presents the use of fission track age of apatite as paleotemperature indicator and its significance in the recognition of the emplacement time and tectonometamorphic history of the Loe Shilman Carbonatite Complex in combination with other radiometric ages.

The K-Ar date of 3.00 ± 2.00 Ma on biotite and V-Pb date of 30.00 Ma on calcitic indicate that the Loe Shilman rocks were emplaced during the Oligocene times. The fission track age of 18.87 ± 1.33 Ma on apatite from Loe Shilman, estimated by us, represents a time during the post-metamorphic uplift history of the area, when these rocks passed through the 115°C isotherm, corresponding to a depth of about 3.5 km from their present position, if a paleogeothermal gradient of 30°C per km is assumed to have prevailed. Based on present work, in combination with other available ages, we support the idea of emplacement of the complex in the Oligocene in contradiction with the earlier view of emplacement of these rocks in the Permo-Carboniferous.

Key words: Carbonatite, tectonics, Loe Shalman, Khyber Agency.

Q/45. Qureshi, A.A., Khattak, N.U., Karim, T. & Waheed, S., 2000. Geology and economic significance of the Loe-Shilman carbonatite complex, Khyber Agency, Pakistan. Geologica 5, 133-144.

The Loe-Shilman Carbonatite Complex consists of carbonatites, syenites, quartz-rich granitoids and gabbroic rocks emplaced along a faulty zone. The complex is the western extension of a 200 km long Alkaline Belt found in the north of the Peshawar Plain. The rocks in the north of the complex are mica schists and limestones of Paleozoic age while those in the south are slates/phyllites and some lime stones of Pre-Cambrian age. The carbonatitic rocks at Loe-Shilman are composed mainly of calcite and/or dolomite with amphibole, mica, pyroxene, pyrochlore/betafite and some ore.

In general, the carbonatites are one of the major sources of Rare Metals (Nb, Y, V, La, Ra, etc.), Earth Elements (REEs), apatite and some other minerals/elements. Uranium is sometimes present in these rocks and is recovered as by-product. Studies were carried out to look into the possibility of existence of these materials in commercially exploitable amounts in the carbonatites. There are reasonable concentrations of some Rare Metals (Nb-upto 3100 ppm, Y-upto 205 ppm, V-upto 890 ppm, and La-upto 588 ppm), REEs (Ce-upto 2900 ppm, Pr-upto 268 ppm, Nd-upto 394 ppm, Sm-upto 70 ppm), apatite (average more than 15%) and U_3O_8 (average 200 ppm). Due to various unique and special applications of Rare Metals, REEs and uranium in metal and nuclear industries and those of apatite as a source material for fertilizer and chemical industries, the Loe-Shilman carbonatites have a special importance.

Q/46. Qureshi, A.A., Majid, C.A., Akram, M., Hussain, M.A., Mateen, A., Khattak, N.U., Javed, M., Hussain, S.S., & Khan, H.A., 1997. Characterization of emerald from Gujar Kili, Swat, Pakistan. *The Nucleus*, 34 (1–2), 57–63.

The green gem variety of beryl family having Cr as coloring agent is known as emerald. Thirteen emerald occurrences are known from Northern Pakistan which are located exclusively in ophiolitic melange of Indus Suture zone. The ophiolitic rocks are source of Cr which colors the beryl to make it emerald. Studies have been carried out for the characterization of emerald from Gujar Killi, a locality in Swat. The emerald is of high quality green to deep green variety. In general it has high Mg, Fe, Cr, V and low Al values as compared to average composition of the emeralds. Two mineralogical phases were identified in the Gujar Killi samples namely beryl and chrysoberyl on the basis of XRD studies. The Cr does not substitute any element rather it is present as an impurity in the crystal matrix. A new etchant (19N NaOH boiling) to reveal fission tracks in 45 minutes is reported.

Key words: Gems, emerald, Swat.

Q/47. Qureshi, A.A., Mateen, A. & Karim, T., 1993. Chemical characterization of carbonatite from Loe Shilman, Khyber Agency, Pakistan. Abstract volume 2nd All Pakistan Science Conference, Aitchisons College, Lahore.

Loe Shilman carbonatite samples were chemically analyzed for major elements in order to classify the carbonatites. On the basis of chemical characteristics the carbonatites were classified into three categories. Calico-Carbonatites: In these rocks the CaO: CaO+MgO+Fe₂O₃+MnO ratio is greater than 0.8. Magnesio-Carbonatites: In these rocks CaO: CaO+MgO+Fe₂O₃+MnO ratio is less than 0.8. Ferro-Carbonatites In these rocks CaO: CaO+MgO+Fe₂O₃+MnO ration is less than 0.8 and MgO is < FeO+Fe₂O₃+MO.

Q/53. Qureshi, A.W. & Tanoli, S.K., 1992b. Early molasse sediments (Murree Formation) in Pathan Algad, southern Kohat. Geological Bulletin, University of Peshawar 25, 85-93.

Of the southern most exposures of the Murree Formation in Kohat those of the Pathan Algad are considerably thick. These consist of interbedded maroon sandstone and red clay with subordinate conglomerate. The conglomerates within the formation are intrabasinal and lag in nature while conglomerate at base of the formation consists of reworked limestone clasts of the underlying Kohat Formation. Two main sand-bodies, one SBI starts at 13m level and is 21m thick and second SB2 at 52 level ranging 2-4m in thickness, were observed. These sand-bodies consist of main channel, point bar, and chute bar deposits. Interbedded sandstone and clay facies which overlie the composite sandstone facies represent levee or crevasse splay deposits. The red clay was deposited in flood plain areas out of suspension. As a whole the Murree Formation in this area displays typical meandering river deposits. Our analysis suggests that the Pathan Algad area lied the margin of the Murree river system where only occasionally the main river flowed. Additionally, there may be a considerable age difference between the exposures in Pathan Algad and those at Dhok Maiki, the stratotype in Potwar area.

Q/54. Qureshi, F.A., 1992-94. Sedimentary petrology of Early Cretaceous Lumshiwal Formation and Eocene Margala Hill Limestone and Lithostructure mapping of Dhamtaur area, Southern Hazara, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 213p.

A comprehensive study of Geology and structure of Dhamtaur area is presented along with special constraints on the sedimentology of Lumshiwal Formation of Early Cretaceous and Margalla Hill Limestone of Early Eocene. Large-scale (1:10000) geological mapping of a small segment of the Lesser Himalaya in the Dhamtaur area is presented. The lithostratigraphic unit range from Upper Paleocene to Precambrian, Hazara Formation being the oldest. Structurally the area comprises NW-SE trending major anticlinorium. The folds are tight to isoclinal and opposing southeast and northwest vergence on the two sides of the core formation. Some anticlines show plunge tot the southeast direction. Almost all faults have vergence parallel to the folds developed in the core on the two sides of the main anticlinorium. Most are reverse faults although some may be of the normal type. Faulting appears to be dipslip to oblique slip and in general involves a maximum displacement of few hundred meters.

A detailed study of sedimentary petrology/sedimentology of Lumshiwal Formation of Early Cretaceous and Margalla Hill Limestone of Early Eocene has been carried out. The object was to study the petrography environment of deposition and diagenesis of the above said formations.

The section of Lumshiwal Formation from Karlan Bazar at Abbottabad Nathia Gali Road, is medium to thick bedded glauconite sandstone. This formation is divided into twenty microfacies. The microfacies overlying Chichali Formation is poor in glauconite and are mainly quartz and carbonate cemented quartz arenites. The other microfacies are mainly quartz; glauconite and carbonate cemented, well to very well sorted, and mature to supermature quartz arenites. The maximum development of glauconite is from central to upper. Upper horizons selectively cemented with flint.

Q/55. Qureshi, J.A., 1997-98. Geological mapping of Rawalakot area with special emphasis on engineering characteristics of geo-material. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 42p.

Geological mapping of Rawalakot area is prepared on the scale 1:12,500 and the total area of investigation is about 100 sq. km. Present work shows that the strength of the geomaterial which is studied for the mineralogical composition of the aggregate of the Murree Sandstone. Los Angle value, crushing value, impact value, specific gravity, water absorption, flakiness index and elongation index were performed according to ASTM standards and the parameters of the strength of material were deduced according to the mineralogical assembly of the Murree sandstone. It was seen that the percentage of quartz and cementing material like calcite in favourable conditions provide strength to the material and the deleterious material like clays due to its swelling potential damages the material when in contact with water. Reserves of the Murree Sandstone as geomaterial of different localities were also estimated for the quarry purposes

Electrical resistivity survey in Masal Talao, Amir Khan Talao, Kachar Talao and Haji Talao (District Peshawar) was carried out in collaboration with Hydrogeology Directorate WAPDA Peshawar. The main purpose of the survey was to determine hydrogeological features such as depth to the bedrock, nature and thickness of aquifers, the quality of groundwater, and to select suitable sites for tubewell installation in the project area.

According to resistivity survey and drilling data the entire area is underlain by low resistive clay with occasional gravels. The overlying alluvium is composed of alternating layers of gravels and clays. Ground water appears to be quite fresh in the entire project area. Water table depth is from 13m to 40m in the area under investigation.

In the project area, twenty-seven probes were carried out. After interpreting the data, the V.E.S. No. 95, 93, 51, 40, 15 and 17 have been selected for the test drilling, however other probe sites also indicate the presence of aquifers in the area but of varying thickness.

The entire area appears to be favorable for tubewell installation, however the yield of water depends upon the nature of aquifers may range from half cusec to one and half cusec in the project area.

Q/64. Qureshi, M.K.A., 1997. Stratigraphical and sedimentological studies of the Mesozoic rocks of the Kala Chitta Range, Northern Pakistan. Ph.D. Thesis, Punjab University, Lahore.

The present research deals with the stratigraphical and the sedimentological studies of the Mesozoic Rocks of the Kala Chitta Range, Northern Pakistan, based upon an extensive field work and detailed laboratory analyses. This study is the first comprehensive version on the depositional environments and the microfacies analysis of the dominantly carbonate shelf deposits. Standard microfacies have been identified among the carbonate succession, whereas the constituent minerals and elements in the siliciclastic rocks, most conspicuously of the Datta Formation (Lower Jurassic), have also been recognized by means of XRD, DTA and chemical analyses for the paleoenvironmental interpretation.

Age diagnostic Early Triassic ammonites from the Mianwali Formation and the planktonic foraminifers from the Upper Cretaceous Kawagarh Formation have also been recorded and illustrated. In addition, palynological data of different formations has been incorporated for the first time from the Kala Chitta Range.

Stratigraphic correlation with Hazara, Kohat, Salt Range, Trans Indus Range and Balochistan Basin has been attempted. New data about the structural framework of this linear fold -thrust belt has also been presented.

Key words: Stratigraphy, sedimentology, Mesozoic, Kalachitta.

Q/65. Qureshi, M.K.A., Butt, A.A. & Sheikh, R.A., 1994. The Kala Chitta foreland fold and thrust belt, Northern Pakistan. *Journal of Nepal Geological Society* 10, Abstract Volume, 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu, Nepal, 104-106.

The present structural framework of the Kala Chitta Range evolved through movement between two detachment surfaces. The Precambrian Attock Slates acted as a basal detachment surface above which large-scale horizontal compression took place to produce the main structural framework of the Kala Chitta Range. The Middle Eocene argillaceous Kuldana Formation behaved as the upper detachment surface giving rise to blind thrusts which were later exposed due to the vigorous erosion of the overlying folded Miocene strata. Despite the severe tectonic activity, strata older than the Triassic are not exposed in the Kala Chitta Range, which appears that these may not have been deposited at all. However, the Precambrian Attock Slates are believed to underlie the Mesozoic rocks because of the intervening position of the Attock Slates between the Kala Chitta Range and the Attock-Cherat Range.

In the Kala Chitta Range, the Triassic to Eocene rocks are repeated constantly in compressed folds and thin sheets. Interpretation of a regional decollement (Cotter, 1933) rooted in the Attock Slates and responsible for the major overthrusting, has proved to be of the fundamental significance for later researchers who are actually substantiating Cotter's concept in one way or the other (i.e. Lechner, 1947; Wadia, 1957; Gansser, 1964; Crawford, 1974; Lillie et al., 1987). The sedimentary veneer has glided and deformed over this surface and the Attock Thrust and the Main Boundary Thrust (MBT) represent the "splays off" of this detachment surface. Late Cenozoic movement along these thrusts has uplifted the Attock-Cherat and the Chitta-Margala Hill Ranges.

Apart from the movement over this basal decollement surface, the Kala Chitta fold-thrust belt has evolved by blind thrusting merging with a continuous upper detachment surface. The Middle Eocene Kuldana Formation is believed to have played the role of an upper detachment surface. This view is supported by the fact that the Kuldana Formation and the overlying molasse deposits which are well exposed all along the southern borders of the fold-thrust belt are not repeated in any of its internal folds. The presence of the Pre-Kuldana Formation deposition (i.e. Margala/Patala/Lockhart) in the footwall of almost all the exposed thrusts, regardless of which formation comprises the hanging wall, also provides a strong evidence that the Kuldana Formation has served as the upper detachment surface. This consistency shows that successive thrusts emplaced at the outer edge of the foothills flattened along a common upper detachment surface formed by the Kuldana Formation.

The recognition of the basal and the upper detachment surfaces gives a distinctive character to the deformational style of the Kala Chitta fold-thrust belt. The sequence of events describing briefly the changes in structural style with different erosion levels, and the development of blind thrusts beneath a continuous upper detachment at all stages of deformation are modelled. It was revealed from the model that the internal deformation of the Kala Chitta Range predates its ramping towards south over the MBT. However, the basement uplift to some extent, might have also been responsible for the initiation of thrusting in the Kala Chitta and the adjoining areas.

During its tectonic history, the Kala Chitta Thrust belt suffered a number of deformational phases. However, in a very generalized sense, the most effective and prominent are three distinct and partly overlapping phases. The first being a north-south trending compressional phase resulting in generally east-west trending fold axes and fault planes. The second NE-SW trending phase formed cross folds and duplex structures, while the third phase resulted into the thrusting and ramping of the whole Kala Chitta belt over the MBT in the south. The overall configuration of the Range indicates that during the final phase of thrusting over the MBT, differential block movement took place, the western block lagged behind in southward movement and much thrusting developed in its extreme northern part (Chhoi-Chak Jabbi area). On the other hand, the eastern block moved ahead towards south, developing extensive thrusting towards its south (Fatehjang-Mahura area). The major faults include the MBT, the Samul Pani-Chak Dalla Thrust, the Ghora Mar-Chak Jabbi Thrust, the Chhoi-Dunga Kas Thrust and their splays and offshoots.

Key words: Paleoenvironment, tectonics, structure, Kalachitta fold and thrust belt.

Q/66. Qureshi, M.K.A., Hassan, M. & Butt, A.A., 1992. Paleoenvironments and tectonic style of the Kala Chitta fold and thrust belt, Northern Pakistan. Regional Postgraduate Training Course in Plate Tectonics, Punjab University, p.41.

Structural modelling of the Kala Chitta range has been attempted after having completed its geological mapping on 1:50,000 scale. The structural style of the Kala Chitta Range is believed to represent an example of a foreland-fold and thrust belt geometry after incorporating the structural entity of its northerly neighbour of the Attock-Cherat Range.

The present structural framework appears to have evolved through movement between two detachment surfaces. The Precambrian "ATTOCK SLATES" are believed to have acted as a basal detachment above which large scale horizontal compression has taken place to produce the main structural framework of the Kala Chitta Range. The middle Eocene argillaceous KULDANA FORMATION appears to have behaved as the upper detachment surface giving rise to blind thrusts which were later exposed due to the vigorous erosion of the overlying folded Miocene strata. The major individual structures are illustrated through a number of Cross Sections as a support to the proposed structural modelling.

Key words: Paleoenvironment, tectonics, Kalachitta fold and thrust belt.

Q/76. Qureshi, S.N., Ahmed, S., Khwaja, A.A., MonaLisa, & Naseem, S., 2000. Gravity modeling and seismicity of the area between Bannu and Kohat. Abstracts, Third South Asia Geological Congress, Lahore, p.82.

A part of active Himalayan fold-and-thrust belt has been investigated along a 131 km long gravity profile (Bannu to Kohat) by gravity modelling. Good agreement exists between the observed and calculated gravity values. The basement dips gradually towards North from about 9 km under Bannu to about 11 km below Kohat.

In this area of blind and emergent faults, variations in Bouguer anomaly coincides well with the known faults like Latamber, Bahadur Khel and Tappi. Other similar Bouguer anomaly variations suggest the presence of blind faults beneath the molasses and/or platform rocks at Domail, Khurram, Banda Daud Shah, Lachi and Gada Khel. Isostatic behavior reveals a local deficit of mass conditions between Latambar-Tappi area.

Seismically the area is active. Three events of $M_b = 4.9$ to 6.0 from Banda Daud Shah, Lachi and Shadikhel confirm the existence of faults. Their focal mechanism solutions are discussed.

Key words: Seismicity, gravity modeling, Bannu, Kohat.

R/7. Raeburn, S.P. & Kerrick, D.M., 1995. Reconnaissance Lithological Mapping in the Karakoram Using Digital JERS-1 and Landsat-5 Satellite Data. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

Kerrick and Caldeira (1993, 1994) hypothesized that the amount and advective flux of metamorphic CO₂ arising from post-collisional metamorphism in the Himalaya orogenic belt may have been of sufficient to have enhanced

atmospheric CO₂ contents and thus have contributed to early Cenozoic greenhouse warming. In reviewing uncertainties in their quantitative analysis of the amount of metamorphic CO₂ generated at depth, they emphasized the need for improved estimates of the proportion of CO₂ source rocks (carbonate protoliths) in the Himalayan-Karakoram orogenic belt. Accordingly, the primary purpose of our study was to further quantify the aerial abundance of carbonate-bearing and calc-silicate bearing lithologies. Because of the logistical difficulties in access and the limited lithologic mapping over the extensive area required for such estimates, satellite imagery was used to aid in such estimates. Using the Karakoram metamorphic complex as a case study, We have investigated the utility of remotely sensed visible and near infrared (VNIR) and short wavelength infrared (SWIR) digital satellite data for lithological discrimination in an area largely free of vegetative cover and bounded by the Hunza, Gilgit and Ishkuman rivers. A thematic map was compiled from two different data sets: Japanese JERS-1 SWIR data which has 4 spectral bands within the SWIR region, and a Thematic Mapper (TM) data which has 2 bands in the SWIR and 4 bands in the VNIR region. Limited JERS-1 data availability required acquisition of digital image data characterized by a low sun elevation angle and snow cover in high elevation areas, whereas acquired Landsat TM data had a higher sun elevation angle and less snow cover. Variation in the intensity of backscattered radiation as a result of topographical effects is a considerable problem in areas of high relief, and requires separate analysis of shaded and unshaded areas. Spectrally distinct units identified using band rationing and principal components analysis techniques were correlated with previously mapped regions in the Hunza valley (Searle, 1991) and extrapolated westward into the less well-mapped area between the Hasanabad glacier and the Karumbar valley. This study provides assessment the utility of digital satellite data in extending reconnaissance mapping to other inaccessible areas of high relief and limited vegetation in the Karakoram.

R/8. Rafiq, M., 1984. Extension of Skhakot-Qila ultramafic complex in Utman Khel, Mohmand Agency, NWFP, Pakistan. Geological Bulletin, University of Peshawar 17, 53-59.

The Utman Khel area in Mohmand Agency Contains bodies of ultramafic and mafic rocks covering an area more than one third of that of the Utman Khel mountains. The ultramafic rocks are emplaced as klippe over the metasediments of Paleozoic age. The central part of the complex generally consists of massive dunite, peridotite, and grades outward into massive to friable serpentinites. At several places, dunite, peridotite and serpentinite are altered to talc, carbonate and carbonate- quartz rock, particularly along shear zones. Steatite and blackwall-chlorite rock form small masses at the margins of the ultramafic rocks, adjacent to the contact with metasediments. Chromite occurs as podlike and lensoidal masses in 54 showings sporadically distributed over six different locations.

The characteristics displayed by the ultramafic rocks of the Utman Khel area are virtually similar to those displayed by the rocks of the Skhakot-Qila complex. Therefore it is appropriate to consider the ultramafic rocks of Utman Khel area as the extension of Skhakot-Qila complex.

R/9. Rafiq, M., 1987. Petrology and geochemistry of the Ambela granitic complex, N.W.F.P. Pakistan. Ph.D. Thesis, University of Peshawar, 272p.

The Ambela granitic complex is a middle to Late Paleozoic batholith consisting of oversaturated (70%), saturated (20%), undersaturated (5%) and basic (5%) igneous rocks. Petrographic study reveals three major divisions of the rocks: Group I includes granites and alkaline granites; Group II includes quartz syenites, alkali quartz syenites, syenites, alkali syenites and feldspathoidal syenites; and Group III consists of basic dykes. Chemical classification based on 166 major element analyses match the petrographic division and the rocks vary from peraluminous (partly metaluminous) to peralkaline in composition. Major, minor and trace element contents of these rock indicate a within plate (continental) origin.

R/11. Rafiq, M. & Jan, M.Q., 1983. A discovery of emerald near Bucha, Mohmand Agency. Geological Bulletin, University of Peshawar 16, 188.

Light green beryl and emerald occur in talc-carbonate and carbonate-quartz rocks located about 200m north of Bucha village in eastern Mohmand Agency. The crystals reach up to 10×5mm in size, however, large crystals are translucent, fractured, and poor in quality. Transparent and clear crystals of light green beryl and emerald are less than 3mm in length and are, therefore, not of a high commercial value.

Key words: Gems, emerald, Mohmand Agency.

R/12. Rafiq, M., & Jan, M.Q., 1984. Emerald and green beryl from Bucha, Mohmand Agency, NW Pakistan. 1st Pakistan Geological Congress, Lahore, p.21

Deep bluey-green emerald and light green beryl occur sporadically in talc-carbonate and carbonate-quartz rock's near Bucha (34° 24'12" N, 71° 36' E). The host rocks have formed along shear zones due to alteration of enclosing ultramafic rocks. However, the source of solutions for this metasomatic process and introduction of Be is not clear. The beryl and emerald have high iron, emerald also having higher MgO content and refractive indices than most of the described natural emeralds. The crystals are variable in clarity and reach up to 10 mm in length; however, gem quality crystals are less than 3 mm long.

Key words: Gemstones, emerald, beryl, Mohmand Agency.

R/13. Rafiq, M. & Jan, M.Q., 1985. Emerald and green beryl from Bucha, Mohmand Agency, NW Pakistan. Journal of Gemmology 19, 404-411.

Deep bluey green emerald and light green beryl occur sporadically in talc carbonate- quartz rocks near Bucha (34° 24.5' N, 71° 36' E). The host rocks have formed along shear zones due to the alteration of enclosing ultramafic rocks; however, the source of solutions responsible for this metasomatic process and introduction of Be is not clear. The beryl and emerald have high iron, the emerald also having higher MgO content and refractive indices than most natural emeralds. The crystals are variable in clarity and reach up to 10 mm in length; gem quality crystals, however, are less than 3 mm long.

R/14. Rafiq, M. & Jan, M.Q., 1987. Fibrolitic sillimanite in sheared rocks of the Ambela granitic complex, northwestern Pakistan. Geological Bulletin, University of Peshawar 20, 181-188.

Two-mica granites in the northeastern margin of the Ambela granitic complex underwent cataclastic deformation. The resulting shear zones acted as pathways for the migration of a water-rich fluid phase that also contained boron and some fluorine. This resulted in 1) formation of fibrolitic sillimanite and white mica at the expense of feldspars and biotite, especially along micro-shears, 2) bleaching of biotite and release of Fe and Ti oxides, and 3) crystallization of tourmaline and fluorite. Some recrystallization / neo-mineralization of feldspar, quartz and muscovite also occurred due to shearing.

Key words: Granites, shear zones, deformation, Sillimanite, Buner.

R/15. Rafiq, M. & Jan, M.Q., 1988. Petrography of the Ambela granitic complex, NW Pakistan. Geological Bulletin, University of Peshawar 21, 27-48.

The Ambela granitic complex occupies the southeastern part of the Buner subdivision of Swat. It is a composite batholith consisting of a variety of oversaturated (70 %), saturated (20 %), and undersaturated rocks (10 %). The batholith may have formed over a considerable length of time, spanning from middle to late Paleozoic. Petrographic studies (800 thin section) allow a three fold grouping of the rocks. Group I include granites, alkali granites and

microporphyrites; these appear to represent the early magmatic episode of the complex. Group II includes quartz syenites, alkali quartz syenites, syenites, feldspathoidal syenites, carbonatite, ijolite, lamprophyre, and associated pegmatites and fenites. Considerable metasomatic changes were associated with successive alkali rich intrusive phases of this group of rocks. Basic dykes (Group III), intruding both Group I and II rocks, represent the last magmatic episode and constitute about 5 % of the complex. This paper presents petrographic details of the various types of rocks in the complex.

Key words: Petrography, Ambela granitic complex, Buner.

R/16. Rafiq, M. & Jan, M.Q., 1989. Geochemistry and petrogenesis of the Ambela granitic complex, NW Pakistan. Geological Bulletin, University of Peshawar 22, 159-179.

The Ambela granitic complex comprises three groups of rocks. Group I, the product of the first magmatic episode, consists of granites and alkali granites which occupy ~70% of the 900 Km² area of the batholith. Group II, following the granites sequentially, comprises quartz syenites, syenites, feldspathoidal syenites and related rocks. Following these, the area was invaded by dolerite dykes which occupy ~5% of the complex. These (Group III rocks) are not discussed in this paper. The granitic rocks range from dominantly peraluminous to metaluminous to mildly alkaline. These were derived from melts produced by crustal anatexis due to crustal thinning and rifting. Different degrees of partial melting and fractional crystallization led to variation the composition of these Group I rocks. With deepening of the zone of magma generation in the crust, the underlying mantle was activated, resulting in the influx of volatiles and alkalis. This led to the generation of magma batches which were successively more SiO₂ undersaturated and alkaline, resulting in the production of Group II rocks. The Ambela batholith appears to have developed during a major phase of crustal thinning and rifting towards the end of Paleozoic.

Key words: Petrography, geochemistry, Ambela granitic complex, Buner.

R/17. Rafiq, M. & Jan, M.Q., 1990. Petrogenesis of basic dykes from the Ambela granitic complex, NW Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, p.45.

Basic dykes intrude the upper Paleozoic granites, alkali granites, syenites and associated rocks of the Ambela granitic complex. These dykes mostly have N 25-450E trend, constitute about 5% of the complex, and from 1 to 7m thick bodies that at places extend for hundreds of meters. Textural, modal and chemical composition criteria have been used to classify these dykes into (1) dolerites of varied assemblages, and (2) Lamprophyres. The dolerites generally display ophitic to subophitic texture and consist of plagioclase (An₃₅₋₅₅), hornblende, pyroxene, epidote, ore (ilmenite and titaniferous magnetite), sphene, and rarely quartz, biotite, chlorite and apatite. The chemistry of the dolerite dykes is suggestive of continental tholeiitic affinity. The lamprophyres are restricted in occurrence and intrude the north-central part of the complex near Koga. Texturally these are panidiomorphic and are composed of amphibole, sphene, albite, apatite and ore. Field data and petrography suggest that these rocks represent the last episode of the alkaline magmatism in the complex.

Key words: Petrography, basic dykes, Ambela granitic complex, Buner.

R/18. Rafiq, M. & Jan, M.Q., 1991. Titanium content of a chloritoid-quartz-ilmenite band in ophiolitic melange near Prang Ghar, NW Pakistan. Geological Bulletin, University of Peshawar 24, 127-132.

Titanium is a valuable engineering metal and has many uses. In the greenstone of the Indus suture melange near Prang Ghar, a 200 m long and 1 to 3.5 m thick band consists essentially of chloritoid (31 to 59 vol. %), quartz (10 to 27%), and ilmenite + Fe-oxide (8 to 25%). The rocks contain very high Al₂O₃, total Fe₂O₃ and TiO₂, and low SiO₂, CaO, MgO and alkalis. The unusual composition may have formed from basaltic precursors of the greenstone by weathering (laterization) or alteration, followed by greenschist facies metamorphism. Chemical analyses of three samples, containing 5 to 10 wt. % TiO₂, warrant further investigation of the area.

Key words: Ophiolites, ultramafics, Indus Suture, Prang Ghar, Mohmand.

R/19. Rafiq, M., Khan, M.A. & Jan, M.Q., 1988. Myrmekite in the Ambela granitic complex, N. Pakistan: A product of deformation and replacement in the feldspar. Geological Bulletin, University of Peshawar 21, 159-165.

The Ambela Granitic Complex in N. Pakistan is locally intersected by strike-slip and thrust faults, which have resulted in the development of relatively, sheared granites. A characteristic feature of the deformed granites is the occurrence of myrmekite in the K-feldspar porphyroclasts, which is otherwise absent in the complex. A detailed petrographic study shows that the myrmekites are localised along those margins of the porphyroclasts which are not strained and which are adjacent to the trails of secondary muscovite. A comparison with the established examples of strain-related myrmekites suggests that though the deformation may be important in the genesis of the Ambela myrmekite, there may be a greater role of metasomatic replacement accompanying deformation.

Key words: Myrmekite, petrography, Ambela granitic complex, Buner.

R/20. Rafiq, M., Khan, M.A., Jan, M.Q. & Ahmad, I., 1988. Petrography and geochemistry of the inclusions from the Ambela granitic complex, N. Pakistan. Geological Bulletin, University of Peshawar 21, 141-145.

Petrography of twelve and geochemistry of three selected samples are presented for the inclusions of the Ambela granitic complex. The inclusions are silicic to intermediate in composition with a metaluminous chemical character. Major element geochemistry is inconclusive with regards to their origin, but incompatible trace elements are in correspondence with the concentration of these elements in the host granites and syenites. A closer match, however, is with the acidic volcanics which now make a part of the country rocks but were probably the early phase of the Ambela granitic complex.

Key words: Petrography, enclaves, Ambela granitic complex, Buner.

R/21. Rafiq, M., Shah, A., Hamidullah, S. & Sayab, M., 1997a. Petrogenetic study of Late Paleozoic sub-volcanic rocks from Peshawar Plain, N.W. Pakistan. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p.50.

Please consult the following account for additional information.

Key words: Petrogenesis, Paleozoic, Peshawar Plain.

R/22. Rafiq, M., Shah, A., Hamidullah, S. & Sayab, M., 1997b. Classification and genesis of late Palaeozoic, volcanic rocks from Peshawar plain, North West Pakistan. Geological Bulletin, University of Peshawar 30, 251-271.

Acidic microporphyries and rhyolites of Late Paleozoic age are intimately associated with acidic plutonic rocks, i.e., the Ambela granitic complex of alkaline igneous province of Peshawar plain. Basic rocks occurring as flows are also associated with these acidic rocks. Field evidences including the association of metasedimentary sequence of Carboniferous age, i.e., Jaffar Kandao and Baroach Formation, provide constraints on the date of their emplacement. The microporphyries and rhyolites have a fine-grained texture with feldspars and quartz as phenocrysts. The rocks are classified as A-type, mildly alkaline and peraluminous on the basis of major and minor element chemistry. Tectono-magmatic discrimination diagrams, Zr and Ta concentration, Hf/Th and Hf/Ta ratios, and low Sr reveals that these rocks are of crustal origin and were emplaced in intra-cratonic rift environment. The Th, Hf and Ta concentrations indicate crustal contamination, and Eu anomaly shows soda metasomatism due to the intrusion of late magmatic fluids in these rocks.

Key words: Petrogenesis, Paleozoic, volcanic, Peshawar Plain.

R/23. Rafiq, M., Shah, M.T., & Ahmad, I., 1984. Note on tremolite zone from the extension of Skhakot-Qila ultramafic complex Utmankhel, Mohmand Agency. Geological Bulletin, University of Peshawar 17, 178-179.

Tremolite rock occurs along the northeast and northwest contact of the ultramafic complex, west of Jindai Khwar near Balola in Mohmand Agency. Tremolite is mostly found in association with actinolite, talc and chlorite along shear zones. Palegreen to green and fibrous to bladed tremolite crystals vary from 3 to 16 mm in length. However, a greyish-green variety (about 2 mm in length) intermixed with talc and chlorite is not uncommon. The blades are commonly broken, bent, and usually tailed out into finely fibrous bundles of asbestiform tremolite. It has large 2V with an extinct angle varying from 15° to 20° , and n_a and n_p refractive indices of 1.60 and 1.61 respectively.

Tremolite mineral from the tremolite rocks was analysed for major oxides by wet chemical methods. These oxides were used for the calculation of mineral formula ($\text{Ca}_{1.68} \text{Na}_{0.20}$) ($\text{Mg}_{4.58} \text{Mn}_{0.02} \text{Fe}_{0.21} \text{Al}_{0.30}$) ($\text{Si}_{7.83} \text{Al}_{0.16} \text{O}_{21}$) (OH_2) on the basis of 23 oxygens; water was not included in the recalculation (Leake, 1978). The mineral was classified as tremolite. This analysis on comparison, has correlation with the tremolite from Feather River ultramafics (Ehrenberg, 1915) and also with tremolite from Ultimo, Italy (Pirani, 1951). In spite of optical properties and chemical data, the presence of tremolite was also established by examination of X-Ray Diffractometer powder pattern. The powder pattern of charge contained 90% tremolite, the remainder being actinolite, talc, and chlorite. Field relationship of tremolite rock with the ultramafics suggests that it may probably be the product of secondary processes. However, more detailed work is required to ascertain the possible origin of this rock.

Key words: Ultramafics, tremolite, Skhakot-Qila, Mohmand Agency.

R/24. Rafiq, M., Shah, M.T., Rehman, M. & Ihsan, M., 1984. Petrochemistry of the rocks from Babaji area, a part of the Ambela granitic complex, Buner, Northern Pakistan. Geological Bulletin, University of Peshawar 17, 31-42.

Geological mapping covering 50 km² around Babaji in Buner, shows that the area comprises of syenites, quartz-syenites and granites. The rocks are distinguished on the basis of field and petrographic observations. Petrochemically (19 analyses) the Babaji rocks are comagmatic and have the characteristics of an extensional type of plutonic suite, associated with rifting. There is a close correlation of available chemical indices of the studied suite with similar rocks elsewhere in the world.

R/25. Rafique, M., 1964-65. Geology and Petrology of Hakle-Mansehra Area. M.Sc. Thesis, Punjab University, Lahore, 170p.

The area mapped lies in the core of syntaxial bend and is designated as "Hakle Area" after the name of the locality. One geologic map is given with extensive readings of joints, foliation, lineation and general bedding.

The area consists of acid igneous rocks and regionally metamorphosed sediments. The acid rocks are Granites (classified as Mansehra and Hakle Granite) whereas the metamorphic include chlorite biotite schists, quartzites and garnet mica schists. A detailed study of Hakle Granite has been made for the first time. From the systematic study of the rocks it is concluded that

Because of the chemical similarities (except Soda which is abundant in Granites) between the Granites and country rocks, a genetic relation can be traced. Again because of field observations and chemical and mineralogical similarities, Hakle Granite is traced to be a late differentiate of Mansehra Granite which underwent potash and boron metasomatism. The previous view of antipathic relationship between tourmaline and biotite of Hakle Granite is contradicted. Structurally the area is folded into anticlines and synclines, the granites occupying the cores of anticlines while metamorphic form the synclines. The space for granites was provided by marginal faults and stoping.

Key words: Petrology, structure, metasediments, granites, Mansehra.

R/26. Rafique, M., Ashraf, M., Din, A. & Faruqi, F.A., 1976. Evaluation of glass sand deposits of Pezu, Bannu District, NWFP, Pakistan. Geological Bulletin, University of Punjab 13, 87-92.

Eight different silica sand samples (of Jurassic age) collected from Pezu region was investigated for their grain size distribution, chemical analysis, and removal of Fe₂O₃ contents and melting behavior. It has been found that sand Nos. 9S and 10S from Chunda after water washing and grading are among the best sands of the country. Sand Nos.

1S (Nar Kasha Tangi), 5S and 6S Terkhobai Ster are the medium quality sands. Most of the iron oxide present in the sands in the form of heavy minerals is of para-magnetic nature and magnet treatment is unnecessary. Sand Nos. 9S and 10S exhibit a good melting behavior.

Key words: Glass, silica sand, Pezu, Bannu.

R/27. Rafique, M., Chaudhry, M.A. & Chaudhry, M.N., 1988a. Chemistry, mineralogy and utilization of Kotli Azad Kashmir dolomite for making colorless glass. *Pakistan Journal of Scientific and Industrial Research* 31, 449-454.

Five dolomite formations of Lateri, Sawar, Kamroti, Nikial and Tattapani of Kotli area of Azad Kashmir have been studied in detail for their use in the manufacture of colourless glass. It has been shown that raw samples due to high iron content (more than 0.1 %) are not suitable for colourless glass making. However, after beneficiation, the iron content is reduced to 0.058% and 0.08% which is acceptable for colourless glass making. Experimental glass meltings containing 3.2 % MgO with the beneficiated dolomite samples gave satisfactory results.

R/28. Rafique, M., Chaudhry, M.A. & Chaudhry, M.N., 1988b. Studies on economic potentials of nepheline syenite of Koga (Swat) for making colorless glass. *Pakistan Journal of Scientific and Industrial Research* 31, 663-668.

Six samples of Nepheline syenite collected from Koga area (Swat, NWF) have been investigated to find their suitability for the manufacture of colourless glass. This work involves geology, microscopic study, crushing grinding, grading, chemical analysis, magnet treatment and glass melting. The iron content in the raw samples varied in the range 0.87 to 2.7 % rendering them unsuitable for colourless glass making. After magnetic separation, Fe₂O₃ is reduced (0.06 %) to a level which is acceptable for colourless glass making. Two glass compositions containing Al₂O₃ 1.5 % and 4.0 % suitable for container and fiber glass have been melted to produce colourless glass. The results are satisfactory.

R/33. Rahman, A., 1961. A gravity study of the granites in the Mansehra area, west Pakistan. Geological Bulletin, Punjab University 1, 15-20.

The results of a gravity survey of the granites and metamorphics near Mansehra are given. The residual gravity anomaly pattern does not, in general, follow very closely the geological structures, and the main mass of granite is thought to be in the form of a sheet. One very marked and circumscribed negative anomaly occurs over a small tourmaline granite intrusion for which a possible form has been calculated. To explain the anomaly a higher density contrast had to be assumed than that given by measurements of actual rock samples.

R/34. Rahman, A., 1964. A preliminary investigation by the self-potential method of a known galena deposit at Sobrah, Hazara District, West Pakistan. Geological Bulletin, Punjab University 4, 103-104.

Shams (1963) has given an account of lead mineralization in the Abbottabad Area, Hazara District. Self-potential survey has been carried out on one of the three galena occurrences which he has mentioned in this area; the Sobrah Lead deposit has been investigated to determine its possible extension and, hence, the feasibility of the economic exploitation of the mineral. In 1959, extraction of Lead was started at the Sobrah deposit, but the work was abandoned after a short time. Since then, no further attempt has been made to reconsider the possibility of mining at this site. Moreover, there exists no account of any Geophysical survey, before the mining was taken up. The only evidences of the deposit are the exposed galena-containing rocks in the nala, in the form of a thin vein, (Shams 1963). This Lead occurrence at Sobrah is an impregnation of Galena in a zone of fracture between the Hazara Slates and the Tanol Formation. To carry out the self-potential survey, an ABEM Self-potential equipment, with porous pots (copper in copper sulphate) was used. In view of the very rugged topography of the area, the gradient method was employed. The gradient of Self-potential was observed between two points, 30 ft. apart, along the profiles shown in figure 1. Because of the hindrance due to the cultivated fields, the lines of the profiles were run only along the accessible paths or along stream beds. The data thus collected was found to be insufficient for drawing the equipotential contours; therefore, only the ranges of the gradient of Self-potential were shown in the map (Fig. 1.). The gradient of Self-potential in the range of 100 to 250 mV/30 ft. was taken as high, that in the range of 50 to 100 mV/30 ft. was considered as medium, while that lying below 50 mV/30 ft. was classified as low. The high and medium gradients were marked on the map, the low gradients were not taken into account.

The high Self-potential gradients were observed to exist between Station Nos. 37-38, 44-45, 100-101, 102, 136-138 and 138-139, and the medium SP gradients were found between Stations Nos. 38-39, 102-103, 103-104 and 147-148. The highest value of gradients (245 mV/30 ft.) was found between Stations No. 136-138 and 138-139. These values were rechecked for shorter electrode-spacings and at different times but were found to be consistent with a deviation of 20 mV/30 ft. A high S. P. gradient observed between stations Nos. 37-38 and 44-45 could be due to some deep-seated ore body, as it shows a scattered type of anomaly. In the map (Fig. 1) the high gradients of S.P., shown on profile IV, lie on a band which also contains the mining pits. The extension of the band is in a direction N 45° W, which coincides with the strike of the ore body, exposed in the mining pits. In order to determine the extension of the ore body in the direction of the strike, two profiles, Nos. V and VI were run. All the S. P. gradient values found on these profiles were lower than 50 mV/30 ft., which probably shows that the galena deposit of Sobrah does not extend continuously beyond the profiles Nos. V and VI. It requires, however, more work to determine whether there are other galena deposits in the direction of the strike. Thus the Sobrah Galena Deposit has a limited extension in the direction of its strike and does not call for a full-scale mining operation.

R/35. Rahman, A., 1990-92. Geological mapping of Nauseri-Muzaffarabad-Garhi Habibullah area and evaluation of landslide hazards on western limb of Hazara-Kashmir Syntaxis. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 55p.

The northwestern part of Muzaffarabad and western limb of Hazara-Kashmir syntaxis is the area of high landslide hazards. Steep slopes silty, sandy and clayey soils, heavy rainfalls, water seepages and under cutting of the river all contribute to the landsliding in the region. The instability of the area has been further increased by road widening and effect of Main Boundary Thrust (MBT), resulting in the form of major landslides such as, slumping, earthflows, rockfalls, sinkholes and combination of these. The active Lohar Gali landslide is investigated in detail because of its large size and proximity to roadways. Soil samples were collected to evaluate engineering properties of material involved in these failures. The investigated area is a limb of Hazara Kashmir Syntaxis of folded and faulted, low grade metamorphic rocks, which have been further deformed by the important Muzaffarabad fault and regionally significant Main Boundary Thrust (MBT).

In addition, a landslide map of the area was prepared by performing field work. All slope failures were classified according to their movement and state, of activity with varying water content (1.5-12.3%), liquid limit (16.1-39%), plastic limit (0-2.0%), shrinkage limit (14.5-28.8%), absorption (0.69-3.9%), compaction (114.5 lb/cu.ft), dry density at 13.55 optimum moisture content, specific gravity (2.51-3.2), slake durability (5.1-24%); grain size analysis and breaking characteristics. The results suggest that slope failure occur due to high swelling potential of soils, active faults and shear failures.

R/37. Rahman, A.U., 1970. Geological report on Dunga Gali, Abbottabad. M.Sc. Thesis, Punjab University, Lahore, 83p.

A brief description of physiography of the area between Dunga Gali and Abbottabad is given with special reference to mass-wasting drainage, -its adjustment to structure, soils and terraces. The stratigraphy of rocks ranging in age from Paleozoic to Eocene is described. An attempt is made to reconstruct the environments of deposition of each formation. A description is given of structural observations made on faults, folds and bedding planes. A brief description of tectonic behaviour of each formation is also described. The Author has discussed very briefly the type of forces and tectonic framework which could create present tectonic style; and also attempted to reconstruct the evolutionary stages of the Himalayan geosyncline during its life span.

R/41. Rahman, F., 1972a. The study of geochemistry of the alteration products of the Susalgali granite gneiss, near Ahl, District Hazara, NWFP, Pakistan. Geological Bulletin, University of Punjab 9, 1-12.

On the Battal-Mansehra road and close to the Ahl rest house north of Abbottabad, Hazara district, there is a huge deposit of soft, friable, white-looking material. This has been repeatedly investigated, in the past, by many workers taking it as a deposit of kaolin clay; the reports have been both in favor as well as against this assumption. However, these reports were almost never based on detailed technical investigation, which had been the cause of widely variable conclusion.

The present paper has been written on the basis of chemical, microscopic, differential thermal and infrared spectrophotometric analyses and also on the basis of geochemical relationships, which exist between the soft, friable deposit and the immediately associated Susalgali granite gneiss. Moreover, it has been discovered that the deposit has got the same mineralogy and almost the same chemical composition as that of the surrounding granite gneiss and the deposit can not be other than but an alteration product of the surrounding rock.

Key words: Geochemistry, granite gneiss, alteration, Hazara.

R/42. Rahman, F., 1972b. The determination of gold by radiochemical and non-destructive neutron activation/radioactive analysis in some of the sulphide ore samples from Pakistan. Geological Bulletin, Punjab University 9, 37-42.

Four sulphide ore samples were selected from different localities in Pakistan, and were analysed by both radiochemical as well as by non-destructive neutron activation techniques. Only the results on gold are being presented in this paper. The nuclear reactor JEEP-II located at Kjeller (Norway), has been used as a source of neutrons. The samples were irradiated at a flux 1.5×10^{13} n/cm²/sec for one hour in case of radiochemical neutron activation experiment, and for half an hour in case of non-destructive neutron activation experiment. Following irradiation and "cooling" for two days, the respective samples were used directly for non-destructive analysis, whereas others were put to gold radiochemistry. ¹⁹⁸Au, half life 2.697 days, has been assayed in both the experiments. A lithium-drifted germanium detector, Ge (Li), has been used, along with a 16 bit computer (NORD-I) with 4K memory, to measure the gold activity.

R/44. Rahman, F., 1978. Estimation of silver by radiochemical neutron activation method and study of its geochemical distributing in selected sulphide ore samples from Pakistan. Geological Bulletin, Punjab University 15, 7-14.

With the intention of studying distribution of silver metal in sulfide ore samples of different composition and different origin, a careful selection of four sulfide ore samples was made. Their silver metal content was estimated by employing radiochemical neutron activation technique. 100 - 200 mg of pulverised, homogenised ore samples were irradiated by thermal neutrons (at a flux of 1.5×10^{13} n/cm²/sec) for 24 hours alongwith standard rock samples and synthetic standards for silver. These irradiated samples and standards were allowed to cool for three

weeks and then their silver content was separated and estimated by making radioactivity measurements of ^{110m}Ag via 657.8 keV . Finally geochemical relationship of silver with other coexisting metallogenic elements, under the then existing environments, was envisaged.

R/54. Rahman, M.A., 1980b. Electron probe data on brannerite and xenotime from District Muzaffarabad, Azad Kashmir. *Contributions to Geology of Pakistan* 1, 45-52.

Uranium mineralization hosted in the graphite schists of the Salkhala Series at Mauji-Reshian area in District Muzaffarabad Azad Kashmir indicated the presence of two sub-microscopic size mineral phases. These mineral phases were analyzed by mean of the electron probe microanalysis and identified as brannerite essentially a uranium titanium oxide and xenotime yttrium phosphorous oxide with thorium. Chemical data by the EPM on these minerals is provided and the results are discussed. The presence of the brannerite and xenotime in the graphite schists of the black shale origin is reported for the first time.

R/55. Rahman, M.A., 1981. Uranium-thorium mineralization in some granitic bodies of the Parachinar area, NWFP, Pakistan. *Geological Bulletin, Punjab University* 16, 23-36.

A uranium-thorium mineralization distributed in some granite gneiss and pegmatite bodies occurs in the Parachinar area, N. W. F. P. Laboratory investigations involving petrography, autoradiography, minerography and chemical analyses were conducted on sixteen selected rock samples from the area. The result indicated that allanite and radioactive epidote, present as accessory constituents of the granitic bodies, were the sources for both uranium and thorium. Another notable mineral was uraniferous limonite, which was present as secondary uranium enrichment, depending upon mobility of uranium and iron during weathering process. The study suggests that the mineralization is present in the form of discretely disseminated grains of allanite and radioactive epidote as well as uraniferous limonite in minor amounts.

R/56. Rahman, M.A., 1984. Mineralogy and genesis of uranium and associated metallic mineralization in graphite schists, District Muzaffarabad, Azad Kashmir. *Abstracts, First Geological Congress, Lahore*, 65-66.

The graphite schist belonging to the Salkhala Formation of Precambrian age is widely distributed in District Muzaffarabad, Azad Kashmir. Geological and mineralogical studies conducted on the graphite schist in the Mauji-Reshian area has indicated the presence of uranium mineralization associated with pyrite, graphite, rutile, chalcopyrite, marcasite, covellite, tetrahedrite and galena. Goethite is present as a secondary mineral.

Laboratory studies involving fission track radiography, autoradiography, mineragraphy, electron probe microanalysis and neutron activation analysis has indicated the presence of uranium and thorium as brannerite and xenotime respectively, as disseminated phases together with secondary uranium concentration in the fracture-filled goethite veins as well as graphite schist breccia.

The ubiquitous association of uranium and pyrite and the higher carbonaceous content of the graphite schist suggest an uraniferous black shale origin for the mineralization. Brannerite and xenotime show detrital character and were probably deposited in the black shale sediments. Secondary uranium is probably derived from organ-uranium complexes which occur in the graphite schist below the zone of oxidation.

Key words: Mineralogy, metallic minerals, graphite schist, Salkhalas, Muzaffarabad.

R/57. Rahman, M.A., 1991. Uranium minerals from Pakistan: A review. *Acta Mineralogica Pakistanica* 5, 99-108.

In Pakistan, at least fourteen U-Th-bearing minerals species occur widely distributed in sandstone, granite, pegmatite, carbonatite and graphite schist rocks. The primary minerals are mainly associated with the acid

intrusives, carbonatites and graphite schists showing the disseminated type of occurrence. Invariably, the mineralizations are associated with minor concentration of uraniferous Limonite due to oxidation by weathering. Secondary U mineralization indicates wider distribution and is mainly associated with the fluvial sandstone of Upper Miocene age. The nature of U-mineralizations and their petrogenetic significance are discussed.

R/59. Rahman, M.A. & Chaudhry, M.N., 1981. Geology and petrography of metamorphic rocks in Mauji and Reshian areas, District Muzaffarabad, Azad Kashmir. Geological Bulletin, University of Peshawar 14, 123-139.

Geological mapping was conducted in 13-km² area in Mauji and Reshian, District Muzaffarabad, Azad Kashmir. The work has involved detailed petrographic studies. Metasedimentary rocks in the Mauji-Reshian area consist of graphite, pelite and arenaceous schists with minor gypsum and calcareous bands belonging to the Salkhalas. These rocks are intruded by biotite granite gneiss and numerous dolerite dykes. The metasediments have been metamorphosed under the greenschist facies conditions. An almandine garnet schist has developed probably in the aureole around the biotite granite gneiss.

The mineralogical assemblage of the schist together with the presence of gypsum and calcareous bands in the area is indicative of flysch type deposits as a result of sedimentation under shallow water marine conditions. The graphite schist is characterized by extremely fine grained quartz averaging 50 µm in size, abundant carbonaceous material and ubiquitous presence of pyrite suggesting a black shale origin for these rocks.

Key words: Petrography, metamorphism, black shale, Salkhalas, Azad Kashmir.

R/60. Rahman, S., 1990-91. Structure, stratigraphy, micropaleontology and petrography of the western limb of the Hazara-Kashmir Syntaxis, Abbottabad and Manglaur areas, Northern Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 144p.

The Abbottabad and Manglaur area lies along the western extremity of the Hazara-Kashmir syntaxis. The area has been divided into two zones on the basis of structure and stratigraphy. Because the rocks of the blocks belong to different stratigraphic provinces and have become in contact with each other tectonically. These zones are Garhi Habibullah-Abbottabad (east of Panjal thrust) and Mansehra zone (west of Panjal thrust).

Rocks east of Panjal thrust in the area consist predominantly of Precambrian to Paleocene sedimentary and very low-grade metasedimentary rock units (Hazara Formation) that represents the first deformation and metamorphism in the Hazara area. Whereas, in west of Panjal thrust, the area consists of Cambrian granite gneisses and very low to low-grade metasedimentary (Tanol Formation) that represent D2 deformation and metamorphism associated with the Himalayan deformation phases. The grade of metamorphism varies from chlorite-grade in the south to biotite-grade in the north. The Mansehra zone is intruded by the Permian Panjal mafic dykes and sills of dolerite and basalts. These dolerite and basalts are mostly fresh. The sedimentary, metamorphic and intrusive igneous rocks of these zones are classified and characterized by petrographic studies. The stratigraphy of the area has been developed in which the Abbottabad group has been divided into three formations which are Sobrah, Kakul and Sirban formations. The redivision was marked by an unconformity between Sangargali and Mahmdagali of the Sobrah and Kakul formations.

The rocks have undergone at least three phases of deformation (D1, D2 & D3) and have been metamorphosed to greenschist facies. The first deformation D1 took place as a result of Hazaran orogeny and produced first fabric (S1) in the Hazara Formation which is generally parallel or slightly oblique to the original lithologic layering S0. D2 is associated thrusting and folding phase. Himalayan orogeny folded S1 into open and closed F2 folds that range in size from small kink bands to larger map scale folds. It caused development of penetrative S2 foliation axial planar

to F2 folds. D3 deformation phase associated with the formation of Hazara-Kashmir syntaxis and formed F3 cross folds.

Key words: Structure, stratigraphy, petrography, Hazara-Kashmir Syntaxis, Abbottabad.

R/61. Rahmanullah, Ahmad, I. & Khan, K., 1999. Petrography of uraniferous quartzo-feldspathic veins and their wall rock from Marghazar, Lower Swat, Pakistan. M.Sc. Thesis, University of Peshawar, 71p.

The Lower Swat area consists of the Cambrian-Ordovician Swat granite gneisses that have intruded the metasedimentary rocks of the Precambrian Manglaur Formation and are overlain unconformably by the Paleozoic-Mesozoic metasedimentary rocks of the Alpurai group. The Swat gneisses contain minor amounts of younger tourmaline granite gneiss particularly at their margins. Besides locally (e.g. in the Marghazar area) the Swat gneisses host several quartzo-feldspathic vein systems, some of which are associated with radioactive element(s) mineralization.

The Swat gneisses are mostly medium-grained xenoblastic and almost equigranular. However at places they display a porphyroblastic augen-flaser texture. They consist of a variety of minerals. These in the order of decreasing abundance include quartz, alkali feldspar, plagioclase, muscovite, biotite, tourmaline, garnet, apatite, zircon and epidote. The metasedimentary rocks that are in contact with the Swat granite gneiss in the Marghazar area and elsewhere in Lower Swat belong to the Marghazar Formation - the lower most unit of the Alpurai group. They are fine- to medium grained xenoblastic and almost equigranular. They consist of quartz muscovite, biotite. Tourmaline, alkali feldspar and iron ore. They show well-developed schistosity due to the preferred orientation of muscovite, biotite and tourmaline. The radioactive quartzo-feldspathic veins are mostly medium-grained, xenoblastic to hypidioblastic and almost equigranular. They consist of distinct layers, which are alternately dominated by quartz and feldspar. With the exception of the radioactive minerals, the mineralogical composition of the vein systems is almost similar to that of the wall rock. In the order of decreasing abundance, the vein minerals include quartz, alkali feldspar, plagioclase, radioactive minerals, Iron ore, epidote, muscovite, biotite and tourmaline. The vein systems are associated with typical wall rock alteration phenomena that include kaolinitization, chloritization and epidotization. Reflected light study reveals that the radioactive minerals in the vein systems consist of pitchblende uraninite and allanite.

Field observations and mineralogical and textural characteristics suggest that the vein systems and their associated radioactive element mineralization resulted from a hydrothermal activity. The preferred orientation displayed by the vein minerals themselves indicates that the hydrothermal activity took place during a major phase of deformation and as such the veins are syntectonic in origin. The source of the hydrothermal solutions which formed the vein systems and their associated mineralization seems to be the relatively young syntectonic tourmaline granite that occurs at the margins of the Swat granite gneisses.

R/63. Raja, M.A.K., 1985-87. The geology and petrography of volcanic and carbonate rocks of upper Haveli (District Bagh) & Balgiran-Manjhote District Muzaffarabad with special emphasis on Dara marble. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 110p.

The project area covers about 417 square kilometers located in District Bagh and Muzaffarabad, Azad Kashmir. The work has involved geological mapping of the area on a scale of 1:25,000 and 1:15,000 respectively. This thesis deals with the geology and petrography of Panjal Volcanics and carbonate rocks of the area. The geological sequence of the area consists of sedimentary, volcanics and metamorphic rocks. Lithologically metamorphic rocks present in the area are Schist, Slates, Phyllites, Quartzite and marble while sedimentary rocks comprise Sand stone, shales, silt stone, lime stone. Volcanic rocks belong to two distinct ages. Dogra trap are of Precambrian age and occur with in

the Dogra Slates. Panjal volcanics or Panjal trap flows are of Upper Carboniferous age and basaltic to andesitic in composition, while mineralogical studies of Dogra trap shows that they are of basaltic composition. Petrographic analysis of Panjal volcanics, Agglomeratic slates, limestone and marble have been carried out. The mineral assemblage in volcanics is plagioclase + chlorite + epidote + Quartz + Calcite, while of agglomeratic slates is Quartz + epidote + chlorite + Calcite + plagioclase the mineralogical assemblage of lime stone and marble is calcite + quartz + muscovite + magnetite. Pb-Zn mineralization in carbonate rocks of Khetar-Treri areas has been interpreted. The evidences are strongly supporting that Pb-Zn mineralization is the result of hydrothermal solution. Petrogenesis of Panjal Volcanics has been carried out. The evidences reveal shallow water or submarine origin of the Panjal Volcanics. Tectonically the area is highly disturbed, being involved in Himalayan orogeny.

R/64. Raja, M.K., 1981-83. Geology and petrology of Lower Yasin Valley, Gilgit Agency. M.Sc. Thesis, Punjab University, Lahore, 85p.

The project, area lies in central Punial area, adjoining to Yasin Valley, Gilgit Agency. The area is located in Karakoram Mountains. Area is intensely disturbed tectonically being involved in Himalayan orogeny. Evidence is provided by crushing and strained effect on minerals. Project area is composed mainly of igneous rocks and metasedimentary rocks. These different rock units are shown on map which was previously prepared by enlargement of toposheet. The major units in the project area are granite, diorite, amphibolite and paragneisse.

Special emphasis was given to the mineralogical description and petrographic analysis of the rock units and is reported in detail. The petrogenesis of these rock units have been discussed as well.

Granite is considered to be a part of Karakoram axial granite, which is emplaced as a partially fused and mobile mass rich in alkali feldspar during synthetic phase of orogeny. Diorite is probably tholeiitic basaltic magma injection. Granodiorite produced during differentiation with decrease of calcic contents. Green stone is metamorphic product of basic igneous rocks. Extensive glaciations of quaternary period is evident and glacial deposits are found commonly. The economic mineral potential of the project area is also discussed.

R/67. Raja, M.K.K., 1987b. General Geology and Petrography of Chham-Traran area, Jhelum valley, Azad Kashmir. *Acta Mineralogica Pakistanica* 3, 116-122.

A geological map of the Chham Traran area, Jhelum Valley is prepared at a scale of 1:50,000 and a detailed description of various rocks units is presented. Pelitic to psammitic, calcareous and carbonaceous rock sequence of the Salkhala Formation is intruded by a body of granite gneiss. The Panjal Formation (volcanics) is thrust over Precambrian Salkhala Formation and over ridden by the Upper Tertiary Murree Formation. Petrography and mineral assemblages of the Salkhala Formation resemble those of low-grade metamorphites. Presence of gypsum bands in the Panjal Formation is of volcanic nature. Economic Geology of the area is also outlined.

R/69. Ramsay, J.G., F.R.S. 1987. The syntaxes of the western Himalayas. Tectonic Evolution of the Himalayas and Tibet. The Royal society Special meeting.

Syntaxial bends are regions where the overall structural trends of fold axes and fault traces make marked regional changes in directions. In the western Himalayas, several such re-entrants are known and in the two major bends of the Hazara and Nanga Parbat syntaxes the structural trends of folds and major suture lines change direction through angles of 180° . Although these syntaxes occur at differing tectonic levels both show overall features of elongated domes or partial domes, and new data suggest that there may be a physical and temporal connection between them.

Several mechanisms have been invoked for forming syntaxial bends: (1) geometric interference within cover structures produced during two separate orogenies or two phases within a single orogeny; (2) reactivation of pre-existing basement structures (folds or faults) during a later orogenic compression; (3) development of complex ramp-flat geometry during the formation of major thrust sheets, especially, that resulting from the formation of oblique-ramps or sidewall-ramps; and (4) differential displacement advance within thrust sheets perhaps associated with partial pinning in or around syntaxial zones.

In the Hazara syntaxis the geometric features of the large-scale structure and small-scale features of folds, cleavage, lineation, and vein systems support the evolution of this syntaxis by progressive change in the regional shortening directions from NE-SW, through N-S and finally to NW-SE directed contractions. The structural features of the Nanga Parbat syntaxis also suggest a complex polyphase movement history with the principal syntaxial form arising relatively late during the regional deformation sequences perhaps as a result of sinistral movement on a deep-seated shear zone.

R/71. Rao, S.R.N., 1941. An algal flora from the Lockhart limestone (Ranikot Series) of the Samana Range (NW India). Mysor University Journal 2(7), 41-53.

Lockhart limestone is the name given by Lt.-Col. L. M. Davies to a compact, massive, grey limestone of some 200 feet in thickness, occurring in the region of Fort Lockhart on the Samana Range between Kohat and Thal. The Samana series as worked out by him consists of 12 beds; beds 8-12 (uppermost members of the sequence) are of Ranikot age, while the base of the series (bed 1) extends down to the Jurassic (or even the Triassic). The Lockhart limestone (bed 10) represents the uppermost portion of the Lower Ranikot and the lower portion of the Upper Ranikot.

R/72. Rasheed, A., 1992-94. Geology of Sirgh area and sedimentary petrology of Kuldana Formation of Darya Gali, South Hazara, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 143p.

A comprehensive study of geology and structure of the area around Dhamtaur & Sirgah is presented along with a special section on the sedimentology of Kuldana Formation. Large scale (1: 10000) geological mapping of the area is, presented. The lithostratigraphic unit ranges from Precambrian to Eocene. Hazara Formation and Patala Formation being the oldest and youngest units respectively. Structurally the area comprises NE-SW trending double plunging folds constituting anticlinoria and synclinoria. The folds in general are cylindrical with a general vergence to the southeast. The folded sequence is disturbed mainly by reverse faults. A small number of normal faults also exist. Faulting is dip slip to oblique slip and in general involves a maximum displacement of few hundred meters. Apart from the regular faults decoupling is frequently noted at the formational boundaries leading to the slip and discontinuity of thin marker horizons. The lower Eocene Kuldana Formation is mainly composed of variegated Series of marl siltstone arenaceous mudstone and limestone. The siltstone horizons are rare but intercalation of sandstone may be found in places. The mudstone as well as calcareous mudstone are generally unfossiliferous. The conditions of deposition vary widely from subtidal to intertidal and supersubtidal. The red beds are either continental or supertidal. Alternately they may have derived their colour by diagenetic processes.

The project area covers about 307 square kilometers, located between Reshian and Jura to the ESE and NE of Muzaffarabad, Azad Kashmir. The work has involved geological mapping of the area on a scale of 1:25,000. In this thesis an attempt has been made to introduce the detailed geology of the area. Bulk geological sequence of the area consists of sedimentary, volcanic, metamorphic and granitic rocks. The area is tectonically, highly disturbed being involved in Himalayan orogeny. For Petrographic analysis sixty thin sections were studied microscopically. Petrogenesis of the rocks particularly that of Jura and Reshian granites are interpreted. Tectonic setting and stratigraphy of the area are described briefly. Major and minor structures of the area are described with the help of figures and maps. Economic rocks and minerals found in the have been described in detail to some extent.

Key words: Petrology, granite, economic minerals, Azad Kashmir.

R/76. Rashid, C.M., Afzal, P.A. & Majid, A.A., 1997. Uranium potential of the Potwar Plateau. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 2p.

Present studies are aimed at decisively evaluating middle Siwaliks (MS) of Potwar region for its uranium potential through geological modeling based upon the AEMC previous work and work of other professional organizations. Numerous radioactive anomalies and availability of sufficient geological data on this region helped to achieve the desired results. Out of comprehensive platform studies only uranium mineralization part is being discussed.

The Potwar Plateau has been divided into four subregions i.e. Northwest (NW). Southwest (SW). Northeast (NE) and Southeast (SE) PP. 8] out of total 127 radioactive occurrences scattered all over the PP were sub to detailed studies. The time-space distribution of anomalous sandstone horizons (ASH). Stratigraphic levels of host rock i.e. lower, middle and upper within this formation, radioactive zones, primary/secondary uranium mineralization and controls of radioactivity were geologically and statistically analyzed.

The radioactive occurrence are clustered in 17 anomalous zones considered as representative, at least partly, of some, above regional clark, uranium remobilization. The anomalous zones have been further sub-divided in 8 first rate and 9 second rate, on the basis of their geological environment and to the density, zone, uranium return and controls there anomalies. Conclusion based upon the syntheses and interpretation of data are as follow:

On regional basis, six (sub) units may be singled out as displaying a much better load in first rate anomalous zones. Time wise, the DPF on a formation basis and the lower NF, then the middle DPF, on a member basis. Space wise, the WPP, more specially its SE corner (lower NF and middle DPF), central part (middle DPF) and NW corner (upper NF and upper DPF).

Key words: Economic geology, uranium, Potwar plateau.

R/77. Rashid, C.M., Afzal, P.A. & Majid, A.A., 1998. Multistage role of tectonic deformation on uranium mineralization in the neogene fluviatile middle Siwaliks of the Potwar Plateau, Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 165-166.

The evolution of uranium mineralization in the middle Siwalik (Nagri and Dhok Pathan Formations) of the Potwar Plateau is characterized by syn to post tectonic sedimentary deformation through space/time. This indicates a sequence of regional events, providing channel ways and media for remobilization and uranium trapping with some reductants or along permeability/ porosity barriers.

The syndiagenetic traps are mainly tectonically induced and associated in space i.e., on the lesser sloping, down thrown side of stream checking and reactivated basement faults. The post middle Siwaliks tectonic deformation caused Uranium epigenetic remobilization and its down dip concentration. It is enhanced to increasing of slope and or/ oxidation i.e., on the upthrown side of stream checking faults, water table checking lineaments.

Detailed analysis of different tectonic elements and their chronology and uranium favourability criteria (availability, remobilization and trapping) in each tectonic regions of the Potwar Plateau (PP) has been carried out. Some interesting correlation parameters have been revealed after studying the impact of the tectonic setting on the uranium mineralization. All the 81 uranium anomalies in the middle Siwalik are grouped into 8 first rate and nine second rate anomalous zones: depending upon extent, nature and controls of radioactivity/mineralization. All the four tectonic regions of the PP i.e. North Potwar Deformed Zone (NPDZ), South Western Potwar Plateau (SWPP), East Potwar Plateau (EPP) and South East Potwar Plateau Corner (SEPP Corner), show different tectonic controls of individual anomalies as well as anomalous zones. In NPDZ the anomalous zones are controlled by minor NW-SE faults and the tight synclinal structures. In the SWPP, the control of uranium is down faulted blocks and incipient gentle folds. In EPP and SEPP corner the anomalous zones are located along W-E to NE-SW thrust faults, mainly on the northern flank of anticlinal structures.

Distribution pattern of uranium occurrences and their relationship with tectonic features (ductile and brittle) indicate western Potwar Plateau comparatively more favourable than the eastern Potwar Plateau. In SWPP appear to be the most favourable area for uranium exploration due to good source (synsedimentary arial volcanism), syn to digenetic remobilization/trapping evidences in the central western Potwar along down faulted blocks and incipient gentle folds as well as epigenetic post tectonic remobilization/trapping along Salt Range Thrust (Fig. 2).

There are six large-scale tectonic units in the SWPP namely:

Either NE trending, north to south; Lower Soan trough, Tamman ridge, Dhok Mosahib Wala trough to the NE and Chakarala basin to the SW (a composite unit most likely subdivided by secondary ridges and troughs), Western Salt Range. Or NW-trending; from west to east; Southern Kalabagh Salt Ranges, Pachnand ridge (rather subdued, but partly closing and possibly offsetting the Dhok Mosahib Wala trough and Chakarala basin).

Moreover the matallotects might be further enhanced by the possible remobilization or trapping action of oil driven products migrating upwards through deep seated active faults from known underlying oil reservoirs and source rocks through release of CO₂, H₂S etc. in the underground waters. Evidences of such migrations upwards have been noted nearby majority of significant anomalous zones located over or close to known oil structures i.e., Jand (Dakhni oil field), Pindigheb (Dhulian), Khaur (Khaur), Tamman Talagang (Kot Sarang), Joyamair (Joyamair), Adhi (Adhi), Dina (Lehri gasfield), Chakarala (Dadhumber oil structure), Dhok Masahi Wala (Dhermud) producing or now barren.

At anomalies level, PanaKhel anomalous sandstone horizon Jand in Upper Nagri Formation indicates genetic relationship with hydrocarbon derived reducing fluids. Oil products contribution is also visible in the form of solid bitumen collected around the Nikki anomaly (Chakarala). It is first clue on the migration of oil products as far as the lower DPF.

R/78. Rashid, M.A., Hussain, M., Master, J.M. & Meissner, C.R., 1965. Mineral deposits of eastern Kohat region, West Pakistan. GSP Records 13(2), 16p.

Key words: Mineral deposits, Kohat.

R/79. Rashid, M.A. & Khan, A.L., 1991. Bed rock aggregate resources of the Attock District, Punjab, Pakistan. GSP, Information Release 409.

Reserve evaluation of selected bed rock aggregate resources of the area comprising Fateh Jang (43 C/10) and Kot Fateh Khan (43 C/11) quadrangles of Attock District in the Punjab Province, is presented.

Limestone and sandstone are the two rock types considered for evaluation. Vast reserves of alluvial clay, commonly used for pottery and brick making, sand and gravel, available in the area but outside the scope of the present work, have not been considered for estimation.

Limestone aggregate resources of the Jurassic Samana Suk, Paleocene Lockhart Limestone and Eocene Margala Hill Limestone Formations exposed in the area, have been estimated as 1734 million tonnes.

Sandstone aggregate resources of the Murree and Kamalial Formations of Miocene age, exposed in the area, have been estimated as 1266 million tonnes.

Key words: Aggregate resources, sandstone, limestone, Attock.

R/80. Rashid, S., 1993-95. Electrical resistivity survey for ground water exploration in Zulmkote Area, District Malakand, NWFP, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 110p.

R/81. Rashid, S., 1994-96. Geology and structure of Barian Area, Hazara, NW Himalayas and Petrography of the Early Cretaceous Lumshiwal Formation. M.Sc. Thesis, Punjab University, Lahore, 124p.

It is the study of Geology and Structure of the Barian area (50 km²) along with a special microfacies study of the Early Cretaceous Formation from Kalas. A large-scale geologic map of the Barian area at (1:10,000) is presented. The area comprised sedimentary rocks from Middle Jurassic to Early Miocene age, tectonically forming a part of the lesser Himalayan sequence in the Galiat area, Hazara. The paleogene and older sequence is mainly limestone and shales of shallow massive shelf facies. The overlying Neogene rocks are gypsiferous marls. Limestone and shale supratidal to Sabkha facies in the lower sandstone, shale continental molasse of Murree Formation in the upper part. Structurally the area comprised NE-SW trending cylindrical to double plunging folds constituting anticlinoria and synclinoria. The folded sequence is disturbed by numerous reverse faults. However, small number of normal faults also exist. Faults are either dip slip or oblique slip and except for the MBT, involves a maximum displacement of few hundred meters.

MBT is the major tectonic discontinuity of regional significance. At Darya Gali the thrust is a high angle feature dipping to the northwest with opposing dips in the rocks on the two sides. The surface expression of the MBT is accompanied by a fault-related escarpment and much degradation, accompanied by landsliding.

The Kalas section of Lumshiwal Formation comprises six facies and sixteen microfacies. The sandstone is predominantly medium grained and only four microfacies are fine grained. Quartz, carbonate and glauconite are the common cements while iron oxides and clay occur as subordinate cements. At Kalas presence of ooids in the lower part of Lumshiwal Formation indicates shallowing of basin and high-energy environment while glauconite in the upper part indicates reducing subtidal environment.

R/82. Rashid, S., Ahmed, S. & Sheikh, M.I., 2001. Natural resources of Islamabad-Rawalpindi northern Punjab, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.47.

Islamabad, the capital of Pakistan is a planned city constructed since about 1960 at the foot of Margala hills just north of the old city of Rawalpindi. The limestone gravel, sand and clay are the most important material resources of Islamabad, which have been utilized as construction material resources. These are limestone/gravel for cement, aggregate for concrete, sand for mortar and clay for bricks and pottery. Huge reserves of these items (limestone, gravel, sand, aggregate and clay) are qualitatively and quantitatively present which can fulfil the demands of constructing materials with rapid increase of population of Islamabad/Rawalpindi Metropolitan area. Abandoned pits of gravels, sand and clay can be reclaimed for recreation parks, reserved forest, waste disposal and agriculture use.

Key words: Natural resources, Rawalpindi, Islamabad.

R/84. Rashid, S., Khan, A.Q. & Asghar, K., 2000. Hydrological studies and groundwater potential of Islamabad region. Abstracts, Third South Asia Geological Congress, Lahore, 158-159.

Islamabad is the capital city of Pakistan situated between latitude 33° 29' and 33°-49' N and longitude 72°-50' to 72°-24' E bordered by Rawalpindi city in the South and Southeast, Margalla hills in the North and Murree Hills in the Northeast. Climatically the area lies in sub-humid region. Annual average rainfall is about 925 mm. Temperature ranges between 3° to 40 °C. Access to city is through Grand Trunk road and Motorway, connected with Peshawar and Lahore. The area is generally an uneven landform covered with alluvial deposits and bedrock outcrops of Miocene Rawalpindi Group (Murree Formation) skirted by Eocene Margalla Hill limestone in the North. The northern mountainous area rises abruptly and appears as Himalayan foothill extension. The area is drained by many perennial streams out of which Korang river, Gumrah Kas, Kantiwali Kas, Tanawala Kas, Bedarwali Kas and Lei Nala are the major constituents of drainage system. During rainy season the velocity of water is very fast in these hill torrents due to high relief and slope of the area.

Hydrogeologically, the area lies in Soan River catchment basin in Potwar Plateau formed as part of Indo-Gangetic synclinorium of Tertiary and Pre-Tertiary sediments, Consolidated and unconsolidated deposits exposed in the area are of sedimentary origin and belong to Eocene to Recent in age. The consolidated deposits are mainly composed of limestone, sandstone, clay, shale and conglomerates. These deposits do not serve as aquifer and water travels through joints, cracks and fissures only. Unconsolidated deposits of recent age are found as terrace gravel and alluvial fill.

Groundwater in Islamabad area occurs in alluvial deposits and hardrock deposits. The transmitting capacity of consolidated deposits is very low. Therefore, it can be considered only for small yields for requirements at the places of acute local shortage of water availability. Nevertheless alluvial aquifers are suitable for large scale groundwater development.

In order to locate the sites feasible for exploitation of groundwater, hydrogeological and geophysical surveys were carried out in 1979-80 referred to Hydrogeology Directorate, WAPDA by Capital Development Authority to overcome the acute shortage of drinking water in the capital city. The work was conducted to locate prospective sites by spot investigation in different sectors selected on priority bases fixed by Capital Development Authority.

The work was completed in two phases, phase-I included sectors F-10, F-11, G-9, G-10, G11, H-9 and National Park area and phase-II covered sectors F-8 and 1-9. Based on the findings of reconnaissance and geophysical survey test drilling and water sampling from various subsurface horizons at 21 locations were carried out. An aquifer test was also conducted to determine the aquifer parameters. Groundwater samples collected during survey and test drilling were got analyzed from WAPDA laboratory. The groundwater quality is good and suitable for drinking, agriculture and other domestic uses. Findings of these studies are summarized in this paper.

R/85. Rashid, S., Malik, M.H. & Khan, M.S., 2000. Elaboration of aquifer system and its application for protection of groundwater contamination in the Dhamrah Kas Basin, Wah Cantt. Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, p.161.

Interdisciplinary investigational techniques 1 (hydrogeological reconnaissance, Geophysical survey, Testhole drilling, installation of tubewells and capacity tests) were used for the interpretation of subsurface hydrogeology of the Dhamrah Kas Basin. A multilayered aquifer system spread over an area of about 150 Sq. Km was proved with the help of 20 test holes and 10 dug wells extending to a depth of 300 to 600 feet. The aquifer is classified as multilayered semiconfined fresh body with an average well capacity of 250-350 gallons. The shallow aquifer (A-Layer) is in severe danger of contamination near northern boundary of the basin through induced recharge from a polluted nullah. The bacterial contamination Coliform Faecal Coliform) has polluted shallow aquifer very severely. Treatment and protection measures are discussed, particularly for elimination of physical and bacterial pollution.

R/89. Rauf, A., 1974-76. Geology of Taghma Area, Swat District, NWFP Pakistan. M.Sc. Thesis, Punjab University, Lahore, 79p.

This report presents a geological map on a scale of 4.735 cms to a km (3 inches to a mile) and petrographic account of the rocks of Taghma area, which were previously mapped as a single units (Upper Swat Hornblendic Group of Martin et al. 1962 and Epidote Amphibolites of Jan et al. 1973). The present mapping on a larger scale has permitted the further sub division of the rocks of the area into various types of plutonic rocks, like peridotites, diorites, hornblendites and pegmatites; metamorphosed rocks, like amphibolites and gneisses; and their secondary alteration products such as China clay and serpentinites.

Petrographic description of various rock types have been included, which is based on the study of more than fifty thin sections, selected from two hundred rock samples collected during field work. The mineralogical data presented in this report includes the optical data on certain selected mineral; their micrometric measurements, refractive indices measured by liquid immersion method, determination of end member composition using 2V and extinction angles. Discussion and conclusions regarding petrogenesis, based on field relations, petrography and mineralogy of various rock units of the area are also given in this report. The structural features of the rocks are also described, based on the three hundred joints and foliation measurements. The foliation and joints orientation diagrams are also included. An account of the economic geology of the area is included, putting more emphasis on that of the china

clay deposits situated inside the Taghma area. Important features of field as well as of thin sections are expressed with the help of photographs.

R/92. Raynolds, R.G.H., 1981. Did the ancestral Indus flow into the Ganges drainage? *Geological Bulletin, University of Peshawar* 14, 141-150.

The Late Miocene, Pliocene and Pleistocene Upper Siwalik Group molasse sediments of the eastern Potwar Plateau are shown to include two distinctive sandstone complexes. The older sandstone complex is white colored and carries granitic pebbles. The younger sandstone complex is brown colored and carries quartzite and igneous pebbles. Palaeocurrent measurements together with preliminary provenance analysis suggest that the white sandstones were deposited by and ancestral Indus River which flowed to the east-northeast across the Eastern Potwar Plateau. This river system was replaced between 4.5 – 5.0 MY ago by a southward flowing ancestral Jhelum River. It is possible that the ancestral Indus River may have drained into the Bay of Bengal Rather than into the Arabian Sea.

Key words: Indus River, sandstone, Miocene, Pliocene, Pleistocene, Potwar plateau.

R/93. Raynolds, R.G.H. & Johnson, G.D., 1985. Rate of Neogene depositional and deformational processes, northwestern Himalayan foredeep margin, Pakistan. In: Snelling, N.J. (ed.), *The chronology of the geological records*. Geological Society, London, Special Publication 10, 297-311.

The dynamics of molasse accumulation and the subsequent structural displacement of a foredeep basin during orogenesis have rarely been chronometrically defined. The Himalayan foothill belt of northern Pakistan and India constitutes a detailed record of molasse sedimentation in a classical foredeep setting. Subsequent deformation of this sedimentary sequence has resulted in the exposure of over 3000 metres of the Neogene and Quaternary aged Siwalik Group. Recently, the development of a magnetic polarity stratigraphy constrained by the fission-track dating of numerous intercalated volcanic ashes has permitted a precise chronostratigraphic statement to be made concerning the accumulation and deformational history of this non-marine sedimentary sequence. Data from numerous localities in northern Pakistan and India document the onset, development, and termination of various events in this sedimentation history with a precision of from ~20000 to ~50000 yrs. Sediment accumulation rates associated with the progressive migration of the foredeep depocentre have been determined to range from -20 to -50 cm/1000 yrs. The southward progradation of lateral facies changes at rates of up to 30 m/1000 yrs together with the southward advance of the basin depocentre at rates of over 20 m/1000 yrs suggest a rough equilibrium between the modelled northward plate motion of the Indian subcontinent and the southward displacement of depositional processes within the foredeep. This illustration of the dynamic involvement of proximal foredeep terraine in the continuing Himalayan orogenesis yields a model potentially useful in similar tectonic settings.

Key words: Stratigraphy, molasses, marine sediments, sedimentation, deformation, Potwar.

R/94. Raynolds, R.G.H., Johnson, G.D., Johnson, N.M. & Opdyke, N.D., 1980. The siwalik molasse: A sedimentary record of orogeny. Geological Bulletin, University of Peshawar 13, 47-50.

The Siwalik molasse basin lies on the southern margin of the Himalayan orogenic belt. Continuously exposed from the Sulaiman Range in western Pakistan to Assam in the eastern India, the Siwalik sediments consist of over 7000 meters of fluvial sediments ranging in age from late Miocene to Pleistocene.

The continuation of the mountain building activity which first uplift the source area to the north, is now responsible for the deformation and hence exposure of these sediments. This deformation characteristically diminishes in intensity southwards from a boundary thrust fault to the undisturbed Indo-Pakistan shield.

The Siwalik sediments have been extensively studied – initially because of their excellent record of late Tertiary mammalian evolution and more recently, because of their record of source area unroofing and changing sedimentary environments.

Key words: Orogeny, sedimentary, molasses, siwaliks.

R/95. Raza, H.A., 1981. Geothermal gradients in Pakistan. Geological Bulletin, Punjab University 16, 71-82.

Hydrocarbons are generated by thermal diagenesis of organic matter. The study of sub-surface temperatures and thermal gradients within the earth, therefore, offers clues for hydrocarbon exploration. Temperature ranges within which particular types of hydrocarbons, for example oil or gas, would form are now well known. Geothermal gradients as determined from bottom hole temperatures recorded during logging operations in 27 wells drilled in Pakistan show that general geothermal gradients in Pakistan are between 1 and 2°F per 100 feet. The gradients are comparatively higher in the south perhaps because of the Cretaceous/Paleocene igneous activity. Oil window i.e. the depth sector having prospects for liquid hydrocarbons, lies at variable depths in different regions but within the depth range 6,000 to 18,000 feet.

Key words: Hydrocarbons, geothermal gradient.

R/96. Raza, H.A., 1984. Estimating the volume of oil and gas resources in Pakistan. Abstracts, First Pakistan Geological Congress, Lahore, 2-3.

There are four standard methods of estimating ultimately recoverable oil and gas: (1) Past Performance extrapolation (2) Volumetric (3) Geologic-Analog (4) Play Analysis. Computer techniques can be combined with these methods to determine probability ranges. The basin area of Pakistan can be divided into a number of petroleum zones on the basis of similarities in producing horizons, types of hydrocarbons and kinds of traps. Some of the aforementioned methods are suggested for these zones to assess the quantity of oil and gas likely to exist in them. The choice of method has been based on the level to exploration in a particular zone.

Key words: Hydrocarbons, Pakistan.

R/97. Raza, H.A., 1986. Evolution of sedimentary basins in Pakistan and their hydrocarbon potential. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, p.12.

Sedimentary basins of Pakistan evolved as a result of plate interactions that went with the Paleozoic formation of the Pangean superplate and its subsequent fragmentation, Cenozoic collision of the Indian and Eurasian plates and subduction of the Arabian plate under Eurasian plate. The ultimate recoverable hydrocarbon resources of Pakistani basins amount to about 53x10⁹ bbl of oil and 143x10¹² cubic feet of gas; the Potwar, Sulaiman and Kirthar subbasins are current producers.

Key words: Hydrocarbons, sedimentary basin, plate collision.

R/98. Raza, H.A., 1991. Petroleum source rock in Pakistan. International Petroleum Seminar, Islamabad.

R/99. Raza, H.A., 1992-93. Plate interactions, basin development and implications for hydrocarbon accumulation in Pakistan. Regional Postgraduate Training Course in Plate Tectonics, Punjab University, 33-34.

Hydrocarbons reside in sedimentary basins which are produced as a consequence of plate interactions. The lithosphere is formed of a network of 13 large plates which converge, diverge or slip-by relative to each other. In this process new crust is created while the earlier is destroyed.

Worldwide more than 600 basins are known which are classified into 5-8 main types based on location, tectonics and deposition. The concept of plate tectonics is the key element in basin classification. Pakistan's 3 sedimentary basins: Indus, Baluchistan and Pishin contain a number of distinct petroleum zones which exhibit varying prospectivities for occurrence of oil and gas. The area suitable for oil and gas exploration in Pakistan forms 2/3rd part of its total area.

Geologically, northern part of the Indus basin contains the most complete sedimentary column (Precambrian to Recent). The plate tectonics were active over Indus basin since Permian and the first collision of the Indian plate, where Indus basin sits, with the Eurasian plate occurred in Paleocene time. The subduction is an ongoing process. The Baluchistan basin contains sediments of Cretaceous-Recent ages. Its tectonics are comparatively young and involve subduction of oceanic crust of Arabian plate beneath Eurasian plate. Pishin basin is also a young basin (Cenozoic) containing flysch derived from surrounding high blocks. Its development took place in plate margin region. Indus basin is the only producing basin of Pakistan which contains more than 80 oil, gas and condensate discoveries including 2 world class giant gas fields, Baluchistan basin is under-explored and Pishin is a frontier, both hold prospects for future.

R/110. Raza, S.M., 1984. Siwalik lithofacies and Himalayan orogeny; A preliminary appraisal. Abstracts, First Pakistan Geological Congress, Lahore, 53-54.

The rocks of the Siwalik Group of the Subhimalayan ranges can be arranged in three mega fining-upward sequence (MFUS) which roughly corresponds to the conventional tripartite subdivision of the Lower, Middle and Upper Siwalik subgroups. The three MFUS's can be recognized by their peculiar lithofacies, heavy-mineral compositions, and faunal characteristics. Recent calibration of the Siwalik sequences in the Potwar Plateau through the magnetic polarity stratigraphy suggest that the Siwalik Group ranges from 18 Ma B.P. to as recent as 600,000 years B.P. Within this temporal framework, each of the MFUS (in ascending order) spans approximately 8 million years, 5 million years and 4.5 million years, respectively. The transition from one to the next MFUS in various parts of the Potwar Plateau may fluctuate on the order of 10~ years.

The deposition of the fluvial Siwalik rocks along the southern foothills of the Himalayan orogenic belt are considered to be the consequence of underthrusting of the Indo-Pak Plate with the Asian plate (s). Thus, the appearance of various tectonic elements and the episodic uplift of the Himalayan mountains are expected to seriously effect and control lithofacies composition of the Siwalik rocks. An approximate correspondence exist

between the development of major Himalayan tectonic elements and the initiation of each of the MFUS. Three of the significant correlations proposed here are the appearance of MCT (around 20-18 Ma B.P.) and the beginning of the MFUS I (around 18 Ma. B.P.), the MBT and the MFUS II (around 10 Ma B.P.), and the MFT coinciding with the establishment of almost modern physiography (around 1 to 0.5 Ma B.P.).

R/112. Raza, S.M., 1997. Vertebrate fauna and taphonomy of the Middle Miocene Chinji Formation in the stratotype Chinji area, southern Potwar Plateau, Pakistan. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. GSP, Records 109, p.74.

Chinji Formation, ranging in age from 14 Ma to 10.8 Ma, is the basal unit of the Neogene Siwalik Group in the Upper Indus Basin. It is lithologically the most distinctive formation of the molassic rocks of the Himalayan foredeep belt being composed of red-brown mudstone and grey sandstone in the ratio of 3:1 to 5:1. The typical "Siwalik- aspect form" characterized by the association of small ruminants, suid, gamphotheres and muroid rodents have been well established during the Chinji times. Faunal distribution, especially the first appearance datum (FAD) in the Chinji Formation suggest two major immigration event at Ca. 14 to 13.5 Ma and 12 Ma. These two events record appearance of a host of bovid, tragulid, hominoid and giraffid species with close affinities with the contemporary East African fauna.

Taphonomic analyses of the Chinji Formation based upon carefully selected twelve localities to represent variety of all depositional context and also ensuring of no prior faunal collection from these sites. These fossil localities represent channel, channel related (e.g. abandoned channels) and floodplain (e.g. paleosol) environments. Each bone assemblage is unique in skeletal element composition, tooth/vertebra ratio, proportions of proximal and distal limb ends, taxonomic frequencies, and body-size distribution. However, tests for correlation and degree of association suggest a basic similarity in skeletal elements and taxonomic distribution regardless of sedimentary context.

The Chinji bone assemblages show a number of similarities to modern assemblages, such as relative abundance of skeletal elements, tooth/vertebra ratios, and proximal-distal limb proportions., Modern bone assemblages from different areas are as different as fossil assemblages from different localities (within similar sedimentary contexts). One important difference is that modern bone assemblages have exceptionally low bone densities. High bone concentration in relatively small areas in the Chinji Formation probably reflect relatively short time-periods of more-than-overage mortality rates. This model does not envisage catastrophies but rather such episodic events as droughts, epidemics, and low rainfall periods. These occur in modern African environments every 50-100 years and do not change overall community composition.

The autochthonous nature of the Chinji faunal assemblages is determined by sedimentary and taphonomic characteristics which permit paleoecological interpretation. Taxonomic frequencies and morphological characters of Chinji bovids, rhinocerotids, and suids, suggest that the Chinji faunal assemblages sample woodland-forest mosaic habitats.

Key words: Palaeontology, Miocene, Chinji Formation, Potwar Plateau, siwaliks.

R/113. Raza, S.M., 2001. The Eocene red beds of the Kala Chitta Range (Northern Pakistan) and its stratigraphic implications on Himalayan Fore Deep Basin. Geological Bulletin, University of Peshawar 34, 83-104.

The Eocene redbeds unit of the Western Himalayas Foredeep basin are critical in two aspects: first, it is the oldest Tertiary sequence containing detritus unequivocally derived from the incipient Himalayas and secondly, it contains a diverse fauna key for understanding the evolution of several modern mammal groups. This sequence is known as the Kuldana Formation in the Kohat-Potwar region (=Upper Indus Basin) and the Upper Subathu formation in Kashmir and Himachal Pradesh. This paper focuses on the lithostratigraphic details of the Kuldana Formation from the Kala

Chitta Range (Kohat-Potwar region), which also has yielded the best Eocene mammalian fauna in the region. It is a mudstoned dominant unit, mainly red to purple in the Lower Kuldana but green in the Upper Kuldana. The Lower Kuldana also contains channel sandstone, immature paleosols and fresh-water limestone with molluscs (*Planorbis*) and algae (*Chara*), suggestive of terrestrial deposition regime with shallow channels, ephemeral lakes and wide floodplains. The Upper Kuldana has relatively thicker limestone interbeds with common oysters and rare benthic foraminifera, indicating return to marginal and shallow marine environment as existed before the onset of Kuldana Formation. This marine transgression, correlated with the early Lutetian highstand, deposited the overlying limestone-dominant Kohat Formation. The Kuldana-Kohat couplet was restricted to the Kala Chitta and Kohat regions whereas the rest of the Western Himalaya foredeep turned into a lowland after the Kuldana and Upper Subathu deposition. The shift from marine to terrestrial environment as witnessed in the Kuldana/Upper Subathu sequence is related to early Eocene Himalayan orogeny, when the incipient Himalayas became highland and started shedding sediments to the Foredeep basin. By early late Eocene, the Neotethys drained out from the Paleogene foredeep and shifted to the Katawaz-Makran basin in the west, which then was the main depocenter for the sediments shed from the Himalayan orogene highlands. These tectonic events produced a chain of highlands along the north and western margin of the Indian plate, providing filter bridges for dispersal and migration of mammals to and from South Asia. The Eocene mammalian fauna from the Foredeep and also from the Ladakh basin is a curious blend of some endemic and a few migrants of Eurasian and North American affinities.

R/114. Raza, S.M., Barry, J.C., Pilbeam, D., Rose, M.D., Shah, S.M. & Ward, S., 1983. New hominoid primates from the middle Miocene Chinji Formation, Potwar Plateau, Pakistan. *Nature*, 306, 52-54.

We report here eight new hominoid specimens, attributable to *Ramapithecus* and *Sivapithecus* 1,2, from the middle Miocene Chinji Formation of Pakistan. Hominoids previously described from the Chinji Formation cannot be precisely located although they most probably come from the upper two-thirds of the formation³⁻⁹. The new material, from the middle portion of the formation, is ~12–13 Myr old based on magnetostratigraphy (refs 10, 11 and N. Johnson, personal communication). Two earlier specimens are supposedly from the underlying Kamial Formation^{6,12}, although the best candidate for an earliest *Ramapithecus* or *Sivapithecus* is an undescribed molar, AMNH 19565B, collected by Brown¹³ from a locality believed to be basal Chinji¹⁴, for which magnetostratigraphy indicates an age of 14.5 Myr (ref. 11 and N. Johnson, personal communication). Small hominoids are definitely known in the older Manchar Formation in Sind¹⁵. Together with the material discussed here, the new specimens record the earliest phases of Asian hominoid evolution following dispersal from Africa–Arabia¹⁶, and the apparent division of large hominoids into 'African' (lineages leading to *Pan*, *Gorilla* and *Homo*) and 'Asian' (leading to *Pongo*) clades at a minimum of 13 Myr¹⁷⁻¹⁹, probably more.

R/120. Raza, T.A., 1993-95. Sedimentology of Murree Formation and lithostructural mapping of Barian Area, Southern Hazara, Northwestern Pakistan. M.Sc. Thesis, Punjab University, Lahore, 120p.

A detailed geological study of a small part of the Attock-Hazara Fold and Thrust Belt in Khaira Gali-Kuldana Area of Galliat was carried out. Geological mapping at the scale of 1:21120 of an area of 50 km² was carried out in detail. The lithostratigraphic units in the study area range in age from Middle Jurassic to Upper Eocene age. Samana Suk limestone of Middle Jurassic age is oolitic dolomitic limestone and represents shallow carbonate shelf sedimentation. The Chichali Formation is composed of black shale condensed sequence deposited in a basin of restricted circulation and represents deepening of basin. This continues into glauconitic Lumshiwal Formation deposited in middle subtidal conditions. Further deepening of the basin deposited pelagic Kawagarh Formation of Cretaceous age. It was deposited in lower subtidal conditions near the shelf edge. This was followed by sudden regression due to contact between Kohistan Island Arc and Indian plate, which resulted in general uplift and continental conditions. Residual Hangu Formation of Danian age was thus developed on to of Kawagarh Formation. This was followed by a rise in sea level and deposition of shelf foraminiferal Lockhart Limestone of Paleocene age which is overlain by Patala Shale, Margala Hill Limestone and Chorgali Limestone and Marl. All these are open shelf foraminiferal deposits. At this point in time collision between India and Asia took place and mixed marine-continental Kuldana Formation developed. This was followed by a rise of Himalaya, which shed debris in the foredeep. This formed fluvial Murree Formation Molasse.

The sedimentary package is composed of lower marine sequence from Jurassic to Middle Eocene dominated by carbonates with a residual laterite horizon of Damina age. The upper part of the package starts from mixed marine fluvial sequence (Kuldana Formation) and an upper molassic sequence (Murree Formation) of Upper Eocene to Miocene age. Structurally the area is mapped in detail and is composed of Chumbu Anticlinorium, Khaira Gali Synclinorium, Kali Mitti Synclinorium and Darya Gali Anticlinorium. The area is also cut by Thrust faults. General trend of the rocks in northeast to southwest. The rocks are cross-folded and double plunging. The folds are tight to isoclinal with a general vergence to southeast. Murree Formation of Upper Eocene to Miocene age is a molassic fluvial sequence deposited by a meandering river system. This sequence was derived from rising Himalaya after the collision of India with Asia in Eocene times. Facies, microfacies, diagenesis and provenance of this formation were studied in detail. For the purpose of forgoing sedimentological studies a section between Darya Gali and Kuldana Chowk was measured and sampled in detail. The Murree Formation is composed of an alternating sequence of gray to greenish gray sandstone and chocolate, maroon and brown shales. Conglomerates-breccias, limestones and marl are minor lithologies. This sequence was derived from rising Himalaya to the north as well as upper part of Kohistan Island Arc. The sandstone is lithic arenites, which are texturally sub-mature and compositionally immature.

R/121. Razvi, M.A., 1984. Seismic exploration of geothermal areas. First Pakistan Geological Congress, Lahore, 43-44.

Different seismic methods for exploring geothermic areas have been used widely in USA, Japan, New Zealand and other countries with great success. Two such methods, refraction and reflection have generally been in practice. In volcanic areas, mostly reflection and partly refraction methods have been applicable. The velocity distribution in such areas are highly complicated. It is very difficult, therefore, to pinpoint cap rock, hot fluid reservoir, fault structure, heat source and other such information's from these data. To overcome this difficulty two remedies have been tried. First is to remove noises and multiple reflections by digital data processing and the second one is to calculate (besides conventional arrival time) wave energy absorption caused by fluid viscosity and high frequency and to study the wave length of a seismic wave to estimate geophysical state in such areas. By first method, very deep structures related to heat source have been discovered and from the second it has been obvious that areas of low frequency wave pattern correspond usually to fluid reservoir. Comparison of geological, geophysical and geochemical data with seismic data will increase the applicability of seismic methods for confirming the suitability and utilization of geothermal potentials for electric power generation and other facilities.

R/124. Reddy, S., 1991. A microstructural and argon laserprobe study of fault rocks developed during Himalayan continental collision: a preliminary study. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Auris, France, 67-68.

Areas of NW Pakistan and Nepal have been selected to investigate the processes and timing of microstructural development associated with fault and shear zone development. In NW Pakistan, a series of ductile-brittle thrust faults associated with the collision of India with the Asian plate, are developed within the Indian plate in the footwall of the Main Mantle Thrust (MMT). These range from synmetamorphic to postmetamorphic in origin, developed at a series of metamorphic grades and are thought to have given rise to the apparent metamorphic inversion observed in the footwall of the MMT itself records of complex deformation history involving thrusting and emplacement of the Indian plate onto Kohistan arc material and subsequent normal reactivation and overprinting (Williams, 1989).

Recent studies have illustrated that the late normal faults are important structural features throughout the Himalayas and show displacement up to about 20-km (Burg et al, 1984). Within the Langtang area of Nepal the North Himalayan Fault is recognized as a large normal fault which places basement gneisses of the Higher Himalayan Group against low grade Tethyan metasediments (Burchfiel and Royden 1985; Herren 1987). Metamorphic grades across the normal shear zone are variable and decrease within the footwall towards the contact with the hangingwall sediments. Within the hangingwall itself, cataclasites associated with the extension developed below greenschist conditions. Beneath the normal fault, high strain rocks of the MCT record inverted metamorphism, but in this case the inversion is considered to be the result of high heat production in the footwall and the insulation effect of the low thermal conductivity sediments in the hangingwall.

Previous studies which have attempted to date deformation within Himalayan fault and shear zones have largely relied on indirect dating methods. These methods have included bracketing deformation by dating pre- or post-deformational intrusions, dating metamorphic recrystallization at temperatures close to individual mineral cooling temperatures and by relating deformation to the rapid cooling established by analyzing a suite of minerals with different isotope blocking temperatures. However, the recent advances in the geochemical investigation of argon isotopes utilizing the laser microprobe system, provide a powerful tool, which is capable of analyzing minerals of different generations with different textural relationships. This enables mapping of mineral grain age contours ("chrontours") and the characterization of argon diffusion profiles across single grains which in turn may be used to constrain the complexities of mineral growth and/ or the thermal phases within a rock. The technique can therefore provide valuable information on timing and understanding of processes taking place in fault zones which record protracted deformation histories characterized by multistage mineral growth, dissolution and fracturing.

This study focuses on the application of the laserprobe to the investigation of the temporal variations of deformation processes and development of fault zones and integrates detailed microstructural observations, utilizing the SEM, with laserprobe dating techniques. This work represents a research program, which has only recently been started. At this workshop meeting, the specific problems associated with these fault zones, and the methodology by which they are hoped to be solved, are presented.

R/125. Reddy, S.M., Kelley, S.P. & Magennis, L., 1992. A Microstructural and ^{40}Ar - ^{39}Ar laserprobe study of a greenschist facies shear zone from the Liachar Thrust, Northwest Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 74.

A sample of banded amphibolite from the Liachar Thrust Zone exposed on the 'Tato Road Section' in northwest Pakistan has been studied using microstructural and ^{40}Ar - ^{39}Ar laserprobe techniques in order to place temporal constraints on deformation within this tectonically complex zone and to understand the relationship between deformation and the resetting of argon isotopes within a natural system.

Early Himalayan amphibolite-grade banding associated with the south-directed overthrusting of the Kohistan arc over India along the Main Mantle Thrust (MMT), has been steepened by relative uplift along the western margin of the Nanga Parbat syntaxis and subsequently overprinted by a discrete shear zone associated with westwards thrusting of the Nanga Parbat Indian basement back onto Kohistan. The shear zone in this sample comprises two overlapping but discrete displacement planes approximately 3mm apart, which are connected through a complex link zone. This zone is characterized by plastic deformation along with fluid infiltration and mineral growth.

Laserprobe analyses of minerals in the zone of deformation show a large variation (over three orders of magnitude at a sub-millimeter scale) in the distribution of apparent ^{40}Ar / ^{39}Ar ages due to the heterogeneous distribution of excess argon between different minerals. Amphiboles both outside and inside the fault zone record old ages, which are

associated with the incorporation of excess argon within the mineral lattice, probably during formation of the amphibolite-grade MMT fabric. Excess argon is also extremely abundant within quartz and feldspar augen (apparent ages > 4Ga). However, biotites exhibit much lower concentrations of excess argon, indicating their equilibration in a relatively excess argon poor fluid (biotite is normally susceptible to a high concentration of excess argon). The difference between excess argon components in amphibole and feldspar and that in the biotite seems to preclude a simple thermal resetting of biotite. It is suggested that the excess component in the biotite was associated with syn-deformational fluid infiltration and the ages of c. 10 Ma obtained from the biotite represent minima for the deformation.

R/134. Rehman, A., 1981-83. Lithostructural mapping of Mansehra Susal and Matial Area District Mansehra with special reference to structural studies. M.Sc. Thesis, Punjab University, Lahore, 109p.

Lithostructural mapping with preliminary structural studies have been made of Mansehra, Khaki, Rihar area district Mansehra at a scale, of 1:1000. An attempt has been made to delineate the boundaries of igneous and metamorphic rocks precisely. Physiographic/Stratigraphic studies and various structural contour diagrams have been drawn to determine axis of minor folds. Orientation of joints has been determined with the help of Rose diagram. Thin sections have been studied to determine different phases of deformation. Attempt has been made to analyse the strain with Flinn's and Ramsay's plots. On the basis of microscopic and mesoscopic analysis it has been tried to interpret the structure and macroscopic scale. On the basis of Kinematic Studies, structure of the area is interpreted.

The report presents interim results of regional geological mapping on 1:50000 scale of about 645 sq. km. covered by 38 O/4 quadrangle in Karak district of North West Frontier Province, Pakistan. The mapped area, a part of the Kohat evaporate basin, is entirely underlain by sedimentary rocks ranging from Eocene to recent. The area is moderately folded with some accompanied faulting. Minerals of proved economic value include rock salt, gypsum and limestone. Clays including calcium – bentonite also occur in limited quantity.

R/140. Rehman, I., 1993. Structural model for the evolution of a part of the eastern Kalachitta Range: Hasanabdal-Fatehjangh transect. M.Phil. Thesis, University of Peshawar, 59p.

The eastern part of the Kalachitta Range occupying the southern periphery of the hill ranges exposes a suite of shelf platform rocks of Mesozoic-Cenozoic age. Stratigraphic column comprises the Samana Suk (Jurassic), the Lumshiwal (Cretaceous), the Lockhart and Patala (Paleocene), the Margala, Chorgali, Kuldana and Kohat (Eocene) and the Murree (Miocene) Formations. The structure of the area is characterized by two distinct styles of deformation controlled by two detachment levels. The lower detachment is at the base of the Samana Suk Formation and the upper one is within the Patala Formation. The deformation between the two detachment levels is controlled by thrusting in the form of a duplex structure, in which the lower detachment is acting as sole or floor thrust and the upper one as roof thrust.

This duplex is best exposed at Katha colony, where the Jurassic Paleocene strata is repeated four times in the form of south verging horses. No folding except for that related with thrusts (open hanging wall anticlines) has been observed in the sequence between the two detachment levels. In contrast the structural style in the Cenozoic strata overlying the upper detachment is fold dominated, with both hinterland and foreland vergence. The structural model of the area is of a forward verging duplex separated from the roof sequence by a passive back thrust in Patala shale. This structure is expressed at the surface by fault related folds with north-south vergence.

R/143. Rehman, J. & Zeb, A., 1970b. Geology of the Shah Dheri-Kabal area, Swat. Geological Bulletin, University of Peshawar 5, 96-110.

This paper presents a geological map and petrography of about 20 square miles of the Shah-Dheri-Kabal area in upper Swat. The previously undivided (? Precambrian) Hornblendic Group of Martin et al, 1962, which covers most of the area, has been divided into Homogenous Amphibolites and Banded Gneisses, Dioritic Rocks, Alpine ultramafic Rocks, and Quartz Diorites and Simple Pegmatites. With the exception of the amphibolites and gneisses, the rocks are considered to be connected with Himalayan orogeny and may be middle Cretaceous to early Tertiary. The Amphibolites, gneisses, and dioritic rocks have generally been metamorphosed to Amphibolite-grade; hornblend, epidote and, in some, garnets are very common. The group has a thrust-faulted contact with the rocks of the lower Swat-Buner Schistose Group (Siluro- Devonian or possibly Ordovician), which cover the southern most part of the area. These are represented by low grade eugeosynclinal sediments metamorphosed to phyllitic schists, marble and green schists. The area is of some economic importance due to the presence of china clay, corundum and magnetite (the latter to the north of the area investigated)

Key words: Geological map, petrography, amphibolites, ultramafic rocks, diorites, Swat.

R/144. Rehman, M. & Haqqani, F., 1983. Petrology of a part of Ambela granitic complex (Babaji syenites) Buner-Swat, North West Frontier Province. M.Sc. Thesis, University of Peshawar, 84p.

Geological investigation in Ambela area aimed at preparation of a thesis in master degree in geology. The area under investigation cover almost 60 square km and consists of syenites, quartz syenites and granites. The rocks studied are a part of Ambela granitic complex and intruded into the Lower Swat Buner schistose Group of Martin et al.

The main syenite and granitic bodies are elongated with general trend of NEE. Contacts between the various rock units are predominantly NEE, and parallel to the general trend of the complex. The rocks comprises of babji Syenite in a northern most zone of Ambela granitic complex.

Petrographic studies and field investigations reveal that it is a calcalkaline type complex, a part of the alkaline igneous province of Peshawar plain which is intruded as a large batholith mass in the compressional release fractures formed at the basal part of the Indian plate.

R/145. Rehman, N. & Faisal, S., 2001. Structure and stratigraphy of a part of North Waziristan south of the Mir Ali and Miran Shah Road. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.73.

The detailed mapping of the study area has resulted in establishing five lithostratigraphic units, ranging in age from Triassic to Cretaceous (Mesozoic sequence). The oldest rocks in the area consist of Spalga Formation of Triassic age, followed by shelf sediments comprising Sarobi and Isha formations of Jurassic age. These units are unconformably overlain by rocks of Cretaceous age, which include Tappi and Zer Ghar formations. The Mesozoic sequence exposed along Mir A-Miran Shah road contains well-preserved fossils of their respective ages: Structurally the area is very disturbed. The structural geometry of the area comprises macroscopic and mesoscopic scale folds and thrust faults. The general structural trend is north-south with slight swing towards northeast and northwest. This longitudinal trend is well followed by the axial trend of the macroscopic scale folds. However, some mesoscopic scale folds do not follow this general trend. A large thrust sheet is spread over the entire mapped area and plays an important role in the tectonics of the area. The thrust sheet is divided into three major thrusts i.e. Miran Shah, Tal and Isha thrusts. Generally, all these thrust faults trend north-south and have moderate surface dips. This thrust sheet emplaces the Triassic rocks over the Jurassic rocks. It is folded along the buckling of the underlying rocks suggesting that thrusting pre- date the folding. The cross sectional view indicates that east verging anticlinal and synclinal folds dominantly control the structure of the area. The folds are open to tight and symmetric to asymmetric inclined towards east. All the structural geometry belongs to compressional regime and an eastward directed tectonic transport associated with the oblique subduction of Indian plate underneath the Afghan plate.

R/147. Rehman, S.S., 1986. The geology and tectonic setup of western margin of Nanga Parbat-Haramosh loop, Gilgit, Northern Pakistan. M.Phil. Thesis, University of Peshawar, 123p.

Part of the western margin of the Nanga Parbat-Haramosh loop has been studied in detail in the present work. The loop represents the tectonic boundary between the Kohistan island arc to the west and the Indian plate to the east. Major rock types, west of the fault are pyroxene-granulites and a sequence of interlayered amphibolite-gneiss-marble. Chemical constraints of these rocks are indicative of their derivation from an igneous parent, in an island arc-type environment. The rocks east of the fault are mostly schists and gneisses of the Nanga Parbat granitoid

group. The fault which separates the two contrasting lithologies is a young, right lateral, reverse fault. It trends roughly north-south and dip steeply east, with an east-side-up displacement, It is the northern extension of Raikot fault locally named Shahbatoot fault. Beside this, two other major active faults are present in the area, both showing evidences of recent activity. Indus River has been laterally offset for about 15 km along Shahbatoot fault. Three episodes of folding have also been recognised in the area, all of them related to younger tectonics and are produced by rapid uplift of the Massif.

R/148. Rehman, S.S., 2000. Conservation of surface water in Pakistan--The controversy of Kalabagh Dam. Abstracts, Third South Asia Geological Congress, Lahore, 163-164.

Despite the fact that Pakistan's economy is heavily dependent on agricultural produce, contributions to her GDP from this sector has been steadily declining from over 35% in 1970's to 24% at present. This has been partly attributed to deficit water availability. The Tarbela reservoir was commissioned in 1974 with a gross storage capacity of 11.62 million acre feet (MAF) but now its live storage capacity is just 11.21 MAF. The Warsak reservoir has completely silted up, while Mangla and Chashma storages have also depleted by 1 MAF. Thus our storage capacity has consequently fallen by about 2.5 MAF so far and if we didn't add to our existing facility, we will soon be faced with acute shortage of irrigation water and hence, decline in crop yield. Increasing population and high demand for more food requires vertical and lateral increase in agriculture productivity, which can only be achieved by conserving surface water and its judicious use. In fact not only the lost reservoir space has to be reclaimed but new storage must be built to preserve the 85% discharge available in summer.

Record shows that the mean annual runoff of the Indus river at Basha has been 50 MAF while at Kalabagh it has been about 90 MAF. Downstream Kalabagh the Indus is joined by the Jehlum and Chenab rivers thereby increasing its total volume to about 147 MAF, annually. Presently about 104 MAF is utilized for irrigation through canals while the remaining 33 MAF is discharged to the Arabian Sea downstream Kotri. According to the revised design, the Kalabagh dam will store 6.1 MAF of water and pose little threat to Sindh and Baluchistan because there will still be a balance outflow of 84 MAF annually available downstream Kalabagh whereas, the water of Jehlum and Chenab rivers will continue unchanged. Thus the interests of lower riparians would not be sacrificed but instead it would only reduce the water discharged downstream Kotri to the sea. The option of Basha dam instead of Kalabagh is not right in terms of conservation of surface water as the available volume at Basha is about 50% less than that available at Kalabagh. It would severely affect the inflow into Tarbela reservoir, particularly during the low discharge months of winter. Besides, it would not be possible to draw canals from the reservoir because of its location and terrain. Thus Basha or Kachura dams can be accepted as additional reservoirs but not as an alternative to the Kalabagh dam. In view of the ever-increasing demand for higher crop yield and cheap electricity, the construction of new dams has attained urgent national priority. The construction of Kalabagh dam is, therefore, a matter of national interest and must be undertaken without further delay.

R/149. Rehman, S.S. & Majid. M., 1989. Petrology of a part of the western limb of the Nanga Parbat-Haramosh Loop, northern Pakistan. Geological Bulletin, University of Peshawar 22, 181-195.

A part of the western limb of Nanga Parbat-Haramosh loop has been studied in terms of petrography and geochemistry of the constituent rocks. In this area a recent fault, the Raikot fault, separates the tectono-stratigraphic zones of the Kohistan Island arc in the west from the Nanga Parbat massif (which forms the basement of the Indian plate) in the east. Major rock types, west of the fault, include a sequence of inter-layered amphibolite-gneiss and gabbros / gabbro-norites. Chemical constants of these rocks are indicative of their derivation from an igneous parent, in an inland arc-type environment. East of the fault, the rocks are schists and gneisses of the Nanga Parbat-Haramosh Group. These rocks, on the basis of major-oxide geochemistry, are shown to be formed from a Proterozoic granitic protolith of I-type origin and are geochemically distinct from the S-type Mansehra and equivalent granites in the Indian Plate.

A Comprehensive study of Geology and structure of Chhangla Gali area is, presented along with special constraints on the sedimentology of Margalla Hill, Limestone. Large scale (1: 7000) Geological mapping of a small segment of the Lesser Himalaya in the Chhangla Gali area is presented. The lithostratigraphic unit range from Upper Jurassic to Upper Eocene, Samanasuk Formation being the oldest. Structurally the area comprises NE-SW trending double plunging folds constituting anticlinoria and synclinoria. The folds are tight to isoclinal with a general vergence to the southeast. The folded sequence is disrupted by a number of high angle dip slip strike faults especially within or on the margins of anticlinoria. A detailed petrographic study of a section of Margalla hill Limestone that comprises 63 microfacies ranging from mudstone, wackestone and packstone, with intercalated marls. The deposition of Margala hill limestone took place in open marine shallow shelf conditions. Diagenetic dolomite and neomorphism of syndepositional micrite has taken place under various conditions during different phases of tectonic activity.

The results of a detailed paleomagnetic study of a 68 m section of Upper Siwalik sediments in the Soan syncline, northern Pakistan, are presented. A palaeolithic artefact and other pieces of struck quartzite were found in situ in a gritstone/conglomerate horizon near the base of the section. Incremental thermal demagnetization was used to remove later magnetic overprints in these sediments, since alternating field demagnetization was shown to be inappropriate. With the exception of the lowest stratigraphic level, the Upper Siwalik sediments examined in the Riwat section show reverse polarity magnetization. The declination values are consistent with a 16° ($\pm 4^\circ$) counterclockwise rotation of the Soan syncline tectonic block since deposition of the sediments. On the basis of the palaeomagnetic analyses and the tectonic and stratigraphic context of the section, our current best estimate of the age of the artefact-bearing horizon is $2.0 \pm 0.2\text{Ma}$.

The evidence of glacial/interglacial cycles within the Quaternary sediments record of the Potwar plateau and adjacent areas of northern Pakistan is reviewed. Thermoluminescence (TL) dating of the loess deposits of the potwar provide a chronology for the late Pleistocene and enables comparison with the record from deep-sea cores from the Indian Ocean and Arabian sea. The record of loess deposition and preservation is used to infer changes in the degree of penetration of the southwest monsoon into the northern part of the subcontinent during the late Quaternary.

Key words: Sedimentation, loess deposits, Pleistocene.

R/159. Rendell, H.M., 1995. Luminescence dating of Quaternary sediments. *Geological Society of London*, special publication, 89, 223-235.

Luminescence techniques have the potential to date Quaternary sediments from a range of depositional environments. Recent developments of optical dating complement thermoluminescence dating techniques, extending their applicability. The age range of samples that can be dated shows a strong dependence on the material involved. Recent work on both dune sands and loess indicates that accurate dating to beyond 500 ka may be possible in certain circumstances. The age range limits for other material may be closer to 100 ka. Examples are given of luminescence dating of material from a range of sedimentary environments.

R/161. Rex, A.J., Searle, M.P. & Tirrul, R., 1985. Field relationships of the Karakoram granite batholith along the Baltoro glacier transect, Baltistan, North Pakistan. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

Key words: Granite, glacier, Baltoro, Karakoram.

R/162. Rex, A.J., Searle, M.P., Tirrul, R., Crawford, M.B. & Prior, D.J., 1988. The geochemical and tectonic evolution of the Central Karakorum, North Pakistan. Philosophical Transactions of the Royal Society London, 326, 229–255.

The Karakoram granite batholith (KGB) of probable mid-late Cretaceous age in Northern Pakistan has been studied along the Baltoro glacier transect. The batholith is 15-20 km wide and extends for at least 100-km in a WNW-ESE direction from Snow Lake and the northern Biafo glacier to the Hushe and Kondus valleys. Major compositional and structural differences exist between the Baltoro area and the Hunza Valley. Along the Baltoro glacier transect the composition of the KGB ranges from biotite granodiorite to muscovite and garnet-bearing monzogranite. Amphibole is totally absent. Locally developed K-feldspar phenocrysts and minor K-feldspar megacrysts granite represent late metasomatic activity. A rare occurrence of orbicular granite with compositionally layered spherical orbicals up to 15-cm diameter was discovered near the Trango Towers in the central part of the KGB. Both the batholith and the country rock to the south are affected by widespread intrusions of pegmatites, aplite and leucogranitic bodies. These intrusions are rich in biotite, muscovite and garnet; tourmaline and other phases indicative of high volatile content are mostly absent. A prominent feature of the batholith is the development of at least 3 joint sets, one dipping approximately 45°N, one subvertical and another subhorizontal.

Both the northern and southern contacts of the KGB are intrusive. The northern contact shows a superbly developed contact metamorphic aureole along the Vigne glacier and Mitre peak near Concordia. Metamorphic protoliths are Baltoro black slates and progressive HT/LP mineral assemblages in hornfels include biotite, andalusite (chiastolite) and sillimanite. The southern margin of the KGB at Paiyu is also intrusive into vertically foliated sillimanite-garnet gneisses. The southern part of the KGB in the Masherbrum area comprises a large migmatite terrain with a vast network of leucogranitic dykes intruding both biotite-rich gneisses, restite and leucosome.

The complete absence of mafic dykes, the absence of an extrusive volcanic component and the abundance of leucogranitic crustal melt material all support the model of a high-heat production (HHP) granite terrain of late orogenic to post orogenic setting. The KGB shows little strain and no strong foliation is developed unlike the high-grade metamorphic terrain to the south.

R/163. Rex, A.J. Tirrul, R., Searle, M.P., Barnicoat, A., Rex, D.C., Crawford, M.B. and Windley, B.F. 1986. Geological and tectonic evolution of the central Karakoram Range. The Royal Society Discussion Meeting on Tectonic Evolution of the Himalayas and Tibet, Organized By Professor R.M. Shackleton, F.R.S., Professor J.F. Dewey, F.R.S., And Professor B.F. Windley.

The central Karakoram north of the Main Karakoram Thrust (MKT) includes three major geological zones. The southern Karakoram metamorphic series and the northern Karakoram terrane are separated by the composite Karakoram batholith. Four major metamorphic-deformation events and three magmatic events are geochronologically well constrained and allow a refined model of tectonic evolution. Low-pressure metamorphism (M1) associated with the Hushe gneiss complex preceded subduction-related magmatism of mid-Cretaceous age. Barrovian metamorphism (M2) was synchronous with crustal thickening during the Eocene that followed the late Cretaceous closing of the Shyok Suture between the Kohistan microplate and the Karakoram. Initial crustal underplating resulted in Oligocene peraluminous magmatism. Continued crustal thickening allowed melting of crystalline basement material and intrusion of the Baltoro plutonic unit at 20 Ma with peripheral contact metamorphism (M3). Retrogressive metamorphism (M4) occurred along the hangingwall of the MKT, a later Tertiary break-back thrust feature.

R/165. Reynolds, P.H., Brookfield, M.E. & McNutt, R.H., 1983. The age and nature of Mesozoic-Tertiary magmatism across the Indus suture zone in Kashmir and Ladakh (NW India and Pakistan). *Geologische Rundschau* 72, 981-1004.

The authors report new Ar⁴⁰/Ar³⁹ ages: 180--150 and 90--100 Ma from monzodiorite and tremolite-actinolite schist of the Kohistan Complex; 44 ± 0.5, 39.7 ± 0.2 Ma from dikes cutting the Ladakh-Deosai Batholith Complex; 130-145 Ma from a diorite in the Shyok melange; and 7.8 ± 0.1 Ma from a late stage monzogranite of the Karakorum Batholith. A 261 ± 13 Ma age from gneiss of the Karakorum Batholith is of uncertain significance.

These dates, previously published ones which we summarize here, and some Sr isotope data suggest the following, (due to subduction switching between the Indian and Asian margins during closing of the Tethys Ocean): Late Cretaceous emplacement of the Dras-Kohistan Cretaceous Island arc, followed by rapid cooling between about 85 and 45 Ma. A quiet phase tectonically on the northern Indian plate during the Palaeocene to early Eocene, when subduction was occurring on the Asian margin.

R/166. Riaz, M., 1990. Structure and stratigraphy of the Northern Gandghar Range, Hazara District, Pakistan. M.Phil. Thesis, University of Peshawar, 48p.

The structure of the northern Gandghar Range is shown to be controlled by the folding and faulting processes. Folding and faulting has apparently exaggerated the true thicknesses of the strata. The majority of the folds (F2) are southeast vergent indicating a southeast-directed thrusting. The other group of folds (F1) is oriented perpendicular to the F2 folds, and indicate a compression direction from the NE, distinctly different from those of the F2 folds which is from the NW. The thrusting system developed in the northern Gandghar Range locally defines a small schuppen or imbricate zone. The stratigraphic status and ages of all the rocks of the northern Gandghar Range have been revised. This study indicated that all the rocks of the northern Gandghar Range are of the Proterozoic or early Paleozoic age.

R/167. Riaz, M., Hylland, M.D., Ahmad, S. & Ghauri, A.A.K., 1991. Structure and stratigraphy of the northern Gandghar Range, Hazara, Pakistan. *Geological Bulletin*, University of Peshawar 24, 71-84.

The northern Gandghar Range comprises four structural blocks, separated by the Baghdarra, Sirikot and Darrah faults. In contrast to the southern Gandghar Range none of them shows a complete succession of stratigraphy. The stratigraphy of the northern Gandghar Range is different from that of the southern Gandghar Range in two ways. Firstly, the northern Gandghar Range has an additional stratigraphic unit, the Tanawal formation that is completely missing from the southern Gandghar Range. Secondly, the Utch Khattack Formation which is so widely developed in the southern Gandghar Range is not found in the northern Gandghar Range. The deformation of the northern Gandghar Range is accomplished by thrusting and associated folding. The nature deformation of each block suggests a piggy-back style of thrusting and attitudes of folds indicate two distinct phases of deformation.

R/173. Richards, R.P., 1996. Twinned hambergite from the Gilgit District, northern Pakistan. Canadian Mineralogist 34, 615-621.

Hambergite crystals from a locality in northern Pakistan occur attached to elbaite, and show two different habits on the same specimen. Neither habit has been previously described. Crystals of the first habit are twinned by reflection on {110} and consist of plates flattened parallel to the twin plane, and bounded by {001}, {100}, {010}, {210}, {110}, and {341}. Crystals of the second habit, including the main crystal on the specimen, are also twinned and have a conspicuously hemimorphic habit. They are double twins by reflection on {110}, composed of a large central crystal in twinned relationship to two platy crystals, one on each side. Twin boundaries are marked by re-entrant grooves, and by optical discontinuity observable even in unpolarized light at low magnification under a binocular microscope. The forms present include those on the platy twins, face {241}. The difference between the two habits results from differences in the effect of twinning on crystal growth in the presence of one or two twin planes. The observed hemimorphism is a property of the twinned aggregate, and does not call into question the holohedral symmetry of untwinned hambergite.

R/175. Ringuette, L., Martignole, J. & Windley, B.F., 1998. Pressure-Temperature evolution of garnet-bearing rocks from the Jijal complex (western Himalayas, northern Pakistan): from high-pressure cooling to decompression and hydration of a magmatic arc. Geological Bulletin, University of Peshawar 31, 13th Himalayan-Karakoram-Tibet International Workshop, 167-168.

The Kohistan terrane located in the western Himalayas is an oceanic arc of Early Cretaceous age accreted to the Asian plate and subsequently obducted onto the Indian plate. It can be observed along a complete tilted section from ultramafic/mafic rocks to supracrustal volcanics. The 150-km² Jijal complex constitutes the lowermost exposed part of this arc, and consists of rocks that probably crystallized in the vicinity of the crust/mantle boundary.

Petrographic observations of garnet-bearing rocks of the Jijal complex attest to the magmatic origin of several mineral species like garnet, plagioclase, clinopyroxene and amphibole, which are incorporated within, or pseudomorphosed by metamorphic minerals. According to experimental data on crystallization of basaltic magmas at high-pressure, garnet may appear on the liquidus of partially hydrated basalts if pressure reaches 2.0 GPa. Very high-pressure granulite, amphibolite and greenschist facies assemblages partly or completely overprint the magmatic assemblage. Consequently, many incompatible phases are present at the thin section scale. Very high-pressure granulite assemblages consist of garnet, clinopyroxene, plagioclase, quartz, $\pm$ amphibole. Most of these minerals are unzoned but their composition varies from grain to grain attesting to disequilibrium at the scale of the thin section, probably due to relict compositions inherited from the magmatic stage. However, most garnets are zoned and display a net increase of grossularite content at their rims, compensated by a simultaneous decrease in the almandine and pyrope contents; this results either from an increase in pressure under isothermal conditions, or from an isobaric cooling, the latter being more likely if magmatic garnet crystallized around 2.0 GPa. The jadeite content of clinopyroxene ranges from 7-19 wt.% and increases toward the rims of magmatic clinopyroxene grains; this increase is also compatible with isobaric cooling of the initial magmatic assemblage. Moreover, the Ca-tschermak content of clinopyroxene ranges from 1-16 wt.%, with Al^{IV}/Al^{IV} increasing toward the rims of the grains. Thermobarometric calculations based on Grt-Qtz-Cpx-Pl net transfer reaction and Grt-Cpx exchange reaction give P-T estimates covering a very wide range of 1.2-1.9 GPa and 750-1150°C. If the magmatic sequence of the Jijal complex is continuous, then the calculated depth-pressure range largely overpasses its thickness, estimated at around 12 km [2]. Similarly, the temperature range shows that relict magmatic compositions have probably been included in the calculations. Therefore, these values reflect disequilibrium or rather a mixing of magmatic and metamorphic equilibria. Nevertheless, average pressures and temperatures calculated for garnet and clinopyroxene cores are 60 MPa lower and 45°C higher than those calculated for the rims. Consequently, the post-magmatic stage of metamorphism is a very high-pressure granulite facies resulting from nearly isobaric cooling. The superimposed lower grade hydrous assemblages consist of tremolite-anorthite corresponding to amphibolite facies conditions, tremolite (anthophyllite)-epidote of the transitional epidote-amphibolite facies, and finally actinolitic hornblende-chlorite assemblages of the greenschist facies. The above assemblages attest to a switch of the isobaric cooling path to a major decrease in both pressure and temperature. This magmatic and metamorphic evolution can be correlated with already known tectonic stages: the 120-80 Ma [3] magmatic stage of the arc (magmatic assemblages); the partial cooling during the 80-65 Ma-old post-accretion stage (very high-pressure granulite facies conditions); the abduction of the arc onto the Indian plate, starting at around 65 Ma [4] (hydration of the granulitic assemblages with the development of amphibolite to greenschist facies assemblages).

R/176. Ringue, L., Martignole, J. & Windley, B.F., 1999. Magmatic crystallization, isobaric cooling, and decompression of the garnet-bearing assemblages of the Jijal sequence (Kohistan terrane, western Himalayas). *Geology* 2, 139-142.

The Jijal ultramafic-mafic sequence is the lowermost exposed part of the Kohistan terrane. Petrography and geothermobarometry show that garnet-bearing assemblage of the Jijal sequence consist of a mosaic of magmatic and metamorphic equilibria. Garnet-bearing magmatic assemblage started their crystallization at a depth >50 km, either at the base of a thickened arc-type crust or within rising magmatic batches in the upper mantle. Quasi-isobaric cooling of magmatic assemblages occurred in the high-P, high-T granulite field without reaching the eclogite field. Subsequently, these assemblages were partly retrograded under amphibolite-to greenschist-facies conditions. This succession of equilibria attests to a switch from a high-P quasi-isobaric cooling regime to a major decompression followed by final cooling at the upper-crustal level. This P-T evolution is best explained by a yet unrecognized tectonic event that consists of partial exhumation of the base of the Kohistan terrane during its accretion to the Asian plate. Final cooling and unloading in turn, could be related to extension following the obduction of the Kohistan terrane onto the Indian plate.

R/178. Robertson, A.H.F. & Collins, A.S., 1999. Significance of the Shyok Suture Zone (Northern Suture) in NW Pakistan (Skardu area): Twofold division into Cretaceous Kohistan arc-margin and Eurasian (Karakoram) continental margin units. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 128-130.

The Shyok Suture Zone (Northern Suture) in Northern Pakistan is a critical lineament that separates the Karakoram Terrane to the north (Eurasia) from the Kohistan Terrane to the south (Cretaceous island arc). The Shyok Suture Zone was widely interpreted as a narrow back-arc marginal basin that opened in the Early Cretaceous between the Kohistan arc and the Eurasian (Karakoram) margin. However, it was recently proposed that the Kohistan arc was formed at a near-equatorial palaeolatitude above a S-dipping subduction zone (Khan et al., 1998). In this model, Kohistan drifted northwards, after its formation, as part of a Neothyan oceanic plate that was simultaneously subducted northward beneath the Eurasian margin and sutured to Eurasia during the Late (pre-75 Ma). The site of any oceanic basin between the Kohistan arc and Eurasia (Karakoram) now forms the Shyok Suture Zone. The Shyok Suture Zone was previously summarized as “*mélange* including sedimentary and tectonic *mélanges* with blocks of volcanic rocks, limestone, quartzite and serpentinite in a shaley matrix” (Geological Map of North Pakistan: Searle and Khan, 1991); however, few detailed studies have been published (an exception being Pudsey, 1986).

We are presently investigating the Shyok Suture Zone in NW Pakistan (Baltistan), centred on Skardu. Ligma/Tarmac area (Le Fort et al., 1994) the suture zone was recently interpreted as a low-grade (greenschist) metamorphic tectonic *mélange*, divided into a “Southern Band”, a volcanic-sedimentary unit, and a “Northern Band”, comprising “tectonic lenses” including ophiolitic lithologies. We first mapped a corridor across the Shyok Suture Zone from the Askole Amphibolite (Gilgit Complex) in the SW (near Dasu) to the Main Karakoram Thrust exposed in tributaries NE of Shigar, combined with detailed units from the structural base upwards: Based ultramafic unit (ophiolitic; ca. 1-km)-overlain by talc-rich sediments (Dasu);

Lower volcanogenic unit: (ca. 4-km)-An intact succession of green volcanoclastic turbidites and volcanogenic debris flow deposits, micaceous shales, fissile tuffs, basic-intermediate-acidic lava flows/breccias and local limestone lenses (upper Turmik valley/lower Skoro valley/Bauma-harel area); Carbonate-volcanogenic unit (ca. 2-km)-Dominated by the “Pakora Limestone”, which is redeposited carbonate (calciturbidites) interbedded with subordinate carbonate debris flow deposits and micaceous sediments. It forms lenses up to 800-m thick and is intercalated with volcanogenic sediments and minor lava flows (Ganto-La/Munbluk/Tisar areas); Upper volcanogenic unit (ca. 4-km)-Heterogeneous volcanogenic sediments (structurally thickened), dark phyllite, pale tuff, silicic and intermediate lava/lava breccias and calciturbidites (Ganto La/Tisar/Skoro R./Bauma-harel areas); Serpentine-basalt-chert complex (<250m)-Imbricated tholeiitic basalt (pillow lava/breccia-analysis in progress), red radiolarian chert and serpentinitized ultramafic rock intercalated with greenish volcanoclastic sediments (Bauma-harel area/Skoro R.); Conglomerate-sandstone-shale (ca. 0.5-km several slices)-Reddish sediments (fluvial?) including well-rounded clasts of mainly volcanogenic lithologies forming thrusts sheets, found locally between units vi) and within viii) (Bauma-harel area); Terrigenous shale-sandstone unit (>2-km)-Dark micaceous shales, subordinate quartzose sandstones and siltstones (turbiditic?) (Bauma-harel R/Skoro R.); Shale-sandstone-limestone-conglomerate unit (>2-km)-Early Carboniferous (and older?) to early Mesozoic? Shallow to deeper marine succession (Bauma-harel area). Serpentinized shear zone-marking the Main Karakoram Thrust, cuts obliquely across units iv-viii and overlain by high-grade metamorphic rocks (Eurasian).

Units are interpreted as: i) oceanic arc basement: ii-iv) a coherent (in the SW) to thrust imbricated (in the NW) Lower Cretaceous arc-margin succession (northward younging; apparent thickness ca. 10-km). Limestones are channelized calciturbidites and not tectonic blocks or slices; v) probably imbricated oceanic arc basement in view of the close association with volcanoclastic sediments; alternatively a highly dismembered remnant of oceanic crust that lay between Kohistan and Eurasia; v-vi) Late Paleozoic-Early Mesozoic? mixed carbonate/siliciclastic shelf sediments overlain by terrigenous unstable slope succession with minor volcanics=imbricated upper levels of the Eurasian margin. Secondly, we investigated Cretaceous volcanic/sedimentary units in a structurally separate area

further S (S of Skardu), previously mapped as Kohistan arc (Yasin Group). Two main points are of note in making a comparison with the Shyok Suture Zone further north (see above):

General facies similarities suggest correlation as relatively proximal units of mainly unit iv) above; Large scale thrust imbrication exists, with included thin slices of serpentinized ultramafic rocks and fluvial? “molasses”.

Thirdly, we investigated lithologies further E (Thalle and Hushi valleys), areas previously mapped as part of the Karakoram Batholith. Well exposed volcanogenic successions there (intersliced with local “molasses”) can be generally correlated with unit iv) (Shigar area). Abundant siliceous tuffs are interbedded with relatively thin bedded lithoclastic/silicic turbidites? However, these rocks are found without the redeposited limestone abundant further west. Overall, the areas studied divided into: Coherent, or thrust imbricated Cretaceous Kohistan arc-margin volcanogenic sediments, volcanics and redeposited limestone, associated oceanic basement (serpentine/lava slices); Paleozoic/Early Mesozoic? Shallow to deeper-marine continental margin successions of Eurasian (Karakoram) affinities. Accreted units e.g. large-scale “olistostromes”, or exotic tectonic melange are restricted to a thin sliver separating rocks with Kohistan affinity from rocks with Eurasian affinity. Petrographic studies do not indicate the presence of any terrigenous (Eurasian-margin) derived sediment within the inferred Kohistan-arc-margin units. This suggests that there must have been a barrier to sedimentation (e.g. an ocean) between Kohistan and Eurasia. However, any intervening Neothyan oceanic crust was subducted with little or no trace. The regional evidence favours collision of the Dras/Kohistan arc with the Eurasian (Karakoram) margin along the Shyok Suture Zone late Cretaceous time (pre-75 Ma). The arc was exposed and underwent shallow fluvial erosion prior to large-scale thrust imbrication, possibly related to Late Cretaceous arc/Eurasian margin collision. Tertiary overthrusting along the Main Karakoram Thrust today conceals much of the suture zone.

R/179. Robinson, J., Beck, R., Edwin, G. & Vincet, R.K., 2000. New structural and stratigraphic insights for northwestern Pakistan from field and Landsat Thematic Mapper data. *Geological Society of America Bulletin*, 112, 364-374.

The remote Waziristan region of northwestern Pakistan includes outcrops of the India-Asia suture zone. The excellent exposure of the Waziristan ophiolite and associated sedimentary lithosomes and their inaccessibility made the use of Landsat Thematic Mapper (TM) data desirable in this study. Landsat TM data were used to create a spectral ratio image of bands 314, 514, and 715, displayed as red, green, and blue, respectively, and a principal component analysis image of bands 4, 5, and 7 (RGB). These images were interpreted in the context of available geologic maps, limited field work, and biostratigraphic, lithostratigraphic, and radio-metric data. They were used to create a coherent geologic map of Waziristan and cross section of the area that document five tectonic units in the region and provide a new and more detailed tectonic history for the region. The lowest unit is comprised of Indian shelf sediments that were thrust under the Waziristan ophiolite. The ophiolite has been tectonically shifted and consists of two separate tectonic units the top thrust sheet is a nappe comprised of distal Triassic to Lower Cretaceous Neo-tethyan sediments that were underthrust during the Late Cretaceous by the ophiolite riding on Indian shelf strata the uppermost unit contains unconformable Tertiary and younger strata. The crust sheets show that the Waziristan ophiolite was obducted during Late Cretaceous time and imply that the Paleocene and Eocene deformation represents collision of India with the Kabul block and/or Asia

R/187. Rolfo, F., Compagnoni, R., Le Fort, P., Lemennicier, Y., Lombardo, B. & Pecher, A., 1995. Metamorphic Evolution of the NE Nanga-Parbat-Haramosh massif and the Ladakh terrain in the Chogo Lungma-Turmik area (Northern Pakistan). Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

Petrographical and geothermobarometrical data from the north-eastern sector of the Nanga Parbat-Haramosh Massif (NPHM) and the overlying Ladakh Terrain are used to constrain the metamorphic history of the thickened Indian Plate crust and of the Ladakh paleo-arc in this tectonically key area (Le Fort et al., personal Communication).

The NPHM consists of high grade paragneiss and orthogneiss, minor granulite (possibly deriving from Permian basaltic dykes) and rare diopside-bearing marbles; near the contact with the Ladakh Terrain, deformed pegmatitic dykes are common (Pognante et al., 1993). In both ortho- and paragneiss the mineral assemblage is quartz-plagioclase-biotite-muscovite-garnet-kyanite-rutile $\pm$ Kfeld spar. Kyanite, defining a S_1 inclusion fabric, is also enclosed in syn-tectonic garnet porphyroblasts. Locally, both fibrolitic sillimanite and kyanite have been found in a single garnet porphyroblast: the former in the core and the latter in the rim. This petrographic evidence, together with the results of geothermobarometry and study of garnet zoning, suggests an early compressional evolution from the sillimanite to the kyanite stability field, followed by a decompressional cooling path in which kyanite is stable during different stages of recrystallization. In mafic granulites, geothermobarometry of the assemblage clinopyroxene (Di-Hd₇₄Jd₂₄Ts₂)-plagioclase-garnet-quartz-rutile $\pm$ hornblende $\pm$ biotite suggests $T=650^{\circ}$ - 700° C and $P=12$ - 15 kb for the metamorphic peak. This climax is followed by a retrograde decompressional evolution in which clinopyroxene is partly replaced by a symplectite of plagioclase (An₃₀) and diopside (Di-Hd₈₀₋₉₀Jd₃₋₈Ts₂₋₈Acm₃₋₄).

The Ladakh Terrain includes medium-grade hornblende-bearing gneisses, the “Askore Amphibolite” of Desio (1963), minor ultramafics and a low-grade volcano-sedimentary series, the “Greenstone Complex” of Tahirkheli & Jan (1979) or “Turmik Fm” of Desio et al. (1985). The “Askore Amphibolite” is intruded by syn- to post-tectonic plutons and related dyke swarms, ranging in composition from granodiorite to gabbro: both the syn-tectonic intrusives and their host rocks share the same metamorphic evolution in the epidote-amphibolite facies. The commonest mineral assemblage in the gneisses is garnet. This assemblage defines the regional metamorphic foliation, and is overprinted by a later static recrystallization at comparable P-T conditions. In spite of similar peak temperatures ($660 \pm 70^\circ\text{C}$), preliminary thermobarometry reveals a marked difference between garnet-epidote-andesine amphibolites exposed close to the NPHM at the top of Turmik Valley, which have apparently equilibrated at high pressures ($10.3 \pm 0.4\text{ kb}$), and biotite-epidote-oligoclase amphibolites outcropping at the mouth of Turmik Valley ($P = 6.2 \pm 0.5\text{ kb}$).

Lens-shaped bodies of metaperidotite, possibly representing relics of the island arc oceanic basement, separate the “Askore Amphibolite” and the “Greenstone Complex”. These metaperidotites are usually antigoritic serpentinites often with talc and magnesite, in which relict cumulus structures are locally recognizable. The ultramafites exhibit a polyphase metamorphic evolution, characterised by an early serpentinization of magmatic olivine, followed by the static growth of porphyroblastic olivine and/or tremolite and, finally, by antigorite development. At the northern tip of the NPHM, where the maximum tectonic thinning of lithological units occurs, cumulitic peridotites are transformed into chlorite-talc-magnetite rocks, which still preserve the original cumulitic structure.

The “Greenstone Complex” mainly consists of low-grade quartz-albite-epidote-Chlorite-carbonate arenaceous slates and conglomeratic schists, in which the clasts are dacite and andesite (possibly deriving from the erosion of the Ladakh paleo-arc) and minor marble, quartzite, amphibolite and serpentinite. Markers of this series are interlayers of light-green quartz-plagioclase-muscovite-chlorite-biotite-epidote phyllites with rhombohedral porphyroblasts of dolomite, and rare plagioclase porphyroclasts almost completely pseudomorphosed by low-iron epidote.

Further north-eastward, a thick band of calcite marbles (“Pakora Limestone” of Le Fort et al., in press) with still preserved remains of post-Valanginian rudists and belemnites in dark calcschist layers (Le Fort et al., 1992), separates “Turmik Fm” from the “Blanzgo Fm” of Desio (1963). The latter includes minor marble and quartzite bands, biotite-amphibole greenschists, oligoclase-andesite biotite-epidote gneisses, phyllitic calcschists, amphibole±epidote prasinites and rare serpentinite lenses. Some muscovite-carbonate schists contain porphyroblasts of Fe-rich chloritoid, whereas graphitic schists contain porphyroblastic kyanite. Sharp differences in mineral assemblages (from lower to upper greenschist facies), together with field evidence of local shearing, suggest that this unit, the nearest to the Main Karakorum Thrust, is actually a thrust stack of sub-units with different metamorphic histories.

R/188. Rolfo, F., Compagnoni, R., Lombardo, B. & Visona, D., 1997. HP-HT Coronitic Reaction in metadolerites and metamorphism of the Higher Himalayan crystallines in the North-Eastern Nanga Parbat-Haramosh Massif, Baltistan (N Pakistan). Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 197-198.

Metamorphism of basalt and dolerite dykes hosted in the north-eastern sector of the Nanga Parbat-Haramosh Massif (NPHM) has been studied in the Stak valley, north of the Indus river, and in Susrut Nala, south of the Indus. Petrographical and geothermobarometrical data on these metabasics are used to constrain the metamorphic history of the thickened Indian plate in the area of maximum convergence with the Asian plate and the intervening Ladakh-Kohistan paleo-island arc (Le Fort et al., 1995).

The north-eastern NPHM consists of a layered unit of high grade paragneiss and minor orthogneiss, both with kyanite-bearing leucosomes. The gneiss hosts granulitized dykes of basalt and dolerite, and metagabbro bodies. Near the contact with the Ladakh Terrain, deformed pegmatitic dykes are common. Boulders of marble, calc-silicate rocks and serpentinitized lherzolite have been found in the moraine of the Kuthiah glacier on the eastern flank of Haramosh. The main petrographic features of ortho- and para-gneiss in the Stak valley have been described by Zanettin (1964), Pognante et al. (1993) and Rolfo et al. (1995). In both ortho- and para-gneiss, the mineral assemblage is quartz + plagioclase + biotite + muscovite + garnet + kyanite + rutile ± K-feldspar. The stable assemblage biotite, muscovite and kyanite defines the main metamorphic foliation; staurolite, which appears in equilibrium with the foliation-forming assemblage, has been found only rarely. A higher grade, possibly earlier, mineral assemblage of quartz - K-feldspar-plagioclase-biotite-garnet-kyanite was only found in gneiss samples from Skango Lungma (middle Stak valley). Usually kyanite defines a S1 inclusion fabric in syn-tectonic garnet

porphyroblasts, but locally, both fibrolitic sillimanite and kyanite have been found in a single garnet porphyroblast, the former in the core and the latter in the rim.

The basalt and dolerite dykes which, occur in the gneiss are usually concordant with the main metamorphic foliation. Geochemically, most dykes have tholeiitic basaltic composition, though a few of them are picritic basalts, with MgO~16,wt % and normative diorite up to 30%. The peak, granulite-facies assemblage of the basalt dykes in Stak valley is garnet + clinopyroxene + plagioclase, with rutile as ubiquitous accessory mineral. Amphibolite facies retrogression is present in some dykes, particularly in the more deformed portions and at the selvages. It is characterized by the growth first of amphibole and later of biotite, and by titanite development at the expense of rutile. In these metabasaltic dykes, geothermobarometry of the granulite assemblage clinopyroxene (Di-Hd81 Jd17 Ts2)-plagioclase (An14-18)-garnet (Aim57-59 Prp16-19 Grs21-24)- quartz - rutile suggests T around 700-750°C and P around 12-13 kb for the metamorphic peak. This climax is followed by a retrograde decompressional evolution in which clinopyroxene is partially replaced by tschermakitic amphibole or, more rarely, by a symplectite of plagioclase (An30) and diopside (Di-Hd80-90Jd3-8Ts2-8Acm3-4).

Coarser-grained metadolerite dykes have been found in a few outcrops of Stak valley, the texturally best preserved metadolerite occurring at the junction of the Goropha and Lecho valleys. This metadolerite has a peculiar coronitic texture and is essentially undeformed, except for minor shearing at the margins. Its importance lies in the possibility it affords of investigating mineral reactions through which the metabasics have passed during the granulite transformation, whereas the mineralogy and structure of the granulitized metabasalts do not allow to see back beyond the P and T at which the granulite assemblage equilibrated.

The coronite metadolerite preserves the original igneous subophitic texture originally defined by euhedral plagioclase laths, anhedral clinopyroxene and orthopyroxene, and minor ilmenite. The igneous clinopyroxene, with a dusty appearance for the presence of very small inclusions, has a metamorphic composition with moderately high Na-content ($\leq$ Jd17) and still contains thin orthopyroxene exsolution lamellae. The inclusions are tiny needles of rutile and ilmenite exsolved from the igneous zoned clinopyroxene. Coronas around clinopyroxene mainly consist of garnet (A1n49-51 Prp22-5 Grs23-27). Orthopyroxene is pseudomorphically replaced by a fine-grained clinopyroxene aggregate (compositionally similar to the large pyroxene crystals) + minor plagioclase (An18-22) $\pm$ biotite and is surrounded by a corona of asymmetrically zoned garnet (A1m55-50 Prp23-26 Grs20-23 from the inner towards the outer corona). This indicates that the granulite facies reaction: Pl + Opx $\rightarrow$ Grt + Cpx has taken place. The partially preserved igneous plagioclase (An40) is usually replaced by a metamorphic oligoclase (An16) often crowded with thin needles of kyanite. Small idioblastic garnet (Aim50-56 Prp20-24 Grs29-20 from core to rim) occasionally grows in the original calcic core. A thick corona of zoned garnet (Aim5348 Prp27-24 Grs24-19 from the inner towards the outer corona) surrounds the original Fe-Ti-oxides, which are transformed to an aggregate of rutile + ilmeno-magnetite.

In the coronite metadolerite, geothermobarometry of the peak mineral assemblages gives P=13-14 kbar and T around 800°C. The highest temperatures are thus preserved in the less deformed rocks. Subsequent deformation and re-crystallization during the retrograde path account for the less extreme conditions recorded in most of the mafic dykes and in the gneiss, where muscovite appears to be stable and to define, together with biotite and kyanite, a metamorphic foliation. Post-granulite-facies retrogression and hydrous infiltration in the metadolerite is recorded by the high-T growth of K-rich (up to 0.51 atoms p.f.u.) hornblende and of biotite, which requires the introduction of K-rich fluids from the host gneiss during the post-peak metamorphic stage. These retrograde reactions were apparently quenched by the fast uplift and cooling of the NPHM. U/Pb ages on monazite (Smith et al., 1992) and ³⁹Ar/⁴⁰Ar ages on micas (Villa et al., 1996) suggest that the granulite-facies metamorphism is Mio-Pliocene, as also shown by the Pliocene ages of white micas in the gneisses and pegmatite dykes of the middle Stak valley (Lauris et al., 1996).

Both the mafic dykes and the host gneiss exposed in the North-Eastern Nanga Parbat-Haramosh Massif show a consistent, relatively simple metamorphic evolution. However, some evidence for a polymetamorphic history is given by the presence of dykes which are slightly discordant to the main metamorphic foliation of the hosting gneiss, and by sillimanite inclusion trails inside garnet porphyroblasts of the gneiss, whose growth is related to a HT-MP event predating the HT-HP event.

Key words: Dolerite dykes, metamorphism, NPHM, Baltistan, Himalaya.

R/189. Rolfo, F., Lombardo, B., Compagnoni, R., Le Fort, P., Lemennicier, Y. & Pecher, A., 1997. Geology and metamorphism of the Ladakh terrane and Shyoke suture zone in the Chogo Lungma-Turmik area (northern Pakistan). *Geodynamica Acta* 10, 251-270.

Metamorphism of the Askore Amphibolite, metabasaltic and metasedimentary medium-grade hornblende-bearing schists at the northernmost portion of the Ladakh Terrane and of the Shyok Suture Zone, mainly a low-grade volcano-sedimentary series, has been studied in the area between the Chogo Lungma glacier and the Indus river halfway between Skardu and Rondu. In the Askore Amphibolite the peak assemblage in the amphibolite facies defines the regional metamorphic foliation, and is overprinted by a later static recrystallization at comparable P-T conditions. In spite of similar peak temperatures (630 - 650 degrees C), geobarometry based on amphibole composition reveals a marked difference between garnet - epidote - andesine amphibolites exposed just above the Main Mantle Thrust at the head of Turmik valley, which equilibrated at high pressures (about 10 kbar) in late Miocene (Tortonian), and biotite epidote - oligoclase amphibolites outcropping at the mouth of Turmik valley, which equilibrated at pressures of c. 6 kbar before late Eocene (Priabonian). The Dasu Ultramafite and other smaller lens-shaped bodies of low-to medium-grade metaperidotite separate the Ladakh Terrane from the Shyok Suture Zone. They are antigorite serpentinites, often with talc and magnesite, in which relict cumulitic structures are locally recognisable. The ultramafites may represent remnants of oceanic lithosphere separating the Ladakh-Kohistan island from the Asian plate, or they may be deep crustal rocks stripped from the basement of the arc. The mostly greenschist-facies Shyok Suture Zone shows the lithology of a calc-alkaline volcano-sedimentary series. It is supposed to be a remnant of a back arc basin of early Cretaceous age, separating the arc from the southern margin of Asia. Chloritoid, kyanite and biotite have been found in individual thrust sheets occurring at different structural levels and totally subordinate in volume to very low-and low-grade rocks. Such sharp differences in mineral paragenesis, together with field evidence of local shear, suggest a complex internal structure for the Shyok Suture Zone. From the head of Chogo Lungma glacier to the Basha valley, close to the contact with the Karakorum Metamorphic Complex, the rocks of the Shyok Suture Zone record a late Miocene metamorphic event at medium pressures and temperatures. Thermobarometric and geochronological evidence suggests that this event can be related to the exhumation and thrusting of the Karakorum metamorphic core over the Shyok Suture Zone.

R/190. Rolland, Y., Maheo, G., Villa, I.M., Pecher, A. & Guillot, S., 2001. NW Himalayan belt granulites, mantle heat advection in a transpressive regime. *Journal of Asian Earth Sciences* 19, p.55.

In the Karakoram metamorphic complex (KMC), the oblique India - Asia convergence has been accommodated by (1) horizontal strike slip motions along the dextral Karakorum Fault (KF) and by (2) intense horizontal shortening with huge isoclinal fold structures and south-vergent nappe stacking (Fig. 1). Within the KF zone (Pangong Massif), granulitic assemblages (melonite scapolite $\pm$ clinopyroxene $\pm$ pargasite $\pm$ plagioclase or orthoamphibole $\pm$ rutile $\pm$ spinel $\pm$ pyrope) are found. Thermobarometry on the metabasites yield conditions of T, 800°C and P, 5.5 kbar. These conditions suggest that the KF, accommodating the lateral extrusion of Tibet, should be a lithosphere-scale shear zone, similar to the Red River fault. Ar $\pm$ Ar data show that the granulitic metamorphism occurred before 32 Ma, and that retrogression in the amphibolite facies conditions occurred at ca. 18 Ma. 2. In the KMC, granulitic assemblages (sillimanite $\pm$ K $\pm$ feldspar $\pm$ garnet) associated with migmatitic layers post-date the southwest vergent nappe piling and polyphased M1 metamorphic history (pre-37 Ma). M2 metamorphic conditions are estimated at T, 750 $\pm$ 800°C and P, 5 $\pm$ 6 kbar. M2 granulitic isograds define an E $\pm$ W thermal anomaly, also marked by migmatitic domes. Far from the zone, in the Shyok Suture zone, Ar $\pm$ Ar amphibole cooling ages range from 52 to 38 Ma. At the rim of the domes, ages decrease from 20 to 13 Ma, and at the core of the dome, young U $\pm$ Pb monazite ages of 6 $\pm$ 7 Ma date the M2 metamorphic peak. Chronological, metamorphic gravimetric (Caporali, 2000) and magmatic data, and the presence of young (9 Ma) mantle-derived plutons in domes area (Lemennicier, 1996), clearly indicate that metamorphism is related to heat advection from the mantle. We propose that this late M2 tectonometamorphic and magmatic evolution is due to Indian slab detachment, initiated at 20 $\pm$ 25 Ma.

R/191. Rolland, Y. & Pêcher, A., 1999. Late structural and metamorphic evolution along the Shyok Suture zone and the Main Karakorum Thrust (NW Himalaya). *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 132-133.

The contact between the Kohistan-Ladakh Arc and the Asian paleomargin (Karakorum) is defined in Indian Ladakh as the Shyok suture zone. Westwards, in the Skardu area (Pakistan) the Arc-Karakorum contact is an imbricate

South vergent thrust system, the MKT (Main Karakorum thrust), with thrust contacts underlined by serpentinite strips. Still farther west, north of the Nanga-Parbat /Haramosh spur (Himalayan high grade gneisses), the MKT is no more a thrust, but a recent vertical and rectilinear fault. Actually, the Arc-Asian margin boundary is often unclear: geochemical studies suggest that some amphibolitic series of the South Karakorum metamorphic pile are parts of the Ladakh Arc, abducted onto the Asian margin, then metamorphosed and deformed during the early south-vergent tectonics (from 67 ± 2 Ma to 35 ± 5 Ma) period of the apparently syntectonic Mango Gusar granite emplacement.

Late metamorphic evolution along the MKT/Shyok suture is marked by local high temperature anomalies, best studied in Skardu area, but also known in Indian Ladakh, South of the Shyok suture zone and Karakorum fault. North of Skardu, late metamorphic isogrades draw an E-W elongated pattern, ablate to the MKT and the earlier structural pattern. It underlines a lineament of kilometric scale domes, from the Baltoro glacier in the east to the Nanga Parbat Himalayan spur in the west. Various thermochronological data from gneisses in the domes or from syn-doming plutonic cores (Hemasil syenite) indicate young ages, most of them less than 10 Ma, to the north as well as to the south of the MKT. Thus they can be interpreted in the light of the very recent to present stress and kinematic data.

The recent tectonic pattern was investigated using strain trajectories, as marked by the late metamorphic foliation, and the stress directions obtained by inversion of post metamorphic striated planes:

-The isogrades pattern, the E-W alignment of domes and the lack of small scale extension shear criteria suggest that the thermal anomalies are linked to a transpressive deformation regime, with along strike and down dip movements on the MKT/Shyok zone,

The MKT, as the dextral Karakorum fault, offset the young metamorphic patterns confirming that the MKT is not the suture, but a very young reactivation of a former contact,

-In the western part of the study area, the stress pattern is quite heterogeneous: the maximal principal stress can be vertical (in the core of the domes, e.g. the Haramosh dome), or horizontal and either parallel or perpendicular to the MKT (shortening perpendicular and parallel to the belt). In the eastern part (Ladakh Shyok zone), preliminary studies give maximal stress position either vertical (in the Ladakh batholith) or gently plunging and perpendicular to the Shyok suture (both side of the batholith, in the Indus and Shyok/Nubra valleys).

As a whole, stress, strain and thermal patterns can be linked to a transpressive deformation regime partly controlled by inherited major crustal discontinuities, with very irregular exhumation and partitioning of the deformation during the oblique Indian-Asian convergence.

R/192. Rolland, Y., Picard, C. & Pêcher, A., 1998. Geology of the Ladakh-Karakorum suture zone (NE Pakistan). Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 168-170.

On the northern side of the MKT/Shyok suture zone, in the Karakorum, the authors distinguished two metasedimentary units: (i) a low-metamorphic unit, characterised by limestones (1 and 3, fig 1). In those limestones up to now very poorly mapped and dated, we have found several occurrences of fossils (mainly bryozoa and crinoid), leading to a late Paleozoic age, (ii) underlying this unit, a amphibolite facies metapelitic unit (5, Fig 1), passing (?) to the Hushe series (Searle and al., 1989).

South of the Karakorum units, an imbricated pile of sedimentary, volcano-sedimentary, volcanic and plutonic rocks is observed, bounded by steeply-dipping irregular contacts, with intricated serpentinitised ultramafic rocks (7). Thus, in this area MKT is a complex melange zone, rather than a well-defined contact as described farther West. The base of the volcanic series (9) are made of alternating basaltic flows (locally displaying pillow-lava structures) and greywackes. Towards the top of the series the lavas are more differentiated and are interbedded with pyroclastic deposits.

The volcano-sedimentary units (the "Greenstone Complex") is made of reworked volcanic and sedimentary deposits, with: (i) metric to hectometric-scale basic volcanic blocks enclosed in a carbonaceous matrix (unit 8b) and (ii) olistolithes constituted of limestone and sandstone blocs enclosed in a shaly volcano-detrital matrix (unit 8a).

Those series are overlain by late discarding molassic deposits, with a shallowing upwards sequence (unit 8c).

To the South, the plutonic rocks (diorites and granodiorites, 1 1) of the Ladakh batholith intrudes the volcano-sedimentary units (9) of the suture zone. Hectometric non-assimilated blocks of marble (10) are visible inside the northern part of the pluton. The lithological and geochemical characters of the volcanic rocks show some affinities with volcanic series of the Shyok suture zone between Karakorum and Ladakh of North western India and of the MKT zone between Karakorum and Kohistan.

R/193. Rosenberg, P.S., 1985. Himalayan deformation and metamorphism of rocks, south of Main Mantle Thrust zone, Karakar Pass area, southern Swat, Pakistan. M.S. Thesis. Oregon State University, Corvallis, U.S.A., 67p.

Karakar pass is located to the south of the Indus Suture or Main Mantle Thrust, between lower Swat and Buner. It comprises sedimentary rocks that have undergone Barrovian type metamorphism. The area also contains granitic plutons, including those with abundant tourmaline. The thesis gives details of Early Tertiary Himalayan deformation and metamorphism.

R/194. Rosenberg, P.S., Lawrence, R.D. & Khan, I., 1984. Deformation and metamorphism of rocks south of the Main Mantle Thrust in Southern Swat, Pakistan. EOS 65, p.1094.

Rocks south of the Main Mantle Thrust (MMT) in Swat, Pakistan consist of metamorphosed shelf sediments of the northern margin of the Indian subcontinent. They form the rear of the Himalayan fold and thrust belt in this area. Rocks in the area include fossiliferous marble (Siluro-Devonian?), graphitic schist, calcschist, amphibolite, quartz-mica-garnet schist and concordant bodies of granitic gneiss. These rocks have undergone at least two main deformations. D₁ produced a pervasive regional foliations (S₁) in both granitic gneisses and metasedimentary rocks. S₁ is generally parallel original layering (S₀) but locally axial-planar to small, tight to isoclinal F₁ folds. D₂ folded S₁/S₀ into open to tight F₂ folds that range in size from small crenulations to folds of kilometer scale. D₂ locally caused the development of an S₂ crenulation cleavage or transposed S₁/S₀. Some rocks have a second crenulation that may be related to D₂ or may represent an as yet undefined D₃. The area has undergone regional metamorphism that was syn- and post-kinematic with respect to D₁. Mineral paragenesis (clinozoisite-amphibole-oligoclase-biotite-garnet-quartz) indicates metamorphism reached transitional greenschist-amphibolite facies to lower amphibolite facies. Temperature-pressure conditions associated with D₂ were sufficient only to allow recrystallization of quartz, carbonate, muscovite and possibly chlorite. Both D₁ and D₂ probably relate to the collision of the Indian subcontinent with Kohistan rocks north of the study area (Maluski and Matte, 1984) suggests D₁ ended 30 my ago. Rapid uplift, probably associated with major Himalayan thrusting, occurred 20 my ago (Zeitler, 1981) and is the youngest possible age of D₂.

R/200. Rossman, D.L. & Abbas, S.G., 1982. An ultramafic chromite bearing rock complex near Dargai, Peshawar division, Pakistan. USGS project report PK-59

The Dargai ultramafic complex in Peshawar Division, Malakand Agency, Pakistan, contains 52 chromite prospects and 4 small deposits. The complex is believed to have been emplaced along a major thrust fault which lies along the front of the Himalayan mountain range. Rocks making up the complex include dunite and harzburgite and a few small gabbro bodies concentrated along the north side of the mass.

Two sets of compositional layering are present. One set is universally steeply dipping and strikes east, parallel to the long direction of the complex. The other set, called the subhorizontal set, is nearly horizontal, but is visible with certainty only on the upper slopes of Bada Sar mountain where the layers extend over an area of several square miles. However, traces of a flat - dipping dunitic zone are visible in the upper part of the main east - trending ridge which extends most of the complex; the extent the subhorizontal may be considerably greater than can be positively shown.

The bulk of the chromite occurs as layers, some of which are parallel to the subhorizontal layering; it is likely that the subhorizontal layering formed by crystal settling, and can, in this respect be regarded as primary. The steeply dipping layers in the peridotite probably transect the subhorizontal set, and at places the structure of the steeply dipping set passes at angles through the chromite zones. The steeply dipping set probably formed from flowage and recrystallization of the original rock.

This differential movement probably has been responsible for destroying or masking the subhorizontal layering in most areas. In many places the steeply dipping layered structure extends across the chromite zones at large angles. This transecting relationship is particularly well shown at the Barjokanri deposit.

Recommendations for further work include: detailed tracing out of all chromite layers and exploration on thickened portions; some surface excavation at the Barjokanri deposits; an economic feasibility study of the possibility of finding, mining, and concentrating disseminated chromite; and developing a practical method of pelletizing chromite fines.

R/202. Rowley, D.B., 1996. Age of initiation of collision between India and Asia: a review of stratigraphic data. *Earth and Planetary Science Letters* 145(1-4), 1-13.

The collision of India with Asia is perhaps the most profound tectonic event to have occurred in past 100 Ma. It is responsible for the uplift of the Himalayas and Tibetan Plateau and has been argued to have been responsible for geological, geochemical, and climatological consequences of global extent. Yet the age of initiation of this collision remains poorly constrained. The literature is replete with estimates that range from the Late Cretaceous (> 65 Ma) to latest Eocene (< 40 Ma) with little consensus in between. This paper reviews the available stratigraphic evidence from the Himalayan region, and concludes that only in the western Zaskar-Hazara region is the age well constrained as starting in the Late Ypresian ($\sim < 52$ Ma). To the east only in the Malla Johar region of the Tethyan Himalayas have potentially syn-collisional sediments been recognized south of the Indus Yarlung Zangbo suture. However, here the correlation of the upper part of the Sangchamalla Flysch is contentious, with correlations ranging from Late Cretaceous to Middle Eocene (Lutetian). In the most eastern sections of Tertiary rocks thus far recognized within the Tethyan Himalayas north and east of Everest (Mount Qomolangma) normal, shallow shelf-type carbonates extend into the Lutetian, without evidence of a change in sedimentation to the top of the section, so the start of collision must be still younger. Along-strike of the Indus Yarlung Zangbo suture thick submarine delta-fan complexes derived from erosion of the Himalayan-Tibet system provide independent estimates that agree with a diachronous collision initiating in the late Ypresian in the west and progressing into and perhaps through the Lutetian in the east. The stratigraphic and magmatic history along the north side of the suture are compatible with such a diachronous history. This diachroneity has important implications for estimates of the accommodation of strain within this orogenic system.

R/205. Rushton, A.W.A., 1973. Cambrian fossils from the Hazira shale, Pakistan. *Nature* 243, 130-142.

Until recently the Abbottabad Group in the Hazara area, western Pakistan, was thought to be Upper Carboniferous-Permian in age. But when Latif found Hyolithid shells in the Hazira Shale Formation at the top of the Abbottabad Group, he suggested that a Lower Palaeozoic age was more probable; on lithological grounds he favoured a Cambrian age for the Hazira Shale². Preparation of Latif's material not only confirmed the presence of Hyolithids (*Circotheca?* and *Linevitus?*) but yielded spicules of the Heteractinellid sponge *Chancelloria* Walcott. *Chancelloria* is known from the Middle Cambrian of North America³, the Ordian of Australia⁴, and from the Lower Cambrian in England⁵. A Cambrian age for the Hazira Shale is therefore fully confirmed. If the Tanakki boulder bed at the base of the Abbottabad Group is of glacial origin¹, it becomes feasible to correlate it with the widespread late Precambrian glaciation.

This study describes the effects of ground water due to pumping out water from 110 tube wells in Bajaur agency, installed by F.A.T.A.D.C. In this study special emphasis was given to record the decline and to ascertain the rate of decline of ground water level due to pumping. Individual tube wells performance in terms of specific capacity test and the properties of the aquifer were also studied.

The study area comprises major portion of Bajaur agency. The area in the west is connected to Mohmand agency, and in the east is connected to Dir. The total survey area measures 788 sq miles. This area is in the form of plains. The top layer of the plains in which these tube wells are installed, is mostly of clay alternated by gravels, boulders, clay and sand. The area is basically igneous and metamorphic in nature.

The main source of irrigation is ground water and only a few farmers resort to barani cultivation. In addition to tube wells, dug wells are also present in this area but used for domestic purposes only. In Bajaur area water is available at various depths ranging from 50 feet to 200 feet which is fit for drinking and irrigation purposes.

S/6. Saeed, A.S., Alam, M. & Khan, M.W., 1985. Groundwater conditions of Rustam area Mardan, N.W.F.P. M.Sc. Thesis, University of Peshawar, 71p.

Wapda has recently started work on ground water investigation in Rustam area. The main objective of the present work in Rustam is to:

1. Increase agriculture production, through improvement of water supply, drainage and through soil reclamation.
2. To improve the economic and financial condition of the farmers.
3. To stimulate economic activity in the area.
4. To provide subsoil drainage, by tube wells, where feasible and by open drains, where tube wells are not feasible.
5. To provide water to present unagricultural areas, if available after supply to the present commanded area.
6. To improve the subsurface water supply to those areas where cultivation is done by rain fall.

The project area is irrigated by persian wells, but most parts of this area in the north of Rustam is cultivated by rain fall.

It has been established from lithologic logs of the test wells drilled in this area, that the subsurface geology of this area includes moderate water-bearing sand and gravels with a considerable thickness of clay over certain area of Rustam unit. The aquifer is generally overlain by clay, silt and clayey shale ranging in thickness from few feet to several feet. The aquifer is not confined in the area, because the water level is very low in test wells. Generally water table ranges in the area from 30-40 feet. Due to low water bearing zones and deep water table there is no water logged area in Rustam valley.

Agriculture production of the area has declined due to non-availability of water for irrigation throughout the year. Mostly the people of this area cultivate their land farms with the help of rain water supply. The analysis of the surrounded wells water and soil sample show that the area has an excellent quality for agriculture. The water contain about 108 ppm of dissolved solids. Majority of the water sample contain less than 540 ppm of dissolved solids. Average contents of solid range from 102-280 ppm

Soil texture is moderately coarse to fine and medium to fine with good porosity and high capillarity. The rate of infiltration is very good. The soil is generally calcareous pedocals and reclaimable with water leaching and is highly productive. The soil of Rustam area is generally nonsalinized, because there is no water logging. Due to fertility of the soil, the production can increase with development of water subsurface resources. Rustam area has pure water of bicarbonate type and permeability is good also. Generally the aquifer of the area is low and has deep water table, so salinity is not seen everywhere.

S/8. Saeed, Q.M., 1982-84. Micropaleontology and stratigraphy of the Jhalar Area-the Kala Chitta Range, Attock District. M.Sc. Thesis, Punjab University, Lahore, 91p.

A geological map of the Jhalar area -the Kala Chitta Range, on a scale of 1" to 0.789 mile or 1:50,000 and covering an area of 16.43 square miles has been prepared to discuss the stratigraphy and micropaleontology of the area. An attempt has been made to discuss the importance of foraminiferal content of these rock units, for determining the depositional pattern and age. The geological sequence of the Kala Chitta Range with a view to recognize the continuity or unique aspects of the lithostratigraphic units in the adjoining area. The various geological events that occur in the area and their geological implications have also been discussed. In the Kala Chitta Range there are some eighteen lithostratigraphic units but the area under discussion comprises ten lithostratigraphic units mostly of marine environments and with non-marine units.

Key words: Micropaleontology, stratigraphy, Kalachitta Range, Attock.

S/9. Safdar, M., 1983-85. Geology and tectonics of Burawai Area, Upper Kaghan valley, District Mansehra, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 125p.

Nearly 114 sq. km. in the vicinity of Burawai, upper Kaghan valley has been geologically mapped, at the first time. This thesis presents first time accounts of geomorphology, lithostratigraphy, petrography and economic geology of the area. The area constitutes rocks representing old Indo-Pak basement rocks, comprising pelites, calc-pelites and marbles have been metamorphosed to kyanite and sillimanite grades. These are intruded by para-autochthonous sheet granites also metamorphosed. Major structure comprises an open synform possibly part of a larger structural basin. The western part comprises the nose of a larger antiform. Marble, biotite mica and kyanite are important mineral deposits which deem further exploration and evaluation. This thesis also includes petrogenesis of the rock units as well as numerous sketches sections and photographs, illustrating the geology of the area.

Key words: Tectonics, structure, Burawai, Kaghan, Mansehra.

S/25. Said, M. & Majid, M., 1977. The Pleistocene history of the terrestrial deposits of Bar Daman area, Peshawar valley. Journal of Science and Technology, Peshawar University 1, 39-47.

The detailed mapping of the Bar Daman area, has revealed the presence of a variety of surface deposits, ranging from siltstone to gravel, sand and loess. It appears that during the second Himalayan glaciation, this area was covered by a fresh water lake, in which siltstone, mainly older loess, reworked by torrents was deposited. This lake was drained away during the following warm phase, and in places, sand was laid on the top of the siltstone by aggrading streams, the early phase of the third Himalayan glaciation is recorded by fac gravels. A fossil soil reflects warm and wet conditions, perhaps an interstadial. The last phase of the third glaciation is characterised by cold and dry conditions as is shown by the thick deposits of loess. The last glaciation is recorded by the formation of fans, while Holocene is marked by large scale changes in the drainage of this area.

S/26. Saif, S.I., 1970. Chromite occurrences in Utmankhel area of Mohmand Agency, NWFP, Pakistan. Geological Bulletin, University of Peshawar 5, 134-135.

The Utmankhel area lies adjacent to Charsadda Tehsil of Peshawar district and its boundary starts about seven miles north of Tangi. In the area under investigation the Peshawar plain skirts the hills where the elevation culminates from 1550 to 5520 feet. The ultramafic outcrops form a linear belt from two to five miles wide and extend for over 25 miles. The important localities in the Utmankhel area from where the chromite has been reported are in the vicinity of Babu, Bucha, Prang Ghar, Daghai and Balola villages. The mineralization is sporadic and lenticular.

Key words: Chromite, geochemistry, Utmankhel, Mohmand Agency.

S/27. Saif, S.I., 1971. A geological traverse through Mohmand Agency and Bajaur, NWFP West Pakistan. Geological Bulletin, University of Peshawar 6, 74-81.

Traverses in Mohmand Agency and Bajaur reveal that the area is underlain by a variety of metamorphic and igneous rocks. Slates, phyllites, schists, amphibolites and interbedded crystalline limestone cover extensive part of the area. Granite, microgranite and diorites are the igneous rocks found in addition to a thick ultramafic body, which is closely associated with the carbonate horizon.

Extensive marble reserves of various grades and shades have been encountered. The carbonate horizon mostly yields pure white, greenish and brownish marble, as well as several varieties of limestone. Big economical blocks of marbles can be extracted. This part of the metasedimentary terrain may be the northern termination of a large fold having connection with the Mullangori structure.

Key words: Metamorphic, igneous, granite, diorite, marble, Mohmand agency.

S/30. Saleem, M., 1983-85. Electrical Resistivity for groundwater potentials in Shekhan, Landai Bala and Shahabkhal Area, District Peshawar. M.Sc. Thesis, Punjab University, Lahore, 31p.

Electrical resistivity survey in Shekhan, Landai Bala and Shahabkhal area was carried out in collaboration with Hydrology Directorate WAPDA Peshawar. The main purpose of the survey was to determine hydrogeological features like depth to bed rock, nature and thickness of aquifers and the quality of groundwater to select suitable sites for tubewell installation in the project area.

According to the resistivity survey and drilling data the entire area is underlain by low resistive clay. The overlying alluvium is composed of alternating layers of gravels and clays. Groundwater appears to be quite fresh in the entire area and seems to be under artesian pressure at many places. The water depth varies from 50 to 70 meters in the area under investigation.

In the project area, thirty one probes were carried out. After interpreting the data, the V.E.S. No. 6, 7, 8, 10, 16, 19 and 22 have been selected for the test drilling, however other probe sites also indicate presence of aquifers in the area but of varying thickness. The entire area appears to be favorable for tubewell installation, however the yielding of water depends upon the nature of aquifers may vary from half cusec to one and half cusec in the project area.

Key words: Resistivity, groundwater, drilling, aquifers, Peshawar.

The Karak mudstone interbedded in an Eocene evaporite sequence, is dominated by R-1 ordered illite-smectite with a 20 to 30% expandable component. Minor phases include kaolinite, chlorite, illite/muscovite, plagioclase, potash feldspar, quartz, dolomite and pyrite. The present illite-smectite was probably originally smectite or highly expandable illite-smectite which underwent conversion to illite-smectite with a low expandable component in a comparatively low-temperature (ca. 100°C) closed-system sedimentary basinal diagenetic environment at a depth of ca. 5 km. Al^{3+} and K^{+} necessary for the conversion reaction were provided through the breakdown of potash feldspar. Burial under a 5 km thick pile of sediments produced some of the observed structures. Whole-rock chemistry presented here suggests that the mudstone formed by severe weathering of acidic source rocks. The influx of freshwater probably flushed out Ba, Rb, Ca and Mn from the restricted basin.

S/38. Salim, A., Sulaiman, E. & Ullah, M., 1988. General geology of a part of Karak District, N.W.F.P., Pakistan. M.Sc. Thesis, University of Peshawar, 40p.

The present work describes the general geology of a part of Karak district (Bahaderkhel and Latumber) on scale of 1:12,500. Various lithological units present in it include, from bottom to top, Bahaderkhel Salt, Jatta Gypsum, Kuldana Formation, Kohat Formation, Kamlial Formation, Chinji Formation and Nagri Formation. The strata of the study area are moderately to highly folded and faulted under the effect of Himalayan orogeny. The folds and faults are classified on the basis of size as regional, local and minor. The folds are generally gentle to open. Major faults strike SW-NE. The map view expression of both normal and reverse slip faults have been observed by the presence of graben faults and tear faults respectively. The tear faults can be easily observed by omission and repetition of stratigraphic sequences. Tear faults are the result of inability of translating a huge regional block as a single unit. The salt tectonic of varying intensities result in the squeezed out diapiric, plug like and domal exposure of Bahaderkhel Salt in the core of the Bahaderkhel anticline. The outcrop pattern very closely shows that all younger formations are sharply wrapping around the Salt and gypsum core. The economic deposits of the area include Rock salt, Gypsum and limestone. The typical favourable structural setting makes the whole region a promising target for the exploration of oil & gas.

Key words: Geology, geomorphology, stratigraphy, Karak.

S/39. Sameeni, S.J., 1994. Microfaunal studies of Lower Margalla Hill Limestone of Bandi area, Hazara, Pakistan. Pakistan Journal of Geology 2 & 3, 45-52.

This paper deals with the micropalaeontological studies of Lower Eocene Margalla Hill Limestone from Bandi area Hazara. Fifteen species of age diagnostic larger foraminifera are recorded including three typical Paleocene species of the genus *Ranikothalia* are reported for the first time from Margalla Hill Limestone and association of the genus *Ranikothalia* along with typical Eocene species confirms its presence in the Lower Eocene (YPRESIAN) deposits of Pakistan.

S/41. Samiullah, Sharafatullah & Nasrullah, 1986. Geology and structure of Karak Quadrangle, Kohat. M.Sc. Thesis, University of Peshawar, 62p.

The present work describes the geology and structures of a part of Karak bounded by latitudes 33° 8' 0" to 38° 11' 27" N and longitude 70° 56' 53" to 71° 1' 37" E of Karak quadrangle. The map was enlarged from 1:50,000 survey of Pakistan toposheet scale. The area is moderate to highly folded and a few faults of considerable extent and significant movement have been observed. The folds are open, plunging with their axes trending EW. In the area, a central anticline is bordered by the two adjacent synclines one on each side.

The Stratigraphy of the area is as follows;

Pliocene	Siwalik Group	Nagri Formation
		Chinji Formation
Miocene	Rawalpindi Group	Kamlial Formation
Eocene		Kohat Formation
		Kuldana Formation
		Jatta Gypsum
		Bahadur khel salt

The rocks of the above two ages (Pliocene and Miocene) are considered to be fluvial in nature and are thought to be composed of the Himalayan Molasse, while the rocks of the Eocene age are thought to be most probably the deposits of evaporite basin.

The rocks have been moderately to highly folded and faulted, and shows two distinct phases of deformation, in harmony with the earlier phases of Himalayan orogeny. The first phase of deformation give rise to the three major F1 folds while the second phase of deformation give rise to the secondary intraformational folds. The faults occurring in the area are mainly two sets. One set comprises of only one fault which is thrust fault. The second set is composed of four diapiric, gravity faults. Both the two sets of faults appear to be associated with the second phase of deformation and are the youngest. The investigated areas has great geological importance partly because of the fact that the younger little deformed rock assemblages here are suited for petroleum exploration. Besides, the presence of abundant economic minerals like rock salt, gypsum and limestone, also make it economically viable area.

(Eds.), Geology, Geochemistry, Economic Geology and Rock Magnetism of the Kohistan Arc. Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad 15, 127-135.

The Jijal ultramafic-mafic complex in northern Pakistan is a small body of a few tens of square kilometers, but has drawn big attention as to be a root zone of the so- called "Kohistan paleo-island arc" (e.g., Jan and Howie, 1981; Bard, 1983), or, a possible fossil of the uppermost mantle to lower crust in the surface-exposed crust- mantle cross section. This short report presents a geological overview of the Jijal complex based on our field survey along the

Karakoram Highway in 1992 and the following petrographical work, as well as the newly obtained Sr-Nd isotopic data on the Jijal complex and their petrogenetic implications.

S/52. Sarwar, A., 1997. Litho and stream sediment geochemical investigations for base metals and precious metals in Timargara, Maidan and Jandul Area, District Dir, Northern Pakistan. M.Phil. Thesis, University of Peshawar, 164p.

The area of study (about 900 sq. km.) is a part of the Kohistan island arc in the northern part of Pakistan. The Kohistan island arc, which is a part of Kohistan-Ladakh island arc, represent a cross section through an intra-oceanic

island arc sequence which develop as a result of the northward subduction of Neotethyan oceanic lithosphere during late Jurassic and Cretaceous time. It is bounded by the Main Mantle Thrust (MMT) in the south and Main Karakoram Thrust (MKT) or Shayok suture in the north in the Pakistani terrane.

The area of study is located immediately north of the MMT in Dir district. It has a complex geology and is mainly composed of amphibolites, metadiorites and metagabbroanorites, metagranodiorites, metagranites and metavolcanics with subordinate amount of hornblendites, ultramafites and tonalites. The area has been investigated for preliminary geology, however, no detail geochemical investigation has been carried out for precious and base metals mineralization. This study has main emphasis on the rocks and stream sediments (both pan concentrates and -80 mesh fine fraction) geochemical survey for gold and base metals in order to delineate areas likely to contain mineralization and be worthy of follow-up work.

The area has been divided into 56 drainage cells ranging from 2-50 km² with an average density of about one site per 15 km². From each cell a pan concentrate and -80 mesh fine fraction were collected for geochemical analyses of Au, Ag, Cu, Zn, Pb, Co, Ni, and Cr, by atomic absorption. The visible gold as piece, speck and color was identified in the pan concentrates at the site. The floats were also examined for alteration and other geological phenomenon at each site. The pan concentrates are dominantly composed of magnetite whereas zircon, quartz, pyroxene, garnet, hornblende, feldspar, tourmaline, chromite and rock fragments occur as minor constituents.

The geochemical data for rock samples, pan-concentrates and fine fractions of stream sediments have been displayed and evaluated by considering various geostatistical methods.

Geochemical maps have also been prepared on the basis of single and multi-elements consideration in order to pin point areas of most interest. These studies show that panconcentrates have higher concentration of all the elements as compared to that of fine fraction. These elements are silicate bounded rather than sulfide bound in stream sediments. The higher concentration of Cu, Pb, Zn, Ni, Cr, Co and Ag could be related to the bed rock rather than to specific mineralization in the area. The anomalous gold, however, could not be directly related to the bed rock but it could possibly be related to the existence of gold-bearing mineralization in the north and north-eastern part of Samarbagh area, the detail geochemical survey is, therefore, recommended for follow-up in the region.

Key words: Stream sediment, geochemistry, precious metals, Timargara, Dir.

S/53. Sarwar, G. & DeJong, K.A., 1979. Arcs, Oroclines, Syntaxes - the curvatures of Mountain Belts in Pakistan. In: Farah, A. & DeJong, K.A. (Eds.), *Geodynamics of Pakistan*. Geological Survey of Pakistan, Quetta, 341-350.

The bent mountain belts of Pakistan are discussed in terms of the convergence of the Indo-Pakistan subcontinent with the Eurasian blocks to the west and north of it. The triangular northwest part of the Indo-Pakistan block was compressed simultaneously from the west, east and north, the latter compression being the most severe. Deformation occurred along the margins and crustal material was expelled, mainly to the south. The Pamir Himalaya Arc, the Nanga Parbat-Haramosh massif, the Hazara-Kashmir Syntaxis, the Bannu-Potwar thrust sheet, the Salt Range Composite Orocline, and the Sulaiman Arc are explained as a result of this north-south compression. The Quetta Syntaxis is seen to result from obstruction of the southward moving sedimentary cover of the Sulaiman Arc by the thick wedge of Neogene sediments in the Sibi trough. Finally, based on geological evidence, it is suggested that a large block (the Khuzdar-Karachi Block), behaving as an independent tectonic unit, is being rotated counter-clockwise at the western margin of the Indo-Pakistan plate. The Khuzdar Knot and the Karachi Arc form the southern and northern parts of the Khuzdar-Karachi Block respectively.

S/63. Sarwar, M., 1987b. The presence of a Chinese stegodont proboscidean in the Siwaliks of Azad Kashmir, Pakistan. Punjab University, Geological bulletin, 22, 72-75.

A stegodont fourth upper premolar is described from the Dhokpathanian of Bhimbhar district Mirpur, Azad Kashmir, Pakistan. The tooth being primitive in structure of its ridge-crests and the crown heights has been compared with the primitive stegodonts. A detailed study has indicated that it is conspecific with the Chinese species, *Stegodon sinensis* Owen. This is the first Stegodont species common to Chinese Tertiary and the Siwaliks. The discovery of Chinese species from the Siwaliks means that the proboscides migration was possible across Himalayas during Lower/ Middle Pliocene.

S/74. Sattar, A., 1985-87. Mineralogical/geochemical studies of rocks, soils and water, Khanaspur Dewal Area. M.Sc. Thesis, Punjab University, Lahore, 103p.

This report gives an account of Mineralogical and geochemical studies carried out in Khanspur and Dewal area. The prescribed area lies to the north of Murree, in extreme east of Abbottabad and southwest of Muzaffarabad. Except an area of about 6 sq. km. which belongs to District Rawalpindi, the area lies in Abbottabad District, N.W.F.P. It is a mountainous region with fairly high relief. Geological mapping of approximately 56 sq. km. on lithostratigraphic basis, at the scale 1:10,000 was carried out. The stratigraphic succession ranges from Datta Formation

(Jurassic) to Murree Formation (Miocene). The lithology is mainly limestone, shales and sandstone. Extensive sampling of rocks, soils and water was carried out and these samples were studied in laboratory and data regarding these studies are given in this report. A brief systematic description of various rock units in hand specimen and thin

section is included. A brief description of chemical staining techniques applied to the limestones and that of performed limestone analysis is also given. A chapter regarding the detail geochemical studies of soils of the project area is also included. This chapter gives an account of all the parameters necessary for soil study and according to these parameters, the soils of the area are categorized as non-sodic, non-saline. Geochemistry of two main streams of the area has also been studied in detail and the data regarding the chemical analysis of the water are reported and interpreted by various graphical techniques. According to these data, the mineral components and other parameters lie within the safe limits, established for water to be used for domestic and agriculture purposes. Chemical characteristics of waters of various springs of the area, originated in different rock units have also been studied and interpreted in detail. Spring waters are also fit for irrigation and drinking purposes. Finally, there is a general discussion about the waters of the area and the effect of various encountered rock units on the chemistry of water passing through them.

S/75. Sattar, A., Chaudhry, M.N. & Mateen, A., 2001. Petrology of amphibolites from higher Himalayan crystalline unite, upper Kaghan valley, NW Himalaya, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 9-10.

The Higher Himalayan Crystalline unit in the Upper Kaghan Valley is composed of a lower basement and an upper cover. The lower basement is composed predominantly of granitoids, migmatites, micaceous quartzites and pelite schists. Marbles, calc-pelite gneisses, graphitic schists, quartzites and amphibolites are subordinate lithologies. The cover to this basement is composed of amphibolite sheets intercalated with marbles grading upward to a sequence of calc-pelite gneisses and marbles which are in turn overlain by pelite schists and micaceous quartzites sequence.

The amphibolites in the Upper Kaghan Valley occur either as feeder dykes in the basement or more commonly as extensive sheets in the basal portion of the cover where these are inter-bedded with marbles and calc-pelites. These metabasic rocks are predominantly garnet amphibolites composed of amphibole, calcic plagioclase, and almandine. Quartz, sphene and magnetite occur as accessories. At places due to retrogression some epidote and chlorite may also be found. Around Besal these rocks have been subjected to eclogite facies metamorphism and are comprised essentially of almandine±omphacite. Quartz, rutile and kyanite occur as accessories. Coesite may occur at places.

Major and trace element geochemical data were plotted on variation and discrimination diagrams and spidergrams with normalization to known basaltic compositions. This data strongly suggest a within plate extensional regime for these metabasic rocks. To be more precise, these are tholeiitic flood basalts with minor sub alkaline to alkaline trend. The geology of the area also supports this conclusion since the emplacement of these bodies is entirely within continental crust and there are no ultramafic and felsic bodies genetically associated with them. Furthermore they occur as concordant sheet like bodies indicating a flood basalt type origin.

S/76. Satti, M.Z., 1991-92. Geological mapping of Nauseri-Yadgar Area and evaluation of geotechnical properties of rock aggregates of the area. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 123p.

The dolomite, limestone and sandstone concrete aggregates have been investigated from Yadgar to Nauseri Area. The evaluation of mechanical properties effect the quality of the aggregates presently being used in civil engineering projects. Mineralogically alkali-aggregate reactive minerals involve silica particularly chert, chalcedony, chlorite and clay minerals. The alkali carbonate reactions involve argillaceous dolomite, dolomitic limestone and agrillites. Concrete deterioration due to alkali silica reaction have been investigated from nearly all major geographical regions of Azad Kashmir. In Yadgar dolomite chert is found. Chert is common in gravels, derived from various limestone formations. These chert seem to show a low level of alkali expansivity, but when this is combined with other forms attack on concrete. It may contribute to durability failures. Siliceous limestone, some of which contain chalcedony are known from Batmang area and some example appear to be a major fracturing concrete deterioration. Agrillites associated with alkali expansive reaction in concrete have been described particularly from Margala Hill Limestone. The test result reveals the use of concrete aggregates from the area after treatments.

S/80. Sawada, Y., Kausar, A.B., Kubo, K., Takahasi, Y. & Takahasi, Y., 1996. Sedimentary structures in the Chilas igneous complex of the Kohistan arc, northern Pakistan. In: Kausar, A.B. & Yajima, J. (Eds.), *Geology, Geochemistry, Economic Geology and Rock Magnetism of the Kohistan Arc. Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad 15*, 173-181.

The Kohistan island arc is exposed in the western Himalaya of northern Pakistan, where it is bounded by the Main Karakoram Thrust (MKT) to the north and the Main Mantle Thrust (MMT) to the south (Fig. 1) The Kohistan arc consists of a series of east-west trending Cretaceous to Miocene sedimentary, volcanic, plutonic and metamorphic rocks. It is widely interpreted as an island arc sequence which developed above the northward subducting Tethyan oceanic plate. Based on Rb-Sr and K-Ar Ages of syn-collisional leucogranites intruded into the Rakaposhi volcanics (Petterson & Windley, 1985;1990; Treloar et al., 1989), the collision between the Asian continent and Kohistan arc probably took place between 102 to 75Ma. Following this, the main collision of amalgamated Asian continent-Kohistan arc with the Indian continent commenced at about 50Ma (e.g. Patriat & Achach, 1984) during which the Kohistan block obducted onto the Indian continent. South of MKT lie the slates, turbidites, volcanoclastic sediments and limestones of the Albian to Aptian "Yasin Group" (Pudsey, 1986) which may have been deposited within and intra-arc basin. The Yasin Group overlies the submarine to subaerial basic to intermediate arc-type tholeiitic volcanics intercalated with limestones of the "Rakaposhi (Chalt) volcanics". The Rakaposhi volcanics and metasediments were intruded by tonalite and diorite during the late Cretaceous to Miocene. These plutons form a vast complex of intrusions in the northern part of the Kohistan arc, termed the Kohistan batholiths by Petterson & Windley (1985)

S/82. Sayab, M., 1997. *Geology of Nanga Parbat Syntaxis along the Astor valley transect, N. Pakistan. M.Sc. Thesis, Department of Geology, University of Peshawar*, 130p.

The Nanga Parbat-Haramosh syntaxis represents the youngest phase of thermal, tectonic and metamorphic activity in the Himalaya. The massif is an active crustal scale antiformal structure comprising Indian plate basement gneisses and cover sequence. The Nangaparbat rocks in the Indus gorge section have previously been divided into grey Iskere gneiss and pink Shengus gneiss. During recent mapping along the Astor valley transect, south of Indus valley, several new lithological units have been identified. These include 1) Mushkin grey gneiss 2) Harchu pink gneiss and 3) Rattu formation. The Mushkin gneiss is a medium-grained, locally porphyroclastic gneiss of grey colour probably representing the basement complex.

Harchu pink gneiss is clearly derived from a sedimentary protolith (as suggested by the preserved relicts of quartzite and calc-silicate components. In addition, certain lithologies of the unit also contains preserved sedimentary cyclic sequence. The Rattu formation comprises meta-pellites, marbles, calc-silicates pods and lenses and is considered to represent a metamorphosed cover sequence. Structural cross-section from north-west to south-east reveals that the Nanga Parbat sequence consists of two crustal-scale antiformal structures with a tight faulted synform in between. It is noticeable that the Mushkin grey gneiss exhumed with respect to the cover sequence at the margins. Field and petrographic data shows that Rattu formation and Harchu pink gneiss reaches up to kyanite and sillimanite metamorphic grades, whereas the Mushkin grey gneiss lacks these minerals. The Mushkin grey gneiss exhibits a great variety of migmatitic (metatexis) structures, indicating that the Mushkin grey gneiss has experienced more severe metamorphic conditions than any other rock unit in the Astor section. Our preliminary studies indicate possibilities of correlation between Mushkin and Harchu gneisses from the Astor valley with the Iskere and Shengus gneisses from the Indus valley, respectively.

S/83. Sayab, M., Butt, K.A., Khan, M.A. & Rafiq, M., 2001. Parallel, sub-parallel drainage pattern in the Surghar-Shinghar Range controlled by Neo-tectonic extension fractures associated with Main Frontal Thrust. Abstracts, 4th Pakistan Geological Congress, Islamabad, 73-74.

The Surghar-Shinghar Range at the eastern margin of the Bannu basin is a N-S oriented antiform in the hanging wall of the Surghar Thrust. The range is bisected by a set of N-S compressional fractures parallel to the axis of the anticline. Orthogonal to this set of fractures is an E-W oriented set of extensional fractures. The age of the Surghar anticline and associated structures is constrained by the sediments involved in the deformation. The Siwalik sediments in the Surghar-Shinghar Range are not older than 7-8 Ma. The involvement of these sediments together with the recent alluvium in the deformation suggests a role of neo-tectonics in the origin of Surghar-Shinghar Range. Based on the stress and strain analyses, we suggest that compressional and extensional fractures in the rocks of the Siwalik Group are the product of the compressional tectonics associated with the Surghar Thrust (Main Frontal Thrust) at the eastern margin of the range.

A study of geomorphology of the Surghar-Shinghar Range using field observations, aided by Landsat TM and SPOT satellite images, suggests predominance of a parallel, sub-parallel drainage pattern across the range. A parallelism between the drainage pattern of the range and the E-W extensional fractures suggests a role of structural control on the geomorphology. The E-W extensional fractures are dilated by seasonal drainage, forming steep gorges, especially in the Siwalik sediments. The Siwalik sediments mostly consist of friable to moderately hard sandstone interbedded with varying proportions of shale horizons. The extensional fractures in these lithologies facilitate drainage along these lines, thereby controlling the geomorphic processes.

Key words: Neo-tectonics, drainage, Main Frontal Thrust, Surghar-Shinghar Range, Trans-Indus Salt Range.

S/84. Sayab, M., Khan, M.A., Butt, K.A. & Pervaiz, K., 1999. Analyses of joints and associated neo-tectonic deformation band shear zones in the Siwalik Group of southern Surghar-Shinghar Range, Trans-Indus Ranges, Pakistan. Geological Bulletin, University of Peshawar 32, 25-39.

This study presents field observations on joints and deformation band shear zones (DBSZs) at the southern flank of the Sarkai-Mochi Mar (SMM) anticline, which is the southern most structure of the Surghar-Shinghar Range. The eastern flank of the anticline is eroded to form steep scarps, exposing the high angle trace of the Surghar Thrust (the Dara Tang fault). Two joint sets NS/NNE and EW/WNW are observed at the southern flank of the SMM-anticline, where the strike of the strata is about east west. These joints are restricted to the hard sandstone bands of the Dhok Pathan and Nagri formations. Field observations show that NS/NNE oriented joints are compressional and E W M

oriented joints are extensional in geometry. The orthogonal relationship of compressional and extensional joints yields rectangular blocks (15x6cm) in the hard sandstone bands. Minor folds with fold axes and axial planes parallel to the compressional joints (NS/NNE) are not uncommon.

The area also contains two sets of strike-slip DBSZs that cut across the sedimentary strata at high angles. The NS steeply oriented DBSZs are strongly banded foliated, with mesoscopic dextral sense of movement. These DBSZs are common and well developed on the south-eastern part of the SMM-anticline. The second set with ~501°- 600° orientation comprising incipient tabular DBSZs with sinistral movement, cut across the fabric of the NS oriented DBSZs. The two DBSZs form a conjugate geometry.

The frequency of these DBSZs is high close to the trace of the Dara Tang fault. Since, the Dhok Pathan Formation is the youngest lithological unit in the area (0.8Ma), the presence of both the joints and DBSZs in the upper levels of the formation suggests on-going neo-tectonics in this region. Based on field evidences, three deformational phases have been suggested for the formation of joints and shear zones. The compressional and extensional joints with a component of folding are formed simultaneously in the first deformation phase. This is followed by the second deformation phase in the form of NS oriented banded shear zones. The third deformational phase is characterized by the oriented tabular shear zones, which sinistral cut the NS oriented banded shear zones at an angle of about 500-600°. The dynamics of the SMM anticline in the context of regional tectonics suggest that the structure experienced compression from west to east during the fold formation. The southern flank of the SMM anticline, where the strike of the beds is east west, is recognized as the plunging hinge area of the fold. Thus, the east-west oriented beds experienced east-west compression and north-south extension in the form of joints and minor folds. We assume that the origin of both compressional and extensional joints in the Mochi Mar and pan of the Qabul Khel areas may be related with the folding of SMM anticline. As the north-south oriented Dara Tang fault (Surghar Thrust) cuts across the sedimentary strata passing at the core of the SMM anticline the DBSZs in the area appear to be dynamically related with this fault.

S/87. Sayab, M., Khan, M.A. & Rafiq, M., 1999. Rotated and displaced clay balls as kinematic indicators along shear zones in sandstones of the Siwalik group of Surghar-Shinghar Range, Trans-Indus Ranges, Pakistan. *Geological Bulletin, University of Peshawar* 32, 89-104.

Neo-tectonic events in the Siwalik Group of Surghar-Shinghar Range are characterized by compressional, extensional and conjugate shear fractures. The compressional fractures are in the form of reverse faults mainly along clay ball scoured surfaces. The sense of shear in these fractures is interpreted from rotated and displaced clay ball geometry. Shearing along these weak planes provide kinematics of clay ball geometrical behavior and their mechanical strength characteristics under surface PIT conditions. Most of the displaced clay balls are moderately hard due to the presence of carbonates, while others constitute some fine carbonaceous material. Thus, the displacement in the clay balls is controlled by their hardness. Some displaced clay balls show nice geometrical arrangement of Riedel fracture sets accommodating strain during shearing. Despite near-surface conditions (i.e., incohesive-brittle) the clay balls, due to the inherited plastic character of clays, form structures resembling those in plastic regimes of deformation. These structures include asymmetric rotated clay balls with tail edges just like in porphyroclasts, while others are equally rotated forming oxidized boundaries within the sandstone matrix with no tail edges. The kinematics of both rotated and displaced clay balls show reverse sense of shear all along the compressional faults.

S/88. Sayab, M., Mazhar, F., Butt, K.A. & Khan, M.A., 2001. Structure of the Surghar Range at its southeastern flank with emphasis on Surghar Thrust. Abstracts, 4th Pakistan Geological Congress, Islamabad, 38-39.

Field observations are made on the southeastern flank of the Surghar Range. The east verging Surghar anticline is deeply eroded in this part of the range, exposing steep scarp of the Surghar Thrust, together with the older formations in its hanging wall. The thrust runs along the eastern margin of the Surghar anticline, bringing Punjab foreland alluvium in contact with upper Permian and Mesozoic rocks in the northern, and Neogene rocks in the southern parts of the fault trace. A number of thrust splays are recognized in the area to the south of Mitha Khattak village, where the thrust splits into several oblique-slip faults. These shear zones are typically brittle, generally cutting across the strata. These shear zones are lined with cataclasites and show distinct asymmetric kinematic indicators commonly found associated with reidel fractures.

Overall the N-S trending Surghar Range is divisible into two anticlines; Makarwal anticline in the north and Sarkai-Mochi Mar anticline in the south. These two are separated by an exceptional low topographic relief, which is defined by a syncline termed Gulapa-Darsola syncline in this study.

Avalanche deposits represent a significant storage of winter snow on the south slope of the Himalaya Mountains, Pakistan, complicating the annual snowmelt cycle because of the differences in ablation of avalanche-transported snow and undisturbed snow. Measurements show very high rates of melting of both snow types, particularly of avalanche snow late in the melt season. The high rates are a function of the low latitude of the study area and the low elevation of the avalanche snow deposits, as well as heat release by condensation. Air temperature was closely correlated with daily snowmelt and appears to hold promise as a predictor, however, data constraints prevent an energy balance analysis of this relationship. Gravimetric measurements show that condensation is important in the snow surface energy exchange and can represent a significant source of energy for snowmelt. Rainfall during warm conditions also makes a more significant contribution to snowmelt than shown in previous studies. The derived temperature-based melt factors or coefficients compare well with published figures from other mountain areas, but their confidence limits are sufficiently wide to produce significant errors in the prediction of basin snowmelt runoff.

S/93. Schärer, U., Copeland, P., Harrison, T.M. & Searle, M.P., 1990. Age, cooling history and origin of post-collisional leucogranites Karakoram Batholith, a multi-system isotope study. *Journal of Geology* 98, 233-251.

U-Pb dating on zircon and monazite from different varieties of leucogranites in the Karakoram Batholith reveals two distinct pulses of plutonism at $25.5 \pm 0.3/-0.8$ and $21.4 \pm 0.3/-0.6$ Ma. In both granites, these minerals contain inherited components, documenting the presence of Precambrian material in the magma source. A crustal origin of the granites, and long crustal residence times of the source rocks are confirmed by highly negative ϵ^{Nd} , strongly positive ϵ^{Sr} , and T^{Nd} DM in excess to 1 Ga. A biotite gneiss and a granitic dike from the Karakoram Metamorphic Complex south of the batholith yield very similar ϵ^{Nd} , ϵ^{Sr} , Sr , T^{Nd} DM. In a Pb evolution diagram, initial isotopic compositions for both the granites and the rocks from the metamorphic complex plot far above the reference field for MORB documenting very close affinity to the Eurasian (Tibetan) continental crust. The striking similarity of isotope signatures between leucogranites and the rocks in the metamorphic complex strengthen the view that granite source material lies in the metamorphic complex. $^{40}Ar/^{39}Ar$ step heating analyses from the leucogranites yield isochron ages of 6.4 ± 0.1 and 7.4 ± 0.2 Ma for biotite, 6.6 ± 0.1 and 6.4 ± 0.1 Ma for muscovite, and 4.6 ± 0.2 Ma for K-feldspar. The two rocks from the metamorphic complex define isochron ages of 10.6 ± 0.1 and 4.7 ± 0.1 Ma for biotite, 14.9 ± 0.3 Ma for muscovite, and 8.9 ± 0.4 and about 4 Ma for K-feldspar. All K-feldspars analyzed contain trapped non-atmospheric Ar components to various degrees. The radiometric ages show that the leucogranites cooled from $750-650^{\circ}C$ at 25-21 Ma to $250-350^{\circ}C$ at 6 Ma, i.e., their cooling through the Ar blocking temperature in mica and K-feldspar occurred 15 to 20 Ma after granite emplacement. This strongly suggests a major and rapid uplift in latest Miocene to Pliocene times. In contrast to the leucogranites, cooling of portions of the metamorphic complex reached mica-K-feldspar blocking temperatures about 5 to 10 Ma earlier, documenting earlier uplift in the Karakoram Metamorphic Complex than in the Karakoram Batholith.

S/94. Schlinger, C.M., Khan, M.J. & Wasilewski, P., 1989. Rock magnetism of the Kohistan island arc, Pakistan. *Geological Bulletin, University of Peshawar* 22, 83-101.

In Northern Pakistan a section of island arc crust is exposed in Kohistan, northwest Himalaya. To better understand how magnetism and magnetic mineralogy depend on metamorphism, crystalline rocks of the Kohistan island arc have been studied, by means of field and laboratory investigations. The results are based on susceptibility and sampling traverses over 500 km in length, and rock magnetic and petrographic study of collected samples. Measurements and sampling concentrated on two profiles through Kohistan, one following the Swat River, the other following the Karakoram Highway. Of the lithologies sampled along these two profiles, the main sequence of interest consists of

rocks of the Kohistan island arc. With the exception of volumetrically minor serpentinized ultramafic rocks, the magnetic lithologies are pyroxene granulite, and gabbro-norite of the Chilas complex. Amphibolites, garnet granulites, metasupra-crustals and Kohistan arc diorites and granites are only weakly magnetized. The same is true Karakoram batholith granitoids. As far as prograde metamorphism of moderate to high-grade mafic rocks in the section is concerned, magnetic pyroxene granulites are strongly magnetized, relative to amphibolite facies equivalents and garnet granulites. Considering all lithologies, the calculated Koenigsberger's ratios are generally less than 2 (110 of 127 samples), commonly less than 1 (89 samples), and rarely in excess of 10 (3 samples), which indicates that the magnetization of these rocks is rarely dominated by remanence. The directions of natural remanent magnetization (NRM) are scattered, with a mean declination not far from zero, and a positive mean inclination. Petrographic and electron microprobe study of mineral assemblages and textures related to retrogressive metamorphism of pyroxene and garnet granulites shows that amphibolite facies overprinting along planar zones was an Fe-Ti oxide-consuming event. Lamellae of magnetite in magnetite-ilmenite intergrowths were replaced by silicates during retrogressive metamorphism of the pyroxene granulites. Regional-scale magnetic structure in this part of the crust is defined by magnetic contrasts between the Chilas complex and the surrounding Kamila amphibolites and Kohistan granites and diorites.

S/96. Schneider, D.A., Edwards, M.A., Kidd, W.S.F., Khan, M.A., Seeber, L. & Zeitler P.K., 1999. Tectonics of Nanga Parbat, western Himalaya: Synkinematic plutonism within the doubly vergent shear zones of a crustal-scale pop-up structure. Geology 27, 999-1002.

Detailed mapping and geochronologic investigations from the eastern, southern, and western Nanga Parbat-Haramosh massif reveal two thrust-displacement shear zones that have a spatial and temporal link with granite plutonism from ca.10 to 1 Ma. The shear zones define a crustal-scale antiformal pop-up structure, with dominant west-northwest-vergent and subordinate east-southeast-vergent thrusting. This substantially different than the surrounding area where the main exposed Himalayan structures are oriented parallel to the orogenic trend and are early to middle Miocene or older. Structures mapped throughout Nanga Parbat demonstrate that its rapid and young exhumation is not due to orogen-scale structural unroofing, and that sustained high erosion rates are required. The observed west-northwest-directed shortening is proposed to be a result of different arc-parallel motion accommodated at the syntaxial bend of the northwest Himalaya.

S/97. Schneider, D.A., Edwards, M.A., Kidd, W.S.F. & Zeitler, P.K., 1999. Geochronologic summary and lithotectonic architecture of the Nanga Parbat-Haramosh Massif, NW Himalaya. Terra Nostra 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 137-138.

The Nanga Parbat-Haramosh massif (NPHM), most notable for its extremely young metamorphic and igneous ages, represents the most northerly exposure of Indian craton. Reworking of the Indian craton in the last 10 m.y. has been of a large enough scale to apparently fully overprint the Himalayan signature. Previously reported leucogranite crystallization ages for NPHM are markedly younger from those reported elsewhere in the Himalaya. Undeformed leucogranites within the massif show a southward younging of accessory mineral U- (Th)-Pb ages: a 10 Ma pluton in the north, to 5 Ma dikes along the Indus and Astor Valleys, and ~2 to 1 Ma dikes, stringers and larger plutons in the south near the main summit (Zeitler and Chamberlain, 1991; Zeitler et al., 1993; Schneider et al., 1997). To the SE and SW of the summit, leucogranites again increase in age: in the SE, a dike which cross cuts the Rupal shear yields monazite ages from 17-9 Ma as well as the Early Miocene Southern Chichi pluton (Schneider et al., this vol.):

to the SW, the much larger, and deformed, Jalhari granite yields monazite ages from 8-2 Ma, and in a separate sample 13 Ma. Thermochronologic results from basement micas are very young and indicate a similar southward-younging pattern, also with a marked age increase to the SE and SW, yielding typical Himalayan cooling ages in those areas.

In the central portions of the massif are found the highest-grade rocks and youngest ages. Zeitler et al. (1993) obtained a ~1 Ma zircon U-Pb age for the Tato pluton. Subsequently, for the Mazeno Pass pluton, the opposite (southern) side of the Nanga Parbat summit ridge from the Tato pluton, we (Schneider et al., 1997) obtained strikingly coincident zircon and monazite U-Th-Pb ages of 1.4 Ma. That the 1.4 Ma age is obtained on both zircons and monazites for a larger body of granite illustrates the degree of very young melting.

A number of the granites cross-cut large crustal scale shear zones, hence post-dating the displacement on, and constraining the timing of, the shear zones. Along the NW margin, a small, undeformed tourmaline-bearing granitic dike, which crosscuts the high strain fabric of the MMT yields an age of 7 Ma, requiring that deformation along the MMT ceased by at least that time. This is in agreement with the conclusions of Pêcher and Le Fort (in press) which suggest that ductile deformation ended around 7-6 Ma on the Nanga Parbat-Karakorum suture to the north. Deformation in the north was due to doming and the entire northern section of the massif behaved as a single crustal block (Pêcher and Le Fort, in press).

Along the Rupal shear zone, south of the Nanga Parbat summit, the 2-1 Ma Rupal dikes also provide key timing constraints on structures and fabrics of the Rupal valley; the oldest crystallization age gives the minimum age of deformation. In this case the oldest dike dated in this study gives an age of 2.3 Ma. Thus, cessation of ductile deformation had to occur before 2.3 Ma. Furthermore, dike emplacement was coeval with cooling where the dike ages are similar to the Ar/Ar biotite cooling ages in the valley. This suggests the dikes were emplaced into shallow crustal levels, the melt having possibly migrated along the Rupal shear and into fractures accompanying the general uplift and erosional unroofing. The ages and structural orientation of the Rupal dikes compare well with those of the dikes and stringers on the north side of the summit which give ages between 3 and 1 Ma (Zeitler et al., 1993). These were emplaced, and somewhat deformed, into the Raikot-Lichar shear zone. Furthermore, monazites from two deformed granites along the WNW margin of the massif (at Jalipur and Diamir) yield ages as young as 5-3 Ma. This implies that deformation in southern Nanga Parbat (south of Indus-Astor confluence) has ceased much more recently (4-3 Ma) than the north (Haramosh; 7 Ma), and the southern NPHM, like the north, may have behaved as a single crustal block, bounded to the south by the Rupal and Diamir shear zones.

Crystallization ages on the SE margin of the Rupal valley are significantly older. Both the geochronology of a thin leucogranite dike (mentioned above) which cross-cuts the fabric of the SE Rupal shear in Chichi valley and the thermochronology of the shear zone rocks constrain the age of that portion of the Rupal shear zone to having ceased by 10 Ma, if not older (Schneider et al., in press).

The basement lithology is fairly monotonous with ages from zircon cores showing a ubiquitous Early Proterozoic inheritance, typically clustering around 1870-1850 Ma. This, as noted by Whittington et al. (1998), is similar to the Early Proterozoic inheritance of the Lesser Himalayan sequence in the central part of the orogen and therefore differs from the High Himalayan Crystallines that are common to the NW Himalaya which NPHM has long been considered a part. The Early Proterozoic zircon inheritance exists in all of the massif's units: gneisses, schists, metasedimentary rocks and larger granite bodies (Zeitler et al., 1989; Zeitler and Chamberlain, 1991; Zeitler et al., 1993; Schneider et al., 1997; Schneider, unpub data). Only a few isolated granites do not contain inheritance: the smaller leucogranite dikes and, surprisingly, the larger Jutial pluton (Schneider et al., 1997). Markedly younger than the other units in the massif, Zeitler et al. (1989) report zircons from a sample of the Shengus gneiss, in NE Nanga Parbat, yielding a 500 Ma inheritance; this sample lies near the generally agreed upon 'basement-cover' contact. Our new results from granitic rocks at Manugush (Bunar Gah, SW Nanga Parbat) indicate a yet another unit, which yields a Cambro-Ordovician age. Zircons from the porphyroclastic garnet-muscovite, -kyanite gneiss with cm long feldspar laths yield concordant U-Pb ages of 480 Ma. A petrologically similar augen gneiss (termed 'lath unit') was described by Edwards (1998) on the SE side of Nanga Parbat (Astor Valley); Foster et al. (this vol.) have obtained —500 Ma monazite ages from the cores of garnets within the lath unit. These samples also occupy the contact between the Nanga Parbat gneisses and the cover sequence. Based upon 1) the 'basement-cover' relationship across a large area, 2) the age, and 3) the similar petrologic nature between the W and E localities, we suggest that the Cambro-Ordovician lath unit was originally a largely continuous unit within the mass if, intruding into the 'basement-cover' contact. Edwards (1998) has suggested that the unit was intruded during, and subsequently underwent some of, the deformation associated with the main displacement of the MMT. The unit may be faulted and eroded away on the active western margin of the massif. Other sections of the NW Himalaya (Pakistan and India) and in Nepal also contain Cambro-Ordovician intrusions which, based on geochemical data, were generated by anatexis of continental crust (Miller and Frank, 1992).

In summary, the Nanga Parbat massif is mostly Early Proterozoic basement with interleaved deformed Cambro-Ordovician granites, reworked and exposed as recent as 2-3 Ma in the summit region. The overall structure, concentric metamorphic isograds and age pattern indicate the appearance of a young gneiss dome 'popping-up' on conjugate shear zones through Indian cover metasediments which have 20-30 Ma cooling ages.

S/98. Schneider, D.A., Edwards, M., Kidd, W.S.F., Zeitler, P. & Coath, C.D., 1998. Magmatism and deformation within Nanga Parbat-Haramosh Massif, Pakistan Himalaya. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 176-178.

Background: A general association of young plutonism, deformation, and cooling within the Nanga Parbat-Haramosh massif (NPHM), Pakistan Himalaya, is clearly recognized (e.g., Zeitler and Chamberlain, Tectonics, 1991). Previously reported leucogranite crystallization ages for NPHM are markedly younger from those reported elsewhere in the Himalaya. Undeformed leucogranite dikes within the massif give U-(Th)-Pb zircon and monazite ages of <2 to 7 Ma (Zeitler and Chamberlain, Tectonics, 1991; Schneider et al., EOS, 1997) with the youngest ages found near the summit regions. Leucogranite dikes occurring near or within major shear zones are typically emplaced into tension gashes that are at a high angle to the principal shear zone orientation and with fracture geometries that are suggestive of subvertical opening. Larger intramassif plutons include 1) Tato, U-Pb zircon rim ages of ~1 Ma (Zeitler et al., Geology, 1993), 2) Mazeno Pass, U-Th-Pb zircon and monazite ages of ~1.4 Ma and 3) Jutial, U-Th-Pb zircon and monazite ages ~10 Ma (Schneider et al., EOS, 1997). The Tato and Jutial plutons lie on the NPHM western margin and have intruded into the active Raikot-Liachar fault system; the Mazeno Pass pluton has intruded along the northwestern tip of the Rupal-Chhichi shear zone (RCSZ). This shear zone is comprised of a large belt of NW dipping, porphyroclastic granitic orthogneiss with a ubiquitous non-coaxial fabric that is consistent with accommodation of southeast vergence of southern NPHM (Edwards et al., 12th HKT, 1997a). Notably, the RCSZ is coincident with a rapid increase in Ar/Ar biotite cooling ages to the southeast (Schneider et al., EOS, 1997). Another significant break in biotite cooling ages occurs across a broad ~N-S trending zone in southwest NPHM. Argon biotite cooling ages on the western side of this zone are 20-30 Ma, whereas on the eastern side (towards the summit) cooling ages are 6 Ma and younger (Schneider et al., EOS, 1997). We present here new geochronologic data from leucogranites within NPHM, which, together with new field observations (Edwards et al., this vol) and previous data (summarized above), can provide significant new constraints on the spatial and temporal association between plutonism and deformation within NPHM.

New data: Edwards et al. (this vol) report a large plutonic sequence (the Jalhari granite) that grades into granitic and porphyroclastic orthogneiss as a result of syn to post-deformational plutonism. This granite and gneiss belt is a ~5 km wide, ~30 km long N-S trending zone that marks the large cooling age discontinuity on the southwest corner of Nanga Parbat. Sense of shear is east side up, consistent with upward and westward displacement of NPHM. Ion microprobe Th-Pb monazite analyses of a deformed, biotite-rich portion of the Jalhari granite (near the village of Diamroi) yielded ages between ~3 and 9 Ma. These ages fall along a line which increases with increasing Th/U ratios. Backscatter/SEM images of the analyzed monazite grains indicate some that have a non-uniform texture, notably lacking clear core-rim zoning patterns. This chaotic textural pattern is too fine to allow analysis of any single composition within a grain, despite the very small beam size (~15-20 microns) of the ion microprobe. However, a few texturally homogeneous grains were analyzed; these yielded the youngest of our obtained ages (~3-4 Ma). Near Garal, 13 km south of the village of Diamroi, we sampled an undeformed medium grained granite, which is adjacent to, and possibly part of, the same Jalhari granite. Ion microprobe analyses of monazite grains yielded Th-Pb ages of 12 Ma. Th/U ratios of these monazites fall along the same trend as those of the Diamroi (deformed) granite. Our interpretation of the Jalhari granite is as follows:

an initial pulse(s) intruded and crystallized as young as ~12 Ma, 2) ongoing synkinematic magmatism (as represented by the patchy monazite grain textures indicative of multi-stage growth history) resulted in further pulses that juxtaposed deformed and undeformed portions of the granite, and 3) final crystallization was around 3.5 Ma. This 3.5 Ma lower age limit is consistent with our cooling ages on the southwestern side of the massif, inboard and east of the Jalhari granite belt.

In southern Nanga Parbat, we sampled a small (tens of cm) little-deformed granite dike which discordantly cuts orthogneiss of the Rupal-Chhichi shear zone in northern Chhichi Gah. Like the Jalhari granite, this granite dike also yielded a scatter of Th-Pb monazite ages, in this case between 9 and 17 Ma; these ages also fall along an increasing line with increasing Th/U ratios. BSE/SEM images of the monazites show a similar appearance to the monazites of

the Jalhari granite. Biotite cooling ages from the northern section of Chhichi Gah give ages of 9-10 Ma (Schneider, unpub data). As within SW NPHM, the cooling ages are concordant to the lower Th-Pb monazite age. We infer that most of the displacement along this ('outboard') portion of the RCSZ occurred prior to 9-10 Ma and, similar to the shear zone associated with the Jalhari granite, plutonism was focused within the shear zone.

Discussion

Our new results indicate a fundamental association between plutonism and the major NPHM shear zones. None of the numerous granites seen within NPMH are of large areal extent and we infer that there has not been a widespread melting event (c.f., High Himalaya leucogranites; e.g., Harrison et al., *Geology*, 1997) but numerous anatectic pulses over the last ~10 Ma (Butler et al., 1997). Magnetotelluric studies show that there is no significant partial melt zone directly beneath NPHM (Park and Mackie, *GRL*, 1997), consistent with anatexis that is restricted to small volumes and/or distinct episodes. The observed proximity of granites to shear zones suggests to us that these anatectic episodes may be related to deformation. We propose a conceptual model where crustal thickening and/or decompression melting promotes small amounts of melting and deformation enhanced melt extraction (e.g. Thompson & Connolly, *Earth-Sci. Rev.*, 1995) allows melt migration to existing (or resulting) shear zones. This process

May be strain rate sensitive, whereby local anatexic episodes are a result of higher strain rates. With deformation enhanced melt migration, sufficient increase in melt percentages are rapidly attained, initiating melt migration that likely focusses within the shear zone (e.g Brown, *Earth-Sci. Rev.*, 1994). These melt-filled shear zones are then sites of thermally weakened material that are the focus of further deformation, including when the material is cooling through the solidus. This creates a positive feedback situation whereby the presence of melt enhances deformation, and within the existing weak (shear) zone periods of granite emplacement continually reoccur.

S/99. Schneider, D.A., Edwards, M.A., Kidd, W.S.F., Zeitler, P.K. & Coath, C.D., 1999. Early Miocene anatexis identified in the western syntaxis, Pakistan Himalaya. *Earth and Planetary Science Letters* 167, 121-129.

Evidence for typical Himalayan Early to Middle Miocene anatexis has remained elusive in the Nanga Parbat massif in the western Himalaya of Pakistan; previous work has identified only young plutonism (10-1 Ma). New U-(Th)-Pb data from the southern Chichi granite, a leucogranite in southern Nanga Parbat, reveal that crustal melting occurred during the Early Miocene. This largely undeformed, fine-grained pluton intrudes the Indian metasedimentary cover sequence adjacent to the Rupal shear, a major shear zone at Nanga Parbat. Th-Pb ion microprobe analysis of monazites from the Chichi granite yield ages between 22 Ma and 16 Ma, with majority of analysis lying at 19-18 Ma. U/Pb zircon analysis yields ages, which fall along a chord with lower intercept age of 19 Ma. The zircons also contain an ~1850 Ma inherited component. These data indicate that the Early Miocene anatexis that is ubiquitous in central portions of the Himalayan orogen, unreported anywhere in the NW Himalaya, also occurred in the western Himalayan syntaxis, and demonstrates that Nanga Parbat has a protracted melting history. A small granitic dike that cross-cuts the outer portion of the Rupal shear yields monazite ages between 22 Ma and 9 Ma, where the young ages correlate with high U concentrations. ⁴⁰Ar-³⁹Ar biotite ages from adjacent gneisses indicate cooling by 10 Ma, requiring significant displacement on this portion of the Rupal shear to be older than ~10 Ma and possibly as old as ~20 Ma.

S/100. Schneider, D.A., Edwards, M.A., Zeitler, P.K. & Coath, C.D., 1999. Mazeno Pass pluton and Jutial pluton, Pakistan Himalaya: age and implications for entrapment mechanisms of two granites in the Himalaya, *Contributions to Mineralogy and Petrology* 136, 273-284.

Zircon and monazite U-(Th)-Pb ion microprobe analysis were performed on the Mazeno Pass pluton and the Jutial pluton, two leucogranite bodies within the Nanga Parbat-Haramosh massif (NPHM), Pakistan Himalaya. Zircon rim ages and monazite ages indicate the Mazeno Pass pluton in southwest NPHM intruded at 1.40 ± 0.05 Ma; the Jutial pluton, to the north, similarly yields concordant zircon and monazite ages suggesting crystallization at 9.45 ± 0.06 Ma. The Jutial pluton was subsequently intruded by leucogranite dikes at 5.3 Ma, as revealed by monazite ages. Concordancy of U-Pb and Th-Pb accessory mineral ages demonstrated the robustness of the technique on young rocks. Both plutons, some of the youngest in the Himalaya, have a general association with nearby shear zones that

we interpret to have played an integral role in granite evolution and emplacement setting ('deformation enhanced ascent'). Together with new field observations, these results provide an insight on the spatial and temporal relationship between plutonism and deformation relating to the development of the massif.

S/101. Schneider, D.A., Edwards, M.A., Zeitler, P.K. & Kidd, W.S.F., 1997. Ion microprobe U-Th-Pb and $^{39}\text{Ar}/^{40}\text{Ar}$ geochronology of Nanga Parbat-Haramosh Massif (part 1). Rupal Valley, southern Nanga Parbat, and Jutial granite, Haramosh area. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 205-206.

The Nanga Parbat-Haramosh massif (NPHM), northern Pakistan-NW Himalaya syntaxial region-is a tectonic half window of partly re-worked, largely Proterozoic, Indian plate rocks that have been exhumed from beneath Mesozoic arc rocks of the Kohistan Ladakh Area. The metamorphic and thermal evolution of this anomalously hot, young massif has remained elusive.

Using UCLA's National Ion Microprobe Facility, young U-(Th)-Pb ages on accessory minerals have been obtained. Single-grain, single-spot analyses were performed on zircons and monazites from basement rock and granites. Single-grain, total-fusion $^{39}\text{Ar}/^{40}\text{Ar}$ laser experiments were performed at Lehigh University to obtain cooling data of biotites in country rocks. We report here new geochronologic data, predominantly from southern NPHM, including the first in-Pb monazite age for a large leucogranite body, the Jutial granite.

We have conducted extensive sampling along the Rupal drainage through the southern flank of Nanga Parbat in conjunction with detailed structural mapping (Edwards and Kidd, this volume). In many cases, the tectonic role identified for mapped principal structures is further supported by results of geochronologic investigations.

The Mazeno Pass pluton (5400m) is a notably undeformed, tourmaline and biotite absent, fine-grained, muscovite granite which cross-cuts foliation of local biotite gneiss. U-Pb zircon analyses record a discordant age with an upper intercept of ~1860 Ma, representing the Precambrian protolith age, typical for the NPHM; this age is consistent with those of nearby gneisses and schists. The lower intercept is defined by a cluster of concordant zircon ages at ~1.4 Ma. Moreover, monazite from the same pluton also yielded a in-Pb age of ~4.4 Ma. Accordingly, we take 1.4 Ma as the intrusion age of the Mazeno Pass pluton.

In the central portion of Upper Rupal Valley (largely between Rupal and Shigiri villages), cm-in scale dykes invading granitic augen orthogneiss are found. These predominantly muscovite rich, tourmaline-bearing pegmatites are abundant throughout the massif and typically trend ~N-S, however, in central Upper Rupal they trend ~W-E and dip N, locally reflecting gneissic fabric (Edwards and Kidd, this volume). We sampled two Rupal dykes and obtained a monazite age of ~1.2 Ma from the first, and zircon and monazite ages of ~2.2 Ma from the second. Such leucogranites within the massif have been suggested to be the result of decompression melting, allowing intrusion at shallow depths (Zeitler and Chamberlain, 1991).

A staurolite-kyanite-garnet schist sampled from Rupal valley, near the village of Tarshing gives U-Pb zircon ages clustering near or below concordia at ~1 860 Ma; furthermore, a few ages also fall along a discordia toward the origin with a lower intercept age of <5 Ma. Approximately 1-km south of Tarshing, up Chichi valley, both the biotite schist and the samples from the eastern edges of a ~SW trending, thick (kms), extensive belt of S-C fabric porphyroclastic granitic augen gneiss (the Rupal Shear Zone, see below) give a suite of total-fusion $^{39}\text{Ar}/^{40}\text{Ar}$ ages of >15 Ma. These differ sharply from the young (1.2 & 2.2 Ma) ages west and north of the Rupal shear zone, and indicate a marked contrast of exposed crustal depths, based upon the large displacements required by Rupal valley structures. An even larger age contrast is found in SW Nanga Parbat: A broad suite of total-fusion $^{39}\text{Ar}/^{40}\text{Ar}$ biotite ages mainly between 20 and 30 Ma are found for the area of Indian cover metapelites in Niat and Barai valleys (5-10 km W of Mazeno pass). Between Thia area and Mazeno / Toshe Gali, there is a steep ~NNE trending belt of faults that can be traced to both (1) the Tato shear in the Raikhot valley, and (2) the large thrust near the Indus at Raikhot/Liachar, where it locally forms the western margin of NPHM (the contact with Kohistan).

We propose that the Raikhot/Liachar southward continuation, and the Rupal shear zone, and other significant structures in the uppermost Rupal valley (Edwards and Kidd, this volume), have accommodated uplift of central Nanga Parbat on the W, S & E sides. We note that here on the Nanga Parbat southern flank, unlike the central and northern regions of NPHM, the shear zones that have accommodated "block uplift" are substantially inboard of the W & E margins (margins of India to Kohistan Ladakh Area). The area within these shear zones has enjoyed prolonged elevated temperatures sufficient to maintain open system behavior of Ar until a period coincident with plutonism and melting nearby. We regard peak metamorphism here to be contemporaneous with plutonism, and not to post-date it.

In the northwestern portion of the NPHM ("Haramosh area"), the Jutial granite is predominantly a two-mica, tourmaline granite, essentially undeformed. It intrudes and cross-cuts the surrounding quartzofeldspathic Nanga Parbat grey gneisses (termed "Jskere Gneiss", Madin et al., 1989). The approximate size of the body is difficult to determine, but our field observations suggest a diameter of at least 5 km. Observations by Butler and co-workers (1992), suggest at least two phases of intrusion can be distinguished. Two samples from the main body of the Jutial pluton were analysed: (1) a medium grained, tourmaline speckled granite and (2) a pegmatitic version of the same rock. The appearance of this second, pegmatitic rock is similar (large muscovite books, tourmaline) to the very young leucogranite pegmatites of the southern portions of the massif. Both samples yielded concordant U-Pb zircon ages of 10 ± 1 Ma. A second igneous phase was also examined. This yielded am-Pb monazite age of 5.2 ± 0.3 Ma. This phase lacks the amount of muscovite that the main body contains. Additionally in this phase, tourmaline is euhedral and roughly equal-granular (1-2 cm) and is distributed homogeneously throughout the rock. Previously reported biotite and muscovite $^{39}\text{Ar}/^{40}\text{Ar}$ cooling ages from the Jutial granite are ~5-6 Ma (George et al., 1995). It is noteworthy that our two new ages for Jutial occupy >50% of the time period occupied by the sudden and recent uplift of NPHM (i.e. since ~10 Ma). This suggests that the history of both plutonism and metamorphism is complex; that of a young, dynamically self-exposing area. The ~5Ma monazite age from Jutial granite is consistent with previous suggestions for young plutonism in both of the high massif areas (Zeitler and Chamberlain, 1991).

In addition to providing precise ages to identify thermal events and associated thermal and mechanical boundaries, our data has modified and refined the data array illustrated in Winslow et al. (1996). This now shows that within NPHM there has been differential exhumation and magmatism from north to south (younger in the south) reaching sufficiently large and well-localized displacements to involve major intra-massif shear zones, hitherto unreported for NPHM. This is a contribution from the Nanga Parbat Continental Dynamics Project

The author described the geology of the North western Karakoram and showed that the rocks can be distinguished into laterally extending zones. The axial Karakoram batholith was considered to form a heterogeneous plutonic mass varying in composition from hornblende granodiorite to biotite granite with little or no hornblende. Such intrusions are considered to be synorogenic and of upper Cretaceous and early Tertiary age. Aplitic granite associated with the tectonic disruption of the region are post tectonic and post Oligocene.

S/108. Schomberg, Col. R.C.F., 1935. Some glaciers of upper Chitral. *The Alpine Journal* 47, 98-102.

On the 8th, 9th and 10th there was severe wind and snow at all points above Camp V. Angtsering added that during his last two days' sojourn above Camp IV the weather was good, but a great depth of snow covered everything but steep rocks.

The valley of the Yarkhun river, which during its course is known as the Mastuj, Chitral, or Kunar, is no more than a rocky trough with many lateral streams. It rises near Wakhan, in the grassy slopes of Baroghil, but it depends for its water supply on the great glaciers that are almost wholly confined to its left side: and it is this left side, with its moraines, fans, and deposits that demonstrate the great part that glaciers have played in the present condition of the Yarkhun valley in Northern Chitral. In summer this river is a swift, turgid, black flood, while its affluents are equally unlovely.

Generally speaking, the rocky formation of the Hindu Raj and the Chitrali Hindu Kush do not lend themselves to glacier making, and in a region of great rock ranges and towering peaks, the glaciers are disappointing, for there is little chance of the snow accumulating on these perpendicular slopes, while the regular and heavy rainfall (to which I shall again refer) militates against any heavy deposits of ice and snow. The hanging glaciers are insignificant, the normal glaciers seem unusually small, and the visitor is disappointed in the somewhat non-Alpine appearance of the region. I certainly was. Perhaps I hoped for too much, but I am reluctant to think that the lack of glaciers in a country where one expects many can be wholly explained by the present era being one of glacial retreat.

At Warsum (Wassum), for instance, the fine glacier torrent flowed from a spectacularly insignificant ice and snow formation. It was only when we reached the Madod stream flowing into the left of the Yarkhun river, opposite the settlement of Shost, that I saw glaciers that would repay a visit. The stream in the early part of a July afternoon was a considerable torrent; we camped at Kand, a very small village high above the river, and some 21/2 miles from the Madod valley. Next day, with Daulat Shah of Hunza, who had a profound contempt for all Chitralis, and a local guide, we started for Madod.

We began badly. Our guide led us, although protesting and reluctant, up the side of a mountain from which he assured us we should see all: and as he was the owner of the valley, we felt he ought to know and so we gave in. My own idea was to skirt the right-hand of the valley and so ascend to the glacier, to which Daulat agreed. We followed instead the proprietor, obeying the rule of trusting the local expert. We toiled up and up to a height of 14,000 ft., and then poked our heads over and looked down on the Madod nala, to discover exactly what we expected that we were right and the expert was wrong.

We had to descend into the nala; tumbling down a steep hillside, no easy matter, but with Daulat as a guide (he had, of course, never seen the place before, but had the true Hillman's instinct) we reached the bottom of the right side of the Madod valley. The stream itself lay beyond, hidden between deep conglomerated cliffs. Above this, on the left, was some poor grazing and a little cultivation. We passed through the latter, then, climbing up the steep moraine, took an hour and a half to cross. A bitter wind blew out of a cloudless blue sky. Finally, in 5 1/2 hours we reached the top of the moraine and were rewarded with a fine view; then finding a sheltered place we were able to enjoy the spectacle in comfort.

The moraine was heaped up in the centre of the valley, but from its apex we found that it sloped away between ourselves and the glaciers in a deep trough. Although the whole valley was filled with the glacier, most of the ice, after casting up this moraine mountain (for so it was), turned aside and flowed to the left where it was piled up high on the grassy slope. It was a strange spectacle to see the ice-sheet climbing up the greensward.

On its right, the glacier had left in its wake a high knife-edge of detritus which deepened the effect of the trough. The glacier immediately below us that is, between the end of the valley and the moraine was covered with stone and rubbish, but there was no sign of any water although we expected to find a small tarn. Our attention was drawn to the head of the valley where, from a circle of abrupt and jutting peaks, fine glaciers flowed down from as many

small colors, filling the bed of the valley with a clear broken mass of glittering ice. Between these flowing glaciers were hanging ones, the entire head of the valley being thus swathed in ice or snow. I estimated the length of this clear ice in the floor of the valley as 1200 yards long. Then it grew dirty as it sank lower, flowing between the old moraine and the left side of the valley. The actual snow deposits were limited to the head of the valley. On the right, facing S.E., there was not a vestige of snow and the roads were peculiarly arid and barren. On the left was a good deal of grass and a few traces of rapidly melting snow. The lower half of the valley as well as the fields referred to above contained willow and birch trees. There were no permanent inhabitants and the barley did not look very promising, but that was due as much to neglect as to the elevation, for we saw a horse calmly devouring the ripening crop and, although the guide drove it away, there was nothing to hinder it from returning. The next glacier visited was the Vedinkot and, on the way up the Yarkhun valley, we passed two or three others after leaving the Madod, but the river was impassable. Several of these glaciers were quite short, and wholly visible from the opposite or right bank. The Vedinkot or Chattiboi (a word which means 'lake-forming') flows N., and then turning N.W. reaches the left bank of the Yarkhun river flowing at its base.

The snout of the glacier ends in perpendicular cliffs of clean white ice, with the river flowing below and lapping these ice-walls. All day and all night the crash of ice falling into the stream broke the silence: and when a large piece was detached there came a noise like thunder. The river, in consequence, was full of large blocks of ice, swirling and jostling together. A remarkable feature of the Vedinkot Glacier, which throughout its length completely filled the bed of its own valley, was that it was joined by the broad North Darkot valley with its own stream flowing in it, but the glacier of which was distant and had not advanced at all. In spite of this, on the left of this same valley, there were hanging glaciers and snow deposits of a considerable extent. The explanation of why this valley was not filled with a glacier like its fellow lies in the original shape of the Vedinkot valley. The steep icefall merged into an almost level sheet of ice, while the gradient suited the flow, continuance, and normal life of the glacier. The North Darkot, however, could not force its way down a longer and unsuitable course; the resistance and friction was greater than its momentum could overcome. The Pasu and Batura Glaciers in Hunza, the Western Aghias in the Tian Shan, and many other glaciers, which continue far down their valleys are largely indebted for their length to the gradient of the valley. Beginning with a steep icefall, but which gradually eases off, the flow of the glacier is moderated and the original momentum is diminished, while at the same time the ice stream can continue its course and preserve its identity far down into the valley.

The action of the sun is also limited to the actual surface of the glacier, of which the edges are protected by the sides of the valley. Again, the liquefaction of the steep icefall is neutralized by the gentler slope lower down. Besides the reasons given there is also, in the case of the South Darkot Glacier, a real failure in the ice of recent years. Some time ago there was a route over the Darkot Pass, down the glacier, to Vedinkot. Then for a number of years the North Darkot Glacier flows south from the Darkot Pass, and should not be confused with the glacier flowing direct into the upper Yarkhun from the same pass: this latter is the Chigar Glacier. It was closed in 1932 it was again passable, which indicates a decrease in the glacier: when crossing the Darkot Pass by the Chigar Glacier I could see that the South Darkot was easy enough. My Wakhi yak drivers, stating they would be at their homes in Vedinkot in a very short time when taking this route, disappeared contentedly down it. Near to Vedinkot was another glacier, the Pechutz or Hot Spring.

This small glacier was in a very large valley compared with its size, and suffers much from solar action on three sides, attacks from falling stones and lateral streams, and was quite a pathetic object, dwindled and shrunk in its too roomy bed. It was not wholly a case of a glacier having carved out a valley that it now fails to fill, for in this arid country a glacier is constantly exposed to outside influences which diminish it considerably. But so far as Vedinkot went, the great glacier more than compensated for the failure of its neighbours to fulfil their role and bring their ice to the river bank. It was a splendid spectacle, this long wall of ice towering over the roaring river. We heard that on one or two occasions spectators had been killed by splinters of the icewall falling across the river; we were very glad that it did not happen to us.

So far as dimensions go the principal feature of Northern Chitral is the great Chiantar Glacier, the true source of the Yarkhun river. This great glacier is, at a conservative estimate, some 20 miles long with an average width of 3-4 miles. Its bulk is most impressive, but is seen to the best advantage from 10 to 15 miles off. Otherwise, it can hardly be called a beautiful sight. Interesting, no doubt, but its flatness and regularity detract from the general effect. The surface of the glacier is singularly smooth, due to the very gentle gradient of the flow. Naturally the glacier is broken by friction near its rocky banks, but in 1933 crevasses were few, while even mere superficial cracks were not numerous, and where I wandered on it, I could have driven over much in a light motor car. The Chiantar was a wonderfully clean glacier, the surface moraine being only abundant near the snout where there were quite a number of fast collapsing tables of immense size. I judged the glacier to be divided into three distinct parts. The head and snout were smooth and regular but, owing to a change in gradient, the centre was much broken by crevasses, yet,

even so, much less than could have been expected. A feature of the glacier was its consistency in width; from a point near its snout, or indeed from any neighbouring high ground, the whole glacier was visible, except for a small part at the head. I have tried to find the meaning of the word 'Chiantar,' which many glaciers bear. In Burishashki, the language of Hunza, Nagir and Yasin, the word means 'spry, sprightly, smart,' but in rather a bad sense. What it means in Shina or in Khowar (Chitrali) I failed to discover. The glacier has one large but unnamed tributary, 6 miles long, flowing in on the left from the S., and which joins the main icestream, but preserving its own individuality, flows on the left side of the valley. Between it and the main glacier is a black band of moraine which is most conspicuous throughout its length. This tributary glacier joins the main one 5 miles from its termination in the Yarkhun river. As I have said, I found it easy to walk over the glacier; of this I did a great deal. I also crossed it with yaks about half a mile above its snout, and experienced little trouble except in getting on and off. I left slightly disappointed with the spectacular effect of this great ice river. The sides of the valley were monotonous and low, so was the smooth and tranquil sheet of ice; it was only by the effort of remembering its great bulk that I kept my interest alive. This vast ice river was, in fact, rather deadening.

The Chiantar Glacier appeared to me to be advancing very slowly. The Yarkhun river was quite unfordable anywhere, at any time, by day or night, though we watched it most carefully, since crossing the ice meant a considerable detour for all of us, and we were anxious to find a ford. All three glaciers, the Madod, Vedinkot, and Chiantar, were slowly advancing, but the other glaciers seen were small, generally static or retreating. From talking with the people it was evident that cloud-bursts are a feature of the country. I was shown tracts of territory near Wassum, for instance, where good arable land had been ruined by summer floods. In some places I saw settlements destroyed by the same cause, and the peasants attributed the damage to the heavy rain. In the Baroghil we heard alarming tales of the heavy and continuous downpours; we only escaped such a deluge by the happy accident of leaving the day before. This heavy rain must greatly affect the glaciers and especially retard vegetation; I think that this interference with the normal life of a glacier accounts for the apparent vagaries of the ones in Chitral. I do not pretend to any elaborate study of the Chitrali glaciers; but it was clear that the smaller glaciers contrasted strangely with their neighbours, and I believe that they had suffered from the effects of a recent cloud-burst, having lost an unusual quantity of their ice, which they were in the less favourable position to replace. I have often watched a sudden storm on a glacier and even a comparatively light shower achieves a great deal. The warm rain corrodes the ice, stones are brought down with a clatter, and ice, rock and much else go rattling down, causing a marked change in even a small formation. It can hardly be argued that the Chitrali glaciers of the upper Yarkhun, whether of the Hindu Kush or Hindu Raj two names for one mountain group are different from others, and yet the ice deposits exhibit a strange inconstancy and waywardness. All I suggest is that the Chitrali glaciers must be modified by these rain-storms which have so greatly altered the formation of the valley itself.

S/109. Schomberg, Col. R.C.F., 1938. *Kafirs and glaciers: Travels in Chitral*. London, Hopkinson, Brighton. 287p, 24 plates.

The book describes exploring the mountains and villages of Chitral, including Tirich Mir.

Following a distinguished career in the British Army, Colonel Reginald Schomberg (1880-1958) became a writer, photographer and explorer travelling throughout Central Asia and the Himalayas between 1927 and 1947.

From the Himalayan Club Journal:

Kafiristan

One used to imagine a mysterious land inhabited by strange men and women, who used bows and arrows and spoke an unknown tongue. Colonel Alexander Gardner did visit the country in 1826, but then he had paid a call to almost every known portion of the earth, and unfortunately most of his records were lost. Mr. McNair, of the Indian Survey Department, carried out a most remarkable expedition in 1883, and Sir George Robertson's visits to the country in the years 1889, 1890, and 1891 were described very fully in his book *The Kafirs of the Hindu Kush*. Since then little has been written of this out-of-the-way patch of Asia.

And now that untiring traveller Colonel Schomberg has given us a book which will gladden the hearts of all lovers of the Himalaya and Hindu Kush.

From the town of Chitral itself, Schomberg went first to the Bum-boret valley, where the Black Kafirs or Kalash live. From there his wanderings took a northerly line always bearing to the east. He visited nearly all the passes over the Hindu Kush, leading from Kafiristan and Chitral into Afghanistan and Wakhan, including the Dorah, the Nuqsan, the Kotgaz, and the Shan Jinali, all of which, with their heights and approaches, are usefully described. It is

interesting to note that the Kotgaz pass, which used to be a route into Badakshan, is now a confused mass of snow and ice and impassable to an ordinary pedestrian.

Schomberg considers that almost all the major glaciers of western Chitral are in retreat, and 'with black unseemly snouts, they look shabby, seedy, and decayed'.

It is when we come to the people themselves, however, that the true value of the book is shown, their superstitions, social customs, pastimes, festivals, and general mode of living being described in detail by a highly trained observer of central Asian tribes. A touch of humour throughout takes the edge off the dreadful laziness and shortcomings of the Chitrali — and makes the book intensely readable.

The Chitrali must be the most superstitious of all mortals. Their fairies are like ordinary men and women except that their heels are in front and their toes at the rear. Surely they must have a sister who inhabits the Khyber, for the Afridis used to tell me of an evil woman whose toes pointed aft, who compelled the lonely traveller to follow her by looking at him over her shoulder, and who then led him to a deserted graveyard to be devoured by goblins and demons!

The book is very fully illustrated with excellent photographs, including a beautiful picture of the peak of Tirich Mir; there is a clear good map, and also a very handy index for reference. An appendix at the end gives a complete historical sketch of Chitral. Altogether this is a remarkable book, which, being up to date, should be of very great use to any Political Officer or traveller in Chitral or Kafiristan.

S/111. Schouppe, M. & Fontan, D., 1993. Geological outline of Neelum Valley (Azad Kashmir, NE Pakistan). Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 77-78.

More than fourteen hundred square km area is being intensively mapped at the scale 1:50.000, between the Neelum River and the watershed separating the Neelum Valley from the Kaghan Valley. New ground is broken in the sense that it is the first time that a systematic regional mapping is undertaken in a zone, which is often forbidden to foreigners due to the political instability between the Indian and the Azad Kashmir. Geological data collected since 1991 greatly improve the understanding of the Higher Himalayan Crystalline (HHC) of Neelum Valley and relatively complete previous field observations made by other authors near the Hazara Kashmir Syntaxis.

Stratigraphy

In the HHC unit of Neelum we have distinguished a basement and a cover. The basement comprises a thick sedimentary sequence intruded by leucocratic garnet-bearing granitoids of pre-Himalayan age (presumably Early Paleozoic). The sedimentary rocks consist of a monotonous alternance of psammitic to pelitic schists with minor intercalations of impure marble. The contact between the granitoids and the schist is generally tectonized. Evidence of intrusive contacts are still observable:

spotted schists with andalusite relics and skarn in the Jagram-Kaichpani area and magmatic contact in the Shardi-Surgun-Gumot area. Basaltic dykes cross-cut at low angle the regional banding of the basement. The cover has been divided into three units (from bottom to top):

unit A: a siliceous sequence made of impure quartzites associated with minor metaconglomerates, and a thick sequence of kyanite-bearing paragneisses.

unit B: an alternance of impure marble (frequently ruby-bearing), calcschist, and amphibolite.

unit C: a thick sequence made of graphite-bearing garnet micaschist. The contact between the basement and the cover is believed to be an old tectonized stratigraphic unconformity. The question remains open due to the lack of well accessible outcrops.

Metamorphism

The regional Himalayan metamorphism of the studied area has been shown to be of Barrovian type (Iron, biotite-chlorite zone to sillimanite zone) with an early eclogitic stage present only in the Shardi-Surgun-Gumot area. In the cover sequence of the Shardi-Surgun-Gumot, a typical kyanite-staurolite assemblage of high temperature amphibolitic facies, is wide-spread developed. Beside this assemblage, a few relics of previous prograde

metamorphism are present. Some chlorite crystals, discordant on the schistosity, attest for a not intensive retrometamorphism in the green schist facies.

The sedimentary sequence of the basement, well developed in the Jagram-Kalapari area, shows a metamorphic zonation consisting in a biotite-chlorite zone, a kyanite-staurolite zone and a sillimanite zone.

Rocks with biotite-chlorite assemblages were encountered near Kundaishahi. These assemblages may represent relics of a prograde phase of Barrovian metamorphism or a pro-Himalayan low-grade phase associated with the emplacement of the granitoids.

Kyanite-staurolite bearing assemblages are not common on the field. The typical assemblage consists in white mica, biotite, garnet, epidote and amphibole. Kyanite and staurolite, visible only in thin section, are associated with the spotted schists. They grow on old andalusite grains, already replaced by white mica and quartz. This suggests that the time of re-equilibration to the amphibolitic condition was relatively short.

Sillimanite appears in the sedimentary sequence with anatectic rocks (agmatites) as small needles or flakes. It is associated with the first appearance of K-feldspar.

In the granitic rocks, the old magmatic white mica is partially or totally replaced by fibrous sillimanite. In the migmatitic gneisses, sillimanite coexists with kyanite and an incipient melting appears in small (dm) shear zones. In the Shardi-Surgun-Gumot area, basaltic dykes cross-cutting the migmatitic gneisses are characterized by, eclogitic assemblages (omphacite+garnet). These eclogitic assemblages are only preserved in the centre of the dykes. Sometimes, they are partly replaced by later discordant growth of hornblende and biotite at the border zone, by green schist assemblages. Eclogites in the same metamorphic setting, have been found also outside the mapped area. They appear in the Lillan Basti area (Kaghan Valley) as strongly deformed pillow lavas and, in Kel area, as dykes cross-cutting migmatitic rocks. Eclogitic assemblages are not found in the Jogram-Kalapari area where the basaltic dykes show an amphibolitic paragenesis with relics of the magmatic texture. The fact that eclogitic assemblages have been found in the Shardi-Surgun-Gumot area and that they are absent in the Jagram-Kalapari area, suggest a different metamorphic P-T-t path for both of them.

Structure

The basement- and the cover rocks of the Higher Himalaya Crystalline of Neelum Valley illustrate the prevalent ductile nature of a complex Himalayan deformation. Four successive phases of folding have been distinguished on the field in both mapped areas ("Jagram-Kalapari" area and "Shardi-Surgun-Gumot" area).

An over spread penetrative schistosity (S1), derived from the preferred orientation of platy and acicular minerals lies subparallel to the banding. It is probably related to a large ductile shear at deep level, associated with isoclinal and intrafolial foldings (F1). This first phase (F1) developed an East oriented stretching lineation (L1) well expressed in some granites and amphibolites of the "Jagram-Kalapari" area. A second phase (F2) folded isoclinally the main schistosity and the banding. This phase brought off the transposition of the basement and cover sequence initiated by F1. Later, a third phase of tight folding crenulated the main schistosity to develop a crenulation cleavage S3, 15° to 25° oblique to the banding. The geometry of all these structures is disturbed by the fourth folding phase, which produced open folds repeated with a wavelength of several kilometres. Their axial planes are subvertical and strike NE-SW. From place to place, the fold axes are sub-horizontal, gently plunging to the NE or to SW. This suggests further gentle deformations expressed in the rocks with a very large wavelength (>20 km). We mention finally a set of small early deformations including kinking of the previous structural planes, different fracture sets and local sub-horizontal thrust planes, constantly characterized by a displacement of the roof to the SW.

S/112. Schoupe, M., Fontan, D., Laduron, D. & Martinotti, G., 1995. Macro- and Mesoscopic Fold Interference Patterns in the Higher Himalayan Crystalline (HHC) and the Lesser Himalayan Crystalline (LHC) of the Kashmir Himalaya. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

Recent structural analysis at Neelum valley (figure 1) has drawn a detailed picture of the major Himalayan deformation phases which have affected the rocks of the Lesser - and Higher Himalayan Crystallines (LHC and HHC) of Azad Kashmir. At least four successive phases of deformation have been recognized in both the Precambrian basement and the Tethyan metasediments of the LHC and HHC. The Kalapari rock fragment, redrawn in figure 2, illustrates the phases of deformation D1, D2a and D2b; the figure 3 illustrates the late phases D2, D3 and D4.

The earliest phase D1 of the Himalayan deformation is a penetrative ductile deformation which predates the peak of the Himalayan Barrovian metamorphism. It is characterized by intrafolial and isoclinal folds and by an axial plane

schistosity S_i , best observed in some D2a fold hinge zones (figure 2). The foliation S_i is defined by the orientation of the platy minerals. In the upper HHC of the Neelum valley, regional D_1 sheath-like folds induce a 180° re-orientation of the F_1 fold axis parallel to the N-S trend of the nappes tectonic transport.

Isoclinal folding also characterizes the early step (D2a) of the syn-metamorphic second phase of deformation (D2). Due to the focal re-orientation of the F_1 axis, the D_1 and D2a isoclinal folds show both coaxial (type 3) and not coaxial (type 2) fold interference patterns. The figure 2 illustrates an arrowhead fold interference pattern of type 2. The D2a phase of deformation has generated a fine penetrative S_{2a} foliation and a mineralogical extensional lineation L_2 , particularly visible in some amphibolites and in some orthogneisses.

A second generation of structures (D2b) has been produced during the D2 phase of deformation. Open, close to tight D2b folds are related to the shearing stress responsible for the syn-metamorphic southwestward overthrusting of the HHC over the LHC along the MCT. Close to the MCT, the crenulation of the early structures has generated a S_{2b} crenulation cleavage in the more pelitic rocks and a fracture cleavage in the more quartzitic rocks. As visible on the figure 2, D2a and D2b folds are coaxial, generating a wavy fold interference pattern (type 3).

The next phase of deformation D3 is only observable at the map scale. It consists in open flexural slip buckle folds with a more than 6,5 kilometers wavelength. The D3 fold axis trend NE-SW. The figure 3 is a synthetic map showing the macroscopic D2a and D3 folds exposed in the Neelum valley. In the lower half of the map, D2a and D3 folds are approximately perpendicular. They produce an intermediate interference pattern: arrow-head, dome and basin structures (type 1-2). On the other hand, the upper part of the map shows a considerably reduced obliquity between the D_1 -D2 and D3 structural trends. In that case, the structures generate a near-coaxial type (2)-3 interference pattern.

A last D4 phase of deformation is mostly expressed by the doming of the earlier structures to build the Hazara Kashmir Syntaxis, of which the eastern flank crosses the Neelum valley along the MBT (lower left corner of the figure 3). In the Neelum valley, the distribution of the Precambrian basement outcrops is related to large domal structures elongated in the NNW-SSE direction, such as the domes alignment of Shikar and Ganja. Tethyan metasediments outcrop inside a large synform ("basin") which trends NNW-SSE and goes through the village of Doarian. Since such large domes and basins do not occur each time D3 folds interfere with D2a folds, we believe that the D4 doming is the main factor of distribution of the basement/cover outcrops. The D4 doming has locally uplifted some previous D3-D2a domes and basins such as those of Shikar and Ganja.

S/113. Schrader, H.W., 1983. Contribution to the study of the distinction of natural and synthetic emeralds. *Journal of Gemmology* 18, 530-543.

Trace element contents of emeralds may be taken as a modern method to distinguish between natural and synthetic stones. It is also possible to differentiate between the localities of the natural emerald according to their chemical composition. The significant chemical characteristics of both natural and synthetic emeralds are discussed. The paper also shows that two emerald analyses from Pakistan have higher V, Sc, Ni, and lower Rb, Cr, and Mn than most other natural emeralds.

S/115. Scott, C., 1992. Glacial sediment production by the steep valley glaciers of the Nanga Parbat massif, Pakistan Himalaya. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 80.

Studies of sediments produced and transported by steep valley glacier systems in the Nanga Parbat massif, Pakistan Himalaya, raise questions -about the universal validity of present day theories of glacial sediment production, which have resulted from the study of European glaciers.

Whilst subglacial processes remain the dominant source of fine particle production, the supraglacial process of debris transport can also be seen to exhibit down-glacier fining of sediment. This view of non-passive transport of debris in the supraglacial zone is supported by Scanning Electron Microscopy of the fine sediment particles produced by these systems, which exhibit a clear down-glacier evolutionary sequence in particle morphology. Co-existing subglacial and supraglacial systems of particle comminution and fine sediment production are envisaged within the Himalayan glacier systems, where glaciers are typically high gradient with lengthy ablation/transport zones and of thick debris mantle cover. A comparison is made with a typical glacier system in the European Alps where fine sediment production is shown to be exclusive to the subglacial zone of traction. Reasons for the difference between these glacial systems are explored including glacial morphology, bedrock control of sediment input and the unique tectonic situation of the Nanga Parbat Massif within the Himalayan belt. The implications of this proposed Himalayan system for present day regional sediment output and for interpretations of Pleistocene valley glacier sediment systems are considered.

S/116. Scott, C. & Derbyshire, E., 1990. Questions posed by a preliminary glacial landform-sedimentary map of the Nanga Parbat Himalaya. In Abstract volume, 5th Himalaya-Karakoram-Tibet Workshop, Milano, 53.

A preliminary map of the glacial landform-sediments associations on the flanks of Nanga Parbat in the Greater Himalaya is presented. It shows the form and distribution of moraines, glaciofluvial outwash, moraine fans, debris fans, talus slopes, protalus ramparts, hummocky moraines and a variety of terrane features.

The terraces are extremely large and are made up of diamictos in some cases over 100m thick. Terrace surface relief, however, rarely exceeds 10m; the small ridges and hummocks appearing to be retreatal end moraines. The present glaciers include several high-gradient ice streams which have advanced across some trunk valleys (such as the Rupal), constraining the trunk rivers and superimposing high lateral moraines (>100m) on the flat valley-floor sediments. Some moraines impound perched proglacial lakes. There is thus marked topographical discordance between the surface of the trunk valley ice-retreat outwash sediments and the late Holocene moraines. Extrapolation of Pleistocene glacial trimlines left by the trunk glaciers and smaller ice streams from the high gradient tributary valleys prevailed at that time. However, any frontal moraine systems in the trunk valleys sedimentary burial has occurred, fills may be several hundred meters thick. The thick terraces downstream, such as those at and below the Astor junction, contain little fluvial material: they may have been emplaced by glaciers and then dissected by the rivers. The map thus poses a number of questions including the mode of deposition of coarse diamictos, the origin of the terraces and their relationships to ice limits, and the relationship of the tributary valley deposits to the lithostratigraphy trunk valley fills.

S/118. Seall, R.R., 1989. A reconnaissance study of the fluid inclusion geochemistry of the emerald deposits of Pakistan and Afghanistan. In: Kazmi, A.H. & Snee, L.W. (ed.), Emeralds of Pakistan: Geology, Gemology and Genesis, 151-164. Van Nostrand Reinhold, New York.

This study documents the geochemical characteristics of the hydrothermal fluids responsible for emerald mineralization in Swat (Mingora Mine 1 and 2, Charbagh, and Barang) and a single sample from Panjsher in Afghanistan. It is concluded that 1) salinities ranged from essentially nil to approximately 20 wt% dissolved salts, 2) the inclusions contain up to 3 mole% of a CO₂-rich component, with up to 0.22 XCH₄, 3) homogenization and decrepitation temperatures ranged from 150 to 349°C, which is equivalent to entrapment temperatures of 250 to 449°C at a confining pressure of 900 bars, and 4) boiling and fluid immiscibility were absent in all stages of hydrothermal activity recorded by these fluid inclusions.

The present data, especially those from the primary fluid inclusions suggest that mixing of a high temperature, high salinity fluid with a lower temperature, less saline fluid may have importance in mineral deposition. The only anomalous features of the fluid inclusions, observed in this reconnaissance study, are that the fluid inclusions from

Mine 2 are less saline than those from Mine 1, Charbagh and Barang, and that the fluid inclusions from Charbagh locally contain hematite daughters. All other fluid inclusion characteristics from the Swat district are indistinguishable from one mine to another. The sample from Panjsher is distinctly different from those of Swat. It contains numerous daughter minerals (including halite and sylvite) in inclusions oriented parallel to the c-axis.

S/119. Searle, M.P., 1989. Thermal model for the Baltoro-Muztagh Karakoram. *Geological Bulletin, University of Peshawar* 22, 1-9.

Following the Eocene (50 Ma.) collision of the Indian and Karakoram plates, crustal thickening and shortening in the Karakoram north of the Neo-Tethyan suture zones resulted in a widespread regional Barrovian metamorphism (M2) south of the Karakoram batholith. Pelitic lithologies are characterised by the assemblage: kyanite-staurolite-biotite-garnet-muscovite-plagioclase-quartz with sillimanite-muscovite and sillimanite-K-feldspar assemblages locally developed. Hornblende and diopside-bearing marbles and garnet-bearing amphibolites are also widespread. The age of this high pressure-high temperature metamorphism is constrained as post-50 Ma. (age of India-Asia collision) and pre-37 Ma. (age of cross-cutting, post-collisional granite plutons).

Intrusion of the 21 Ma. Baltoro batholith comprising compositions ranging from biotite monzogranite to two-mica leucogranite caused a high temperature-low pressure thermal aureole of contact metamorphism in the country rock. Andalusite-bearing hornfels along the northern contact of the batholith indicates maximum pressures of 3.5 kbars (350 MPa). A 750 increase in temperature in Kyanite sillimanite grade gneisses approaching the granite contact along the Baltoro glacier is modelled as the thermal upwarping of pre-36 Ma. Barrovian metamorphic isograds around the 21 Ma. contact aureole isotherms along the margins of the Baltoro batholith. Post-metamorphic folding of the early Barrovian metamorphic isograds is related to thrust culminations along the hanging-wall of the Main Karakoram Thrust - a reactivated breakback thrust along the older Shyok suture zone.

S/121. Searle, M.P., 1991a. *Geology and Tectonics of the Karakoram Mountains*. John Wiley and Sons, New York, 358p.

This well produced book is a detailed compilation of the author's contribution as well as those of the earlier worker's contribution. It contains many figures, including geological maps, sketches, satellite imageries, field photographs, photomicrographs and tables. The book is divided into four parts: part 1, regional tectonic setting comprises Geological and Geophysical Constraints (Chapter1), Tectonics of Central Asia (Chapter 2), and Tectonics of the Himalaya (Chapter 3). Part 2, the greater Karakoram, comprises general statement, and Kohistan (Chapter 4), western Karakoram --Chitral-Yasin (Chapter 5), Hunza Karakoram (Chapter 6), Northern Karakoram Terrain (Chapter 7), Karakoram batholith --Baltoro, Biafo, Hushe areas (Chapter 8), Karakoram metamorphic complex (Chapter 9), and eastern Karakoram -- Siachen-Nubra-Ladakh (Chapter 10). Part 3, Physical Geography consists of Quaternary and Present Glaciations (Chapter 11), and Geomorphology, Climate and Neo-tectonics (Chapter 12). Part 4, Orogenic processes comprises chapter 13 on Pre-Collision Crustal Evolution and Chapter 14 post --Collision Crustal Structure and Evolution. There are fifteen pages of references, and index and geological map of the Central Karakoram at 1:250,000 scale. The book also contains a summary of all the radiometric ages spanning Cretaceous-Tertiary that were available by 1991.

Key words: Geology, tectonics, Karakoram.

S/122. Searle, M.P., 1991b. A new geological map of the central Karakoram at 1/250,000 scale. *Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Grenoble, France*, 75.

A new geological map of the central Karakoram based largely on the last five field seasons mapping is presented. The map covers the area from the Hunza Valley in the west to the Baltoro-Siachen glacier divide in the east, and

from the Shimshal valley and Skamri glacier in the north to the Nanga Parbat massif and the Deosai plains in the south. The High Himalayan terrane of the Nanga Parbat-Haramosh massif forms part of the northwestern syntaxis of the Himalaya. The Kohistan terrane to the west and the Ladakh terrane to the east of the Nanga Parbat are continuous eastwards with the Trans-Himalayan batholith in southern Tibet. These terranes are bounded along the south by the Indus Suture Zone or Main Mantle Thrust and along the north by the Shyok suture zone or Main Karakoram Thrust.

The Karakoram terrane is continuous eastwards to the Lhasa Block in south Tibet, and is made up of three domains: the Karakoram metamorphic complex in the south, the Karakoram batholith and the northern Karakoram domain composed mainly of sedimentary rocks with structural culminations of high-grade gneisses along the K2-Braod Peak Range.

S/123. Searle, M.P., 1993. Structure, Metamorphism and Cooling History of the Central Karakoram (North Pakistan). Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 50.

Prior to the Eocene (ca. 50 Ma) collision of the Indian and Asian plates, the southern margin of Asia in the Karakoram region was dominated by a series of Andean-type plutonic belts (Hushe gneiss, Muztagh Tower gneiss, K2 orthogneiss) and regional low-pressure andalusite, staurolite and garnet-grade metamorphism (M1). Crustal shortening, thickening and regional metamorphism following collision occurred between 50-37 Ma and has been dated by a U-Pb zircon age from the Mango Gusar two-mica leucogranite which cross-cuts syn-metamorphic fabrics in the country rocks. Thermobarometry of kyanite and sillimanite-grade rocks indicates peak metamorphism (M2) at around 7000C and 8-9 kbars. Temperatures increase northwards along the Baltoro glacier transect towards the contact with the Baltoro granite where in situ partial melting begins in the sillimanite gneisses. Post-metamorphic folding of M2 isograds was associated with deep crustal gneiss domes and initiation of the Main Karakoram Thrust in the south. Post-M2 thermal relaxation followed from 37-25 Ma after which localized high heat concentrations at the base of the thickened crust caused widespread crustal melting and intrusion of the Baltoro granite at 25-21Ma. A high-temperature, low-pressure thermal aureole (M3) along the northern contact of the Baltoro monzogranite leucogranite is synchronous with the 21 ± 0.5 Ma U-Pb zircon crystallization age of the granite. The Mitre contact aureole contains the assemblage: andalusite + cordierite + biotite + muscovite + chlorite + plagioclase + quartz and indicates pressures less than 3.5 kbars. The increase of T along the southern contact of the Baltoro granite is interpreted as the thermal upwarping of pre-37 Ma M2 isograds by 21 Ma M3 contact metamorphic isotherms. In the southern Karakoram pressures up to 10 kbars were attained by 37 Ma ago meaning that around 37-km of overburden has been eroded since the Eocene-Oligocene boundary giving a time-averaged exhumation rate of 0.95mm/year. The 21 Ma Baltoro granite crystallized at temperatures above 750oC and pressures above 10 kbars equating to depths of burial between 26-35 km. The exhumation or unroofing rate, which includes processes of uplift and erosion is between 1.2-1.6mm/year. Subduction of Indian continental crust and mantle lithosphere northwards beneath the Karakoram and Tarim Basin continental crust southwards beneath the KunLun and the northern Karakoram has created a lithospheric-scale pop-up structure with its axis of maximum uplift aligned along the Karakoram.

S/124. Searle, M.P., 1996a. Geological evidence against large-scale pre-Holocene offset along the Karakoram fault: Implications for the limited extrusion of Tibetan plateau. *Tectonics*, 15, 171–186.

Two end-member models proposed to accommodate the convergence between India and Asia north of the Himalaya are (1) homogeneous crustal thickening of the Tibetan plateau and (2) continental escape, or extrusion, of Tibet and southeast Asia, away from the indenting Indian plate. Foremost among the arguments supporting the latter would be large-scale (≥ 1000 -km) offsets and high present-day slip rates along the major strike-slip faults bounding the postulated extruding crust, notably the Altyn Tagh Fault along the northern margin of Tibet and the Karakoram Fault along the SW margin. Satellite photographic interpretation and field mapping in the Karakoram mountains in Pakistan, the Nubra-Siachen area of north Ladakh, and the Pamirs in Xinjiang show that although the Karakoram Fault is extremely active today, geological offsets along the right-lateral fault are probably less than 120 km. The 21 ± 0.5 Ma Baltoro monzogranite-leucogranite batholith has been rotated clockwise about a vertical axis 35° – 40°

into NW-SE alignment, parallel with the Karakoram Fault, east of the Siachen glacier, with a maximum offset of 90 km across the fault. The Bangong-Shyok suture zone similarly has a dextral offset of 85 km. The course of the Indus River, which was antecedent to the rise of the Ladakh, Karakoram, and Himalayan ranges, has been offset dextrally by 120 km south of Pangong Lake. If present-day slip rates (approximately 32 mm/yr) (Avouac and Tapponnier, 1993) are correct, only 4 Ma are required to obtain a 120-km offset. There is no geological evidence for any larger-scale pre-Holocene offsets, and it is suggested that the Karakoram Fault cannot have accommodated major eastward lateral motion of Tibetan crust. The fault has also exerted little or no influence on surface topographic uplift, cutting obliquely across the highest peaks of the Karakoram. Dextral motion along the central part of the Karakoram Fault has been transferred in the north to the Rangkul, Murghab, and Karasu transpressional faults in the central Pamir. North of Tashkurgan, the Karakoram Fault shows mainly normal motion around the Kongur and Mustagh Ata gneiss domes (metamorphic core complexes) and the extensional Muji graben. Minor dextral displacement has occurred along the Shiquanhe Fault, but this motion cannot be linked to the Jiale Fault of east Tibet. The southern end of the Karakoram Fault merges with the Indus (Yarlung) suture zone near Mount Kailas and does not cut across the Himalaya. The lack of large-scale geological offsets along the Karakoram Fault, together with its very recent initiation (?5 or 4 Ma), suggests that it is related to the Pliocene-Quaternary northward indentation of the Pamir, and not to any long-term extrusion of Tibetan crust following the Indian collision.

S/125. Searle, M.P., 1996b. Cooling history, erosion, exhumation and kinematics of the Himalaya-Karakoram-Tibet orogenic belt. In: Yin, A. & Harrison M. (Eds.), *The Tectonic Evolution of Asia*, Cambridge University Press, 110-137.

The cooling histories of metamorphic and magmatic rocks, as determined through the use of thermochronometers and radiogenic isotope systems, combined with thermobarometers, can provide useful constraints on our determinations of depths of burial and exhumation rates. This chapter reviews the reliable geochronologic data on segments across the Himalaya-Karakoram-southern Tibet orogenic belt, and cooling histories for each zone are inferred.

Southern Tibet and the Karakoram have been sub-aerial landmasses since the mid-Cretaceous and could have been topographically high, Andean-type continental margins prior to the collision of India at 60-50 Ma. Thick continental red-bed deposition, abundant calc-alkaline volcanism, and granite magmatism suggest a thickened crust along southern Asia as far back as about 150 Ma. The collision of India with the southern margin of Asia (Kohistan-Karakoram-Lhasa terranes) may have been diachronous, occurring earlier in northern Pakistan (ca. 60 Ma) than in Ladakh-southern Tibet (ca. 50 Ma). Following the collision, crustal thickening and the timing of peak metamorphism were diachronous both along the Himalaya (pre-40 Ma northern Pakistan; pre-31 Ma Zaskar; pre-20 Ma eastern Kashmir and western Garhwal; 11-4 Ma Nanga Parbat) and across the strike of the High Himalaya, propagating southward (in Zaskar, southwestward) with time. Thrusting along the base of the High Himalayan slab (Main Central Thrust, active 21-18 Ma) was synchronous with north-south (in Zaskar, northeast-southwest) extension along the top of the slab (South Tibetan Detachment zone). Kyanite and sillimanite gneisses in the footwall formed at pressures of 8-10 Kbar and depths of burial of 28-35-km, at 30-21 Ma, whereas anchimetamorphic sediments along the hanging wall have never been buried below about 5-6-km. Exhumation rates are far greater in the High Himalayan zone (1.4-2.1 mm/a) and southern Karakoram (1.2-1.6 mm/a) than along the zone of collision or along the northern Indian plate margin. The High Himalayan leucogranites span 24-9 Ma in the central Himalaya, and anatexis occurred at 21-19 Ma in Zaskar, approximately 30 m.y. after the collision.

The Karakoram underwent high-temperature high-pressure metamorphism during the Eocene (50-37 Ma) and widespread lower-crustal melting (Baltoro monzogranite-leucogranite batholith) and upper-mantle melting (lamprophyre dikes) during the early Miocene (25-21 Ma). Uplift of the rocks and erosion, resulting in exhumation of middle- and lower-crustal rocks during the Neogene, were controlled by major thrusts and normal faults, and to a lesser extent by the increasing intensity of the monsoon at 8-6 Ma. The cooling histories show that significant crustal thickening, widespread metamorphism, erosion, and exhumation (and, therefore, probably significant topographic elevation) occurred during the Eocene-Oligocene in the Karakoram and southern Tibet, and during the early Miocene along the central and eastern Himalaya, before the onset of the monsoon, before the major changes in climate and vegetation, and before the onset of east-west extension on the Tibet Plateau.

S/126. Searle, M.P., Crawford, M.B. & Rex, A.J., 1992. Field relations, geochemistry, origin and emplacement of the Baltoro granite, Central Karakoram. *Transactions of the Royal Society of Edinburgh: Earth Sciences*, 83, 519-538.

The Miocene Baltoro granite forms a massive plutonic unit within the Karakoram batholith, and is composed of comagmatic monzogranites and leucogranites with a mineralogy consisting of quartz-K-feldspar-plagioclase-biotite $\pm$ muscovite $\pm$ garnet, with accessory sphene, zircon, monazite and opaques. Geochemically the Baltoro granites are mildly peraluminous, and show a calc-alkaline trend on trace-element normalised diagrams with high LIL/HFS element ratios and negative Nb, P and Ti anomalies. REE are strongly fractionated with little or no Eu anomaly. Leucogranites are depleted in most elements compared to monzogranites with notable exceptions being Rb, K and the HREEs. Initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are 0.7072-0.7128, considerably lower than High Himalayan leucogranites (0.74-0.79), and are indicative of a lower continental crust source. The probable petrogenesis of the Baltoro granite involves dehydration melting of a biotite-rich pelite to produce a voluminous, hot, water-undersaturated magma which could then separate from its source and intrude through an already thickened and still hot crust. Fractional crystallisation of the monzogranites produced the leucogranites and a pegmatite dyke swarm. A suite of lamprophyre dykes including amphibole-rich vogesites and biotite-rich minettes intrude the country rock, dominantly to the north, around the Baltoro granite. These calc-alkaline shoshonitic lamprophyres are volatile-rich mantle-derived melts intruded around the same time as the granite, indicating simultaneous melting of the mantle and lower crust beneath the Karakoram during the Miocene, approximately 30 Ma after the India-Asia collision which initially caused the crustal thickening. Intrusion of mantle melts provided heat to promote crustal melting and may have selectively contaminated the granite magma.

The Baltoro granite intrudes sillimanite gneisses with melt pods along the southern margin indicating temperatures above 700 °C at the time of intrusion. Locally, internal fabrics and numerous aligned xenoliths along the southern margin in the Biafo glacier region indicate steep, southward-directed thrusting during emplacement. Along the northern contact, the Baltoro granite intrudes anchimetamorphic to greenschist facies metasedimentary rocks with an andalusite-bearing contact aureole. Northward-directed culmination collapse normal faulting during Miocene emplacement is inferred, in order to explain the P-T differences either side of the pluton. This also provided an extensional stress regime in the upper crust to accommodate the rising magma.

Key words: Geochemistry, Baltoro granite, Karakoram.

S/127. Searle, M.P., Crawford, M.B., Rex, A.J. & Rex, D.C., 1990. Origin and emplacement of the Baltoro granite, central Karakoram. In *Abstract volume, 5th Himalaya-Karakoram-Tibet Workshop, Milano*, 54.

The Miocene Baltoro granite forms a massive plutonic unit within the Karakoram batholith, and is composed of comagmatic monzogranites and leucogranites with a mineralogy consisting of quartz-K-feldspar-plagioclase-biotite muscovite garnet, with accessory sphene, zircon, monazite and opaques. Geochemically the Baltoro granites are mildly peraluminous, and show an calc-alkaline trend on trace element normalized diagrams with high LIL/HFS element ratios and negative Nb, P and Ti anomalies. REE are strongly fractionated with little or no Eu anomaly. Leucogranites are depleted in most elements compared to monzogranites with notable exceptions being Rb, K and the HREEs. Initial $^{87}\text{Sr}/^{86}\text{Sr}$, ratios are 0.7072-0.7128, considerably lower than High Himalayan leucogranites, but still indicative of a melting source in the lower continental crust.

The Baltoro granite was intruded at ca. 25-21 Ma from a lower crust-melting site into an already thickened and metamorphosed crust, approximately 30 Ma after the India-Asia collision. The Baltoro granite intrudes sillimanite gneisses with melt pods along the southern margin indicating temperatures at the times of intrusion of above 650°C. $^{40}\text{Ar}/^{39}\text{Ar}$ biotite ages of 7.9 ± 0.2 Ma combined with previous U-Pb, Rb-Sr and K-Ar dating show that the Baltoro granites was intrude into already hot country rock and maintained high temperatures for ca. 7 Ma. this was followed by very rapid Pliocene-Pleistocene uplift-erosion and exhumation rates. Active crustal shortening and thickening occurred by syn-metamorphic deformation. Numerous aligned xenoliths along the southern margin indicate southward directed thrusting during emplacement. Along the northern contact the Baltoro granite intrudes metasedimentary rocks at maximum P-T conditions of greenschist facies, with an andalusite-bearing contact aureole. Northward-directed culmination collapse normal faulting during Miocene emplacement is inferred, in order to explain the P-T differences either side of the pluton.

S/128. Searle, M.P., Fraser, J.E., Hildebrand, P.R., Parrish, R.R. & Noble, S.R., 2000. Structural and Thermal Evolution of the South Asian Continental Margin along the Karakoram and Hindu Kush Ranges, North Pakistan. Abstract Volume, 15th Himalaya-Karakoram-Tibet Workshop, (Chengdu) China, 82-83.

Prior to the Collision and accretion of the Kohistan arc terrane during the late Cretaceous and the Indian plate after the early Eocene, the southern margin of Asia along the Hindu Kush, Karakoram and Lhasa block terranes was an active Andean-type continental margin. In south Tibet this margin was dominated by the calc-alkaline Ladakh-Gangdese granite batholith, associated andesitic volcanic rocks and continental red-beds. In contrast, the southern Karakoram exposes deep crustal metamorphic rocks and crustal melt leucogranites. New U-Pb age dating from the Hunza Valley and Baltoro Glacier region has revealed four spatially and temporally distinct metamorphic episodes. M1 sillimanite grade metamorphism in Hunza was a late Cretaceous event, probably caused by the accretion of the Kohistan arc to Asia. M2 was the major kyanite and sillimanite grade event during late Eocene-Oligocene crustal thickening and shortening, following India-Asia collision. Numerous melting events resulted in the formation of crustal melt granites throughout the last 50 Ma with multiple generations of dykes and very large scale crustal melting along the Baltoro monzogranite-leucogranite batholith during the late Oligocene-early Miocene. M3 metamorphism was a high- T, low- P contact thermal metamorphism around the Baltoro granite. In Hunza, younger staurolite grade metamorphism has been dated by U-Pb monazites at 16 Ma, with the Sumayar leucogranites intruded at 9.5 Ma crosscutting the metamorphic isograds. In the Baltoro region the youngest metamorphism, M4, is the sillimanite grade Dasso gneiss core complex dated by U-Pb on monazites as late Miocene-Pliocene (5.4 ± 0.25) Ma with Precambrian protolith zircon cores (1855 ± 11) Ma. Numerous gem-bearing pegmatite dykes cross-cut these rocks and are thought to have been intruded within the last 2~3 Ma. Structural mapping, combined with U-Pb geochronology shows that major metamorphic events can be both long-lasting (up to 20 Ma) and very restrictive, both in time and space.

The Hindu Kush range also has abundant sillimanite, kyanite and staurolite grade metamorphic rocks, but in contrast to the Karakoram, U-Pb dating shows that the most metamorphism was pre-collision of both Kohistan and India. U-Pb ages of monazite, xenotime and uraninite from gneisses, migmatites and leucogranites show that this high-T low-P metamorphism spanned the Jurassic-early Cretaceous and was probably related to magmatic heat from the Andean-type granites intruded along the margin. The only evidence of post-collisional crustal melting is the 24 Ma Gharam Chasma leucogranite with its associated dykes. The Hindu Kush is however one of the most seismically active continental zones known on Earth, with a narrow zone of earthquakes extending down to 300-km depth. This reflects the active subduction of lower Indian plate continental crust beneath the Hindu Kush-Pamir range today. The Hindu Kush, Karakoram and S. Tibet all represent the southern margin of the Asian plate, yet all have entirely different geology, structural, metamorphic and magmatic histories and seismic expression.

S/129. Searle, M.P., Khan, M.A., Fraser, J.E., Gough, S.J. & Jan, M.Q., 1999. The tectonic evolution of the Kohistan-Karakoram collision belt along the Karakoram Highway transect, north Pakistan. *Tectonics* 18, 929-949.

The Kohistan arc terrane comprises an intra-oceanic island arc of Cretaceous age separating the Indian plate to the south from the Karakoram (Asian) plate to the north within the Indus suture zone of north Pakistan. The intra-oceanic arc volcanics (Chalt, Dras Group) were built on a foundation of dominantly mid-ocean ridge basalt (MORB)-related amphibolites of the Kamila Group. The subarc magma chamber is represented by multiple intrusions of a huge gabbro-norite complex (Chilas complex), which includes some ultramafic assemblages of residual mantle harzburgite and dunite, layered cumulates, and hornblendites cut by late stage dikes of hornblende + plagioclase pegmatites. The Chilas complex norites intrude the Gilgit metasediments of lower amphibolite and greenschist facies in northern Kohistan, which also form xenolithic roof pendants within the top of the Chilas complex. Along the southern margin of Kohistan, Jijal and Sapat complex ultramafics (dunites, harzburgites and websterites) form remnant suprasubduction zone ophiolitic mantle rocks along the hanging wall of the Main Mantle Thrust, the Cretaceous obduction plane along which Kohistan was emplaced onto Indian plate rocks. Garnet granulites of the Jijal complex, formed at 12–14 kbars, represent original magmatic lower crustal rocks subducted to

depths of at least 45 km and metamorphosed during high-pressure and high-temperature subduction of earlier arc-related rocks. Obduction of the Sapat ophiolite and Kohistan arc occurred between $\sim$ 75 and 55 Ma.

The closure of the Shyok suture zone separating Kohistan from the Karakoram plate must have occurred prior to 75 Ma, the age of the Jutal basic dikes which crosscut the closure-related fabrics, mainly late north directed backthrusting in the lower Hunza valley. Andean-type granitoid (gabbrodiorite-granodiorite-granite) emplacement along the Kohistan-Ladakh batholith ended at the time of India-Asia collision, $\sim$ 60–50 Myr ago. Postcollisional crustal thickening along the Karakoram led to multiple episodes of metamorphism from latest Cretaceous and throughout the Tertiary. Sillimanite grade metamorphism in Hunza was actually pre-India-Asia collision and may have resulted from the earlier Kohistan collision. Localized and sporadic crustal melting episodes across northern Kohistan (Indus confluence and Parri granite sheets) and the southern Karakoram (Hunza dikes and Sumayar and Mango Gudar leucogranites) occurred from 51 to 9 Ma and culminated in the huge Baltoro monzogranite-leucogranite intrusion 25–21 Myr ago. A vast network of leucogranitic and pegmatite dikes containing gem quality aquamarine + muscovite $\pm$ tourmaline $\pm$ garnet $\pm$ biotite quartz are younger than 5 Ma and form the final phase of intrusion in the Haramosh area and parts of the southern Karakoram area.

S/131. Searle, M.P. & Owen, L.A., 1999. The evolution of the Indus River in relation to topographic uplift, erosion, climate and geology of western Tibet, the Trans-Himalayan and high Himalayan Ranges. In: Meadows, A. & Meadows, P. (Eds.), *The Indus River, Biodiversity, Resources, Humankind*. Linnean Society of London, 210-230.

The Indus River is one of the major antecedent rivers of the Himalayas, its drainage course having been initiated prior to the uplift of High Himalayas. The source of the Indus is north of Mount Kailas (6,714 m) in the southern part of the Tibetan Plateau, and it collects drainage from the northern slopes of the Trans-Himalayan ranges. In the far western part of the Tibetan Plateau the course of the Indus River has been offset by about 120-km north-west along the active Karakoram Fault, a 700-km long dextral strike-slip fault which may have been active only for the last 4-5 Ma, with slip rates of 20-30 mm/year. South of the Pangong Lake the Indus river cuts westward through the Ladakh granite batholith and then follows the trace of the Indus Suture Zone (the zone of late Collision between Indian and Asia) for about 200-km in Ladakh. The late Tertiary Indus molasses sediments in Ladakh show that this section of the Indus River was initiated possibly as long ago as the middle Eocene (45 Ma). The uplift of both the Ladakh range and the High Himalayan ranges post-dated the initiation of the Indus drainage course. The steepest gradient of the Indus River is in Baltistan (north Pakistan) where it cuts right through the middle of Nanga Parbat (8,125 m)-Haramosh (7,409 m) massif, the north-western most part of the High Himalayas, eroding a deep gorge and creating some of the largest single slopes on Earth. Radiometric dating from metamorphic rocks and crustal melt granites from Nanga Parbat shows that metamorphism and melting may have occurred as recently as 2.3-1.0 Ma ago. This indicates that uplift, erosion and exhumation rates are exceptionally high. Combining petrological, thermobarometric and geochronological data, exhumation rates for Nanga Parbat are around 4.5-6 mm/year. Uplift of this region has influenced regional glaciations and dramatic climatic changes during late Tertiary and Quaternary times. The Indus Valley has been continuously modified by glacial and fluvial erosion, whilst earthquake-induced landslides have frequently caused damming and subsequent breaching of river, resulting in severe flooding, such as the great Indus flood of 1841. Erosional products are transported along the Indus River southwards to the plains of the Punjab and Sindh, and eventually into the Indus fan in the Arabian Sea.

S/132. Searle, M.P., Parrish, R.R., Tirrul, R. & Rex, D.C., 1990. Age of crystallization and cooling of the K2 gneiss in the Baltoro Karakoram. *Journal of Geological Society, London*, 147, 603-606.

The mountains of K2 (8611 m) and Broad Peak (8047 m) in the Baltoro Karakoram (northern Pakistan) are composed of plagioclase–hornblende and biotite–hornblende–K-feldspar orthogneisses and amphibolite–facies paragneisses, intruded by garnet–biotite–muscovite–tourmaline leucogranitic veins. A U–Pb zircon age of 115–120 Ma was obtained on an orthogneiss from the south face of K2. ^{40}Ar – ^{39}Ar analysis on hornblende yields a plateau age of 90.6 ± 1.8 Ma, consistent with a mid-Cretaceous phase of magmatism, concomitant with early subduction-related components of the Karakoram batholith (Muztagh Tower unit, Hunza plutonic unit). We interpret the K2 gneiss as representing a culmination of mid-crustal rocks along a discontinuous but wide zone north of the Karakoram batholith.

S/134. Searle, M.P., Rex, A.J., Tirrul, R., Rex, D.C., Barnicoat, A. & Windley B.F., 1989. Metamorphic, magmatic and tectonic evolution of the Central Karakoram in the Biafo-Baltoro-Hushe regions of N. Pakistan. In: Malinconico, L.L. & Lillie, R.J. (Eds.), *Tectonics of Western Himalayas*. Geological Society of America, Special Paper 232, 47-74.

The central Karakoram can be divided into three main tectonic units from north to south: a northern Karakoram terrane, the Karakoram batholith, and the Karakoram metamorphic complex. In the Baltoro Glacier region the Karakoram magmatism includes intrusive suites that predate and postdate the India-Eurasia collision. The oldest subduction-related phases include Jurassic hornblende to biotite monzogranite of the Hushe complex, and Cretaceous (ca. 82 to 75 Ma) hornblende-biotite metagranitoids of the Muztagh Tower unit, all of which were deformed during the India-Kohistan-Karakoram collision. Volumetrically dominant is a postcollisional granite, the Baltoro Plutonic Unit (BPU), which consists of biotite monzogranites to two-mica $\pm$ garnet leucogranites and pegmatite-aplites of mildly peraluminous affinity. The BPU represents the youngest magmatic phase of the composite Karakoram batholith with a U–Pb age of 21 ± 0.5 Ma and K–Ar mica cooling ages ranging from 11.7 to 5.25 Ma.

The Masherbrum migmatite complex (MMC), one of a series of such complexes along the southern margin of the batholith, immediately predates the BPU. Leucocratic dikes that cross-cut the MMC yield an Rb–Sr age of 14.1 ± 2.1 Ma and K–Ar ages of 17 to 10 Ma. The BPU is interpreted as a crustal melt ultimately derived from deep crustal levels and may not be related to leucogranite generation associated with the migmatite terrain to the south. Petrogenesis of the BPU is fundamentally different from that of the High Himalayan granites and may involve a degree of selective mantle contamination.

Four major metamorphic-deformation phases can be distinguished in the central Karakoram. The earliest, M1, is represented by low-pressure andalusite–staurolite–bearing assemblages that are spatially associated with igneous components of the Hushe complex of Jurassic age. The dominant thermal event was a widespread Barrovian-type metamorphism (M2), which was syntectonic to the main deformation and overprinted M1 assemblages. M2-related structures are cut by the 37.0 ± 0.8 Ma Mango Gusar two-mica granite pluton. M2 kyanite–garnet–plagioclase–quartz–muscovite–biotite–staurolite assemblages indicate minimum pressure temperature (P–T) conditions of 550°C and 5.5 kbar (550 MPa).

Thermal effects related to intrusion of the BPU constitute M3. Along its northern margin at Mitre Peak, the assemblage andalusite–cordierite–chlorite–biotite–muscovite–quartz–plagioclase indicates a *maximum* pressure of 3.75 kbar (375 MPa, $\approx$ 12.5-km depth). Along its southern margin at Paiyu, the presence of granitic melt pods with sillimanite, muscovite, plagioclase, and quartz indicates a minimum pressure of ca. 3.5 kbar (350 MPa) and a

temperature 75° higher than local M2 assemblages. The replacement of kyanite by sillimanite and the appearance of granitic melt pods approaching the BPU along the Baltoro Glacier transect, may be an M3 overprinting of M2. M4 (<5 Ma) is a syntectonic retrogressive metamorphism along the hanging wall of the Main Karakoram Thrust—a breakback thrust responsible for the recent uplift of the Karakoram.

Structural culminations of midcrustal rocks occur in the K2 and Broad Peak areas within Carboniferous-Lower Cretaceous sediments of the Gasherbrum Range. Metamorphism of the K2 gneiss (dominantly biotite-hornblende-K-feldspar orthogneiss) occurred during middle to Late Cretaceous time. Pegmatite dikes dated as 70 to 58 Ma (K-Ar-mica) cut the gneisses.

Key words: Metamorphism, magmatism, tectonics, Biafo, Baltoro, Central Karakoram.

S/135. Searle, M.P., Rex, A.J. Tirrul, R., Windley, B.F., Onge, M.S.T. & Hoffman, P., 1986. A geological profile across the Baltoro-Karakoram Range, N. Pakistan. *Geological Bulletin, University of Peshawar* 19, 1-12.

The Karakoram batholith along the Baltoro glacier transect separates a northern sedimentary domain with structural culminations of high-grade gneisses (K2 gneiss) from a southern high-grade metamorphic domain. The Baltoro plutonic units range in composition from biotite granodiorite to garnet bearing two-mica leucogranite; they have no mafic dyke and no volcanic component. The Baltoro granite is interpreted as being crustally derived from partial melting of deeper level rocks equivalent to the high-grade metamorphics in the south. The relationships between metamorphism, crustal-scale ductile shearing, migmatization and magmatism are discussed.

S/136. Searle, M.P. & Tirrul, R., 1990. Structural and thermal evolutions of the Karakoram crust. In: *Abstract volume, 5th Himalaya-Karakoram-Tibet Workshop, Milano*, p.55.

Prior to the Eocene (ca. 50 Ma) collision of the Indian and Asian plates, the southern margin of Asia along the Karakoram plate was an Andean-type margin dominated by tonalitic-granodioritic magmatism of Jurassic-Lower Cretaceous age (Hushe gneiss, Muztagh Tower gneiss and K2 orthogneiss) and associated low pressure andalusite, staurolite and garnet grade metamorphism (M1). Following India-Asia collision, crustal shortening, thickening and regional Barrovian metamorphism (M2) occurred between 50-37 Ma. Thermobarometry of kyanite-grade metapelites indicate burial to depths of around 30-35 km. Simultaneous solution of the garnet-biotite geothermometer with the garnet-muscovite-biotite-plagioclase and garnet-Al₂SiO₅-quartz-plagioclase geobarometers indicates peak M2 P-T conditions of 696±20°C at 8.6kbars ±0.7kbars (860Mpa). Temperatures may have exceeded 700°C in sillimanite-grade metapelites to produce in situ partial melting and leucogranitic melt pods. Peak M2 metamorphism occurred prior to 37±0.8 Ma, the crystallization age of the Mango Gusar two mica granite pluton which crosscuts syn-metamorphic deformation fabrics.

Post M2 thermal relaxation followed from 37-23 Ma after which localized high heat concentrations at the base of the thickened crust caused widespread crustal melting and intrusion of the Baltoro granite batholith at 25-21 Ma, with compositions ranging from biotite monzogranite to garnet two-mica leucogranite. A high temperature-low pressure thermal aureole (M3) of contact metamorphism is synchronous in age with the 21±0.5 Ma zircon age of the Baltoro granite. Andalusite hornfels along the northern contact of the batholith (Mitre thermal aureole) indicates maximum pressures of 3.5 kbars (350 Mpa). A 75°C increase of temperature in kyanite-sillimanite grade gneisses approaching the granite contact along the Baltoro granite is modeled as the thermal upwarping of pre-37 Ma. Barrovian metamorphic M2 isogrades around the 21 Ma contact aureole M3 isotherms along the margins of the Baltoro batholith. A thermal model for the west Himalayan-Karakoram collision belt is presented based on a scaled crustal cross-section using all the available pressure, temperature, time and depth constraints.

S/138. Searle, M.P., Tirrul, R., Rex, A.J. & Windley, B.F., 1985. A Geological transect across the Baltoro-Muztagh Karakoram from K2 to the Shigar valley. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

The Karakoram plate north of the Shyok suture zone consists of three major domains:

a northern sedimentary domain (Carboniferous-?Cretaceous) with structural culmination of high-grade metamorphic rocks (K2 gneiss; Falchan Kangri gneiss); the Karakoram granite batholith (KGB) and a southern high-grade metamorphic domain. These Karakoram rocks crop-out along the hanging-wall of major late-stage thrust-the Main Karakoram Thrust (MKT)- that dips north and places mid- to lower crustal rocks over unmetamorphosed sediments and volcanics of the Tethyan Shyok suture zone. The Shyok suture is thought to have closed during the mid- to late Cretaceous with deformation progressing southwards across Kohistan to the Salt Range during the Tertiary.

South of the Karakoram batholith along the Baltoro glacier- Braldu River transect a high-grade metamorphic terrain consists of kyanite, sillimanite, andalusite, staurolite, garnet and cordierite-bearing paragneisses and sillimanite-K-feldspar-bearing orthogneisses. Numerous garnet-biotite + muscovite + tourmaline + beryl leucogranitic dykes and veins intrude the metamorphic sequence. Garnet, hornblende, diopside, biotite-bearing marbles and amphibolites are interbanded within the sequence. Anthophyllite and jadeite bearing metamorphosed ophiolitic rocks with rare very fresh harzburgites (olivine + orthopyroxene + chrome spinel) occur in two localities within shale and marble units. Many of the higher peaks south of the Braldu gorge consist of andalusite schists with normal downward-increasing metamorphism.

North of the MKT lineations, defined by sillimanite and hornblende needles, plunge E or SE. Foliation in the Panmah, Biafo and Braldu valleys is folded around giant doubly-plunging dome structures which may be late-stage thrust culmination related to late brittle S and SW-directed thrusting along the MKT.

S/139. Searle, M.P. & Treloar, P.J., 1992. Conference Report: 7th Himalaya-Karakoram-Tibet Workshop. Journal Geological Society, London, 149, 1045-1047.

The first Himalayan Workshop held in Leicester University was so successful that it was then agreed to hold the informal conference and workshop annually. Subsequently the Himalayan Workshops were held in Vandoevre-les-Nancy, France in 1986, London (1987), Lausanne, Switzerland (1988), Milan, Italy (1990) and Grenoble, France (1991). The upsurge in research throughout the Himalayan and Tibetan region in the last ten years has warranted these annual meetings, and the dissemination of new research throughout the Himalayan community has been invaluable. This year the meeting was held in the Department of Earth Sciences, Oxford University, under the auspices of The Geological Society, London from 6-8 April 1992. Over 120 participants from 15 countries attended.

S/142. Searle, M.P., Windley, B.F., Coward, M.P., Cooper, D.J.W., Rex, A.J., Rex, D.C., Tingdong, L., Xuchang, X., Jan, M.Q., Thakur, V.C. & Kumar, S., 1987. The closing of Tethys and the tectonics of the Himalaya. *Bulletin of Geological Society of America* 98, 678-701.

Recent geological and geophysical data from southern Tibet allow refinement of models for the closing of southern (Neo-) Tethys and formation of the Himalaya. Shelf sediments of the Indian passive continental margin which pass northward into deep-sea Tethyan sediments of the Indus-Tsangpo suture zone were deposited in the Late Cretaceous. An Andean-type margin with a 2,500-km-long Trans-Himalayan (Kohistan-Ladakh-Gangdese) granitoid batholith formed parallel to the southern margin of the Lhasa block, together with extensive andesites, rhyolites, and ignimbrites (Lingzizong Formation). The southern part of the Lhasa block was uplifted, deformed, and eroded between the Cenomanian and the Eocene. In the western Himalaya, the Kohistan island arc became accreted to the northern plate at this time. The northern part of the Lhasa block was affected by Jurassic metamorphism and plutonism associated with the mid-Jurassic closure of the Bangong-Nujiang suture zone to the north.

The timing of collision between the two continental plates (ca. 50-40 Ma) marking the closing of Tethys is shown by (1) the change from marine (flysch-like) to continental (molasse-like) sedimentation in the Indus-Tsangpo suture zone, (2) the end of Gangdese I-type granitoid injection, (3) Eocene S-type anatectic granites and migmatites in the Lhasa block, and (4) the start of compressional tectonics in the Tibetan-Tethys and Indus-Tsangpo suture zone (south-facing folds, south-directed thrusts).

After the Eocene closure of Tethys, deformation spread southward across the Tibetan-Tethys zone to the High Himalaya. Deep crustal thrusting, Barrovian metamorphism, migmatization, and generation of Oligocene-Miocene leucogranites were accompanied by south-verging recumbent nappes inverting metamorphic isograds and by south-directed intracontinental shear zones associated with the Main Central thrust. Continued convergence in the late Tertiary resulted in large-scale north-directed backthrusting along the Indus-Tsangpo suture zone. More than 500 km shortening is recorded in the foreland thrust zones of the Indian plate, south of the suture, and > 150 km shortening is recorded across the Indian shelf (Zaskar Range) and the Indus suture in Ladakh. There was also large-scale shortening of the Karakoram and Tibetan microplates north of the suture; as much as 1,000 km shortening occurred in Tibet. The more recent deformation, however, involved the spreading of this thickened crust and the lateral motion of the Tibetan block along major approximately east-west-trending strike-slip fault zones.

S/143. Secord, C. & Vyvyan, M., 1939. Reconnaissance of Rakaposhi and Kunyang Glacier. *Himalayan Journal*, 11, 156p.

As this account does not have an abstract, first few paragraphs of the report are given below.

The papers published below are the record of two parts of one brief expedition which was planned to explore the basin of the upper Kunyang glacier of the Hispar Muztagh. On the way Messrs. Secord and Vyvyan succumbed to

the temptations of Rakaposhi and explored its western approaches. Mr. Secord then had to return unexpectedly to England, and Mr. Vyvyan carried out single-handed a rather less ambitious reconnaissance of the Kunyang glacier.—Ed.

Rakaposhi (Campbell Secord).

Rakaposhi towers 20,000 feet above the Hunza and Gilgit rivers which almost encircle it, and the first glimpse of it from Taliche, 40 miles away in the Indus valley, persuaded Michal Vyvyan and myself to have a closer look at it before proceeding to our intended destination up the Hispar glacier. After a day of pleasant ease at Gilgit, therefore, we set off early on the 4th July for a flying trip to the Jaglot nullah which would lead us into the recesses of the mountain's mighty western ramparts.¹

It was exciting to be skilfully ferried across the raging Hunza river on a skin raft, but the 20 miles up its arid left bank seemed interminable on—or off—the decrepit ponies supplied to us with only one saddle between them. Hospitable villagers at Matur Das compelled us to rest during the midday heat by hiding our ponies, providing shady couches and apricots galore, and talking volubly in Burushaski. It was a pleasant spot, perched high above the river, its stone-walled orchards oddly reminiscent of the Italian lake-district. The afternoon's monotony was abruptly terminated by a 600-foot climb straight up the cliffs fringing the river-bed, and we emerged on the edge of a lovely fertile hanging valley—our nullah, at last! The village of Jaglot lay nearby among well-cultivated fields, a startling contrast to the desert we had left below. We discarded the ponies and pushed on up three successive valley steps, camping, as night fell, beyond the uppermost hamlet, with morainal detritus visible in the narrowing gap beyond.

Intense curiosity roused us early next morning, and we walked rapidly upwards, following cattle-tracks along the beautifully treed moraines, as far as a high glacial mound at the junction of two affluents. A delicate cirque of 20,000-foot peaks enclosed the southern branch, but it was the view eastwards which riveted our attention. Rakaposhi soared nearly 16,000 feet directly above us, its western face a mass of tremendous ice-falls enclosed by north-western and south-western ridges of extraordinary beauty, which sprang from a large plateau lying at about 23,000 feet, and which extended at a very high level outwards almost as far as we stood. From the plateau rose the summit pyramid, about 2,500 feet high. It was a fine introduction to the high mountains of Asia.

S/145. Seeber, L. & Ambruster, J., 1979a. Seismicity of the Hazara Arc in Northern Pakistan, decollement versus basement faulting. In: Farah, A. & DeJong, K.A. (Eds.) *Geodynamics of Pakistan*. Geological Survey of Pakistan, Quetta, 131-147.

A telemetered seismic network in northern Pakistan covering most of the Hazara arc, the arcuate foreland thrust-fold belt between the Western Himalayan Syntaxis and the Sulaiman Range of Baluchistan, is producing a wealth of seismic data that give new insight into the tectonics of this area. The Indus-Kohistan Seismic Zone (IKSZ) and the Hazara Lower Seismic Zone (HLSZ) are parallel, deeply reaching faults buried under a 10 to 30 km thick layer, presumably a sedimentary or metasedimentary prism. The seismic zones appear to be straight northwestern extensions of the frontal faults of the Himalaya beyond the Western Himalayan Syntaxis where these faults bend sharply to the south at the surface. The IKSZ, by far the more active of the two seismic zones, is associated with underthrusting toward the northeast. A 12 km thick, mostly aseismic layer appears to flake off the underthrust basement and slide over the leading edge of the overthrust block. In contrast, the HLSZ defines a steeply dipping basement fault that probably merges upward and southward with a shallow dipping surface of decollement between the basement and the sedimentary rock sequence that outcrops in the Salt Range.

The eastern portion of the geologically prominent Hazara fault corresponds with a zone of low seismicity during the network operation, from 1973 to 1977. However, a magnitude mb 5.2 (USGS) earthquake that occurred near Rawalpindi on February 14, 1977, caused severe damage and some loss of life. The hypocenters of the main shock and aftershocks indicate a rupture surface between 12 and 18 km depth; if extrapolated to the surface, the trace of the rupture plane almost coincides with the Hazara fault trace. The rupture plane dips to the southeast, and

experienced a left-lateral strike slip during the earthquake. This evidence indicates either that the adjacent section of the Hazara fault cannot be considered presently active as the northwestward-dipping thrust described from surface evidence, or that the February 14 rupture occurred below a decoupling layer and the effect of this active strike slip movement is not evident at the surface.

In the southern part of the Hazara arc, the northwestern portion of the Punjab Seismic Zone and the seismicity at the Trans-Indus Salt Range are associated with a set of parallel strike-slip faults striking north-northwest. This faulting involves the entire thickness of the crust (about 35 km) and can be traced at the surface across the Trans-Indus Salt Range. The low seismicity in the Potwar Plateau and in the Bannu basin indicate that the ongoing decollement is either occurring by aseismic creep, or by rare large earthquakes

S/147. Seeber, L. & Ambruster, J., 1984. Some elements of continental subduction along the Himalayan front. *Tectonophysics* 105(1-4), 263-278.

Detachment tectonics, in which the subducting basement is not internally affected by thrusting; and a steady state system, in which the pattern of deformation and topography are invariant, uplift is balanced by erosion and the material can experience subsequent “phases” of deformation by migrating through the system, are proposed to be the fundamental mechanisms of convergence at the Himalayan arc. Both surface and subsurface data are more consistent with these concepts than with more familiar concepts widely used in current models: intracrustal thrusting and evolutionary tectonics, where superimposed phases of deformation are interpreted as distinct phases. The belt of intermediate-magnitude thrust-earthquakes, the topographic front at the High Himalaya and the Main Central Thrust (MCT) are associated with the same fundamental element, the basement thrust front (BTF), which traces a small circle in the central portion of the Himalayan arc. Fault plane solutions indicate thrusting in the radial direction of this arc. This radial convergence at the BTF implies that Tibet is extending laterally at a rate similar to the rate of convergence across the BTF. This extension cannot be unidirectional and must be parallel to the BTF, if the circular shape of the BTF is invariant.

S/148. Seeber, L. Ambruster, J. & Farhatullah, S., 1980. Seismic activity at the Tarbela dam site and surrounding region. *Geological Bulletin, University of Peshawar* 13, 169-191.

The earthquake activity associated with the major faults of the Himalayan front in the Hazara arc region, including Tarbela dam, is discussed in terms of the active tectonic structure of this front. Moreover, the earthquake potential at the Tarbela site arising from the Indus fault system is evaluated by extrapolating the earthquake magnitude distribution.

The active tectonics associated with plate convergence in the Hazara arc region of the Western Himalayas has been modeled primarily by using earthquake data from the seismic network centered at Tarbela. The near-surface structural trends in Hazara are distinct and separated from the trends along the Himalayan front in the Kashmir by the Hazara-Kashmir syntaxis. In contrast, the deeper structures, which are active within the basement in Hazara, are continuous with and linear extensions of the northwest trending structures of the Himalayas in Kashmir. Thus, the arcuate structures in Hazara are only thin-skin. A major detachment fault decouples the sedimentary and metasedimentary layer of the thrust-and-fold belt from the underlying basement. The relative motion on the detachment obtained from seismic data is consistent with the southward vergence of the structures in this belt.

Three families of active faults recognized as potential sources of destructive earthquakes in the Hazara arc region and, in particular; at the Tarbela dam site: the basement faults; the detachment fault; and faults within the sedimentary layers. Available intensity and instrumental data indicate that the Himalayan Basement Thrust and associated transverse or tear faults are the locus of most of the epicenters; however, the largest ($M > 8$) and most damaging earthquakes occur on the Himalayan Detachment. The Hazara arc is included in the tectonic province of

the Himalayan front, thus the Basement Thrust and the Detachment are identified with corresponding structures in Hazara, and the earthquake potential is estimated accordingly.

A layer of thick Intracambrian salt is associated with the Detachment in the Hazara arc region. The low-strength properties of this layer may cause the slip on this portion of the Detachment to occur aseismically. In this case, major Detachment earthquakes analogous to those known from the central section the Himalayan front would not be expected in the Hazara region.

The sedimentary layer in the Tarbela network region of the Hazara arc is mostly aseismic except for the Tarbela seismic zone (TSZ), centered near the Tarbela dam site. This sharply defined volume of seismicity is probably associated with anomalous rock properties rather than an isolated zone of crustal deformation. Thus, the faults active within the TSZ may slip aseismically in the sedimentary layer outside the TSZ.

The maximum credible earthquake in the TSZ is assigned a magnitude 6.5, a maximum surface acceleration of 0.5g, and is associated with the surface rupture of one of the faults in the Indus valley at the Tarbela site. From a quantitative study of earthquake-magnitude distribution a repetition time of 1200 years is obtained for the maximum credible event. This implies a probability of 1/24 that this event will occur during a 50-year lifetime of the dam. The maximum probable earthquake at the Tarbela site in 50 years is a M=5.5 event. The rate of seismicity along the Indus fault system at the Tarbela site is 50 times higher than the average seismicity for the Hazara arc region. However, the level of seismicity on the TSZ is well below the seismicity associated with some of the other seismic zones within the Hazara arc. Most prominent among these is the IKSZ.

Key words: Seismicity, Tarbela Dam, tectonics.

S/149. Seeber, L. & Armbruster, J.G., 1983. Continental subduction along the northwestern and central portion of the Himalayan arc. *Bollettino di Geofisica Teorica ed Applicata (Pamir-Himalaya Volume)* 25, 409-425.

Three prominent features, 1) the topographic front of the High Himalayas, 2) the narrow belt of thrust earthquakes and 3) the Main Central Thrust are closely interrelated and are manifestations of the Basement Thrust Front (BTF), a fundamental element of active convergence along the Himalayan arc. These features and the BTF are continuous over 2500km and are correlated with the boundary between two portions of the overriding unit: the more rigid Tethyan slab, downdip from the BTF and upthrust at this boundary (High Himalayas); and the less rigid sedimentary wedge, updip from the BTF and pervasively deformed (Lesser Himalayas and Sub Himalayas). The details of the subsurface active structures in the Hazara region, as deciphered from earthquake data from a local seismic network, are strikingly discordant to the surface structures and suggest a major subhorizontal detachment. Seismic hazard in the Hazara arc region depends largely on whether the active detachment in this region slips aseismically or by great earthquakes, as does the detachment along the rest of the Himalayan front.

S/150. Seeber, L., Armbruster, J.G., Quittmeyer, R.C., Zeitler, P.K., Kidd, B., Edwards, M. & Koons, P.O., 1998. Northwest-directed shortening at Nanga Parbat: An active tectonic regime regionally controlled by strain partitioning along the Himalayan Arc and locally accelerated by topographic stress at the Indus River Gorge. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 178-180.

A very active regime of northwest-directed shortening in the Nanga Parbat area is manifested by both earthquake and geologic data, including brittle faults in crystalline rock and structures in Quaternary sedimentary rocks of the Indus and Gilgit valleys. Northwest and northeast directed shortening at Nanga Parbat and along the Himalayan front a few hundred km to the south, respectively, are at a wide angle and are thought to reflect distinct elements in the collisional regime. Northwest shortening at Nanga Parbat is interpreted as internal deformation within the Himalayan overriding block. At the scale of the Asia-India continent collision, northwest-directed shortening at the northwestern terminus of the Himalayan arc is interpreted as the result of strain partitioning along the arc. Earthquake focal mechanisms show radial convergence across the arc. Radial convergence with an undefining footwall block (India) requires arc-parallel extension in the hangingwall block (Tibet), which is indeed geologically and seismologically observed. This "intraplate" deformation in Tibet is driven by strain partitioning. Relative to the

Himalayan arc, northwest convergence at the terminus of the back arc in Nanga Parbat is along strike and in the same direction as arc-parallel extension in Tibet, the main portion of the back arc, and may balance it out, at least in part. Thus, Nanga Parbat is interpreted to be structurally the western boundary of Tibet. Many earthquakes in and near the Nanga Parbat massif were recorded by the ~60-station network we deployed on and around the massif during 1996 and from a more modest deployment in 1995. 130 single-event focal mechanisms were quality selected from the 340 accurate hypocenters located in the vicinity of the massif (100x100 km). The massif is particularly active on the northwestern flank, where topographic relief is the largest. The seismicity is very shallow, from above sea level, to a maximum depth of 6 km asl where it is sharply cut off below the axis of the massif. Focal mechanisms suggest a subhorizontal detachment at this boundary. This detachment ramps up into a thrust fault toward the northwest aiming toward the mapped surface trace of the Lichar thrust. Transport on this structure is generally to the northwest. Footwall-block seismicity is limited to the western side of the NPA. Hangingwall-block antithetic thrusting is illuminated on the southeastern side of the massif and correlates with mapped structures. While we resolved some earthquakes on thrust faults, most of the observed seismicity is from a set of subparallel shallow normal faults striking west to southwest and dipping south to southeast. These faults accommodate extension approximately in the same direction as the transport on the underlying thrust fault. Seismogenic normal faulting is concentrated in the region with highest relief on the western limb of the antiform, between the Indus River and the Nanga Parbat ridge. This faulting can be interpreted as gravity-driven collapse of the eastern wall of the Indus gorge by book-shelf-like block rotation about horizontal-axes and also as flexural slip in the overturned northwestern limb of the Nanga Parbat anticline. The superposition of shallow horizontal extension above crustal shortening at Nanga Parbat may exemplify the effect of topographic stress in regions of convergence and mountain building. The rapid uplift of the Nanga Parbat massif is associated with the northwest-verging Nanga Parbat antiform (NPA) and the southeast-dipping Lichar thrust fault, which outcrops along the northwestern flank of the massif. The Lichar fault and the NPA are interpreted to be coupled active structures (a thrust fault and a fault-propagation fold) that accommodate much of the northwest shortening, but, generally, not all of it. Previous and ongoing work by others suggest a continuous belt of northwest shortening from the western Syntaxis to the Main Karakorum Thrust, for over 200km along strike of the NPA. Furthermore, preliminary results from a survey of brittle and Quaternary tectonic structures in the Indus and Gilgit valleys show west- to northwest-directed shortening in the Kohistan terrane, suggesting that this shortening is, generally, over a belt broader than the massif. Northwest shortening in Kohistan is coupled with two prominent Quaternary transcurrent fault zones, one along the Gilgit River valley, left-lateral and striking west-northwest, the other along the Indus River valley, right-lateral and striking west-southwest. These faults are interpreted to serve as accommodation structures separating broad belts of northwest shortening south of the Indus and north of the Gilgit rivers from a much narrower portion of the belt in between. Along the portion of the belt flanked by the Indus gorge and the outcropping Lichar thrust, shortening seems to be confined to the massif, within and east of the Indus Gorge. This tectonic model is supported by the earthquake data, which show a remarkable lack of seismicity west of the Indus River, across from the very active northwestern flank of the Nanga Parbat massif. This remarkable pattern of regional shortening is thought to stem from the effect of the Indus gorge on the tectonic regime. A very large stress is derived from the combined effect of the weight of the mountain and the lack of weight along the gorge. The tectonic regime responds to this superposed topographic stress by increasing the rate of slip on the Lichar thrust in an attempt to fill the gorge from below. This attempt is futile, given the effectiveness of the river to remove material and to maintain its grade. In this hypothesis, the northwest-directed shortening is taken up completely at the gorge, where the gorge is parallel to the massif. Effectively, therefore, the southwest trending portion of Indus River between the Astor and the Diamir confluences casts a stress shadow to the northwest and shunts the shortening. Topographically driven accelerated slip on the basal thrust along this portion of the gorge may also account for the height along the corresponding portion of the Nanga Parbat massif. Once established, the drainage pattern in active mountain building orogens may have a much greater effect on the tectonics than vice versa.

S/152. Seeber, L. & Gornitz, V., 1983. River profiles along the Himalayan arc as indicators of active tectonics. *Tectonophysics* 92(4), 335-367.

Longitudinal profiles along sixteen major transverse Himalayan rivers add important constraints to models of active continental subduction and its evolution. These profiles are characterized by a zone of relatively high gradient that cannot be associated with differential resistance to erosion in all cases. The base of the zone of increased gradients correlates with (1) the topographic front between the Lesser and High Himalayas, (2) the narrow belt of intermediate-magnitude thrust earthquakes, (3) the Main Central Thrust zone (MCT). These features define a small circle in the central portion of the Himalayan arc. These correlations suggest that the discontinuity in the river profiles and the other features are controlled by a major tectonic boundary between the rising High Himalayas and the Lesser Himalayas. No sharp increases in gradient are observed near the Main Boundary Thrust (MBT), except on a few rivers, such as the Jhelum or Kunhar, where the MBT lies close to both the MCT and the seismic belt. Thus, it is unlikely that the MBT is a major tectonic boundary. The diversion of river courses along the MBT and around anticlines in the Sub Himalayas has probably been caused by aggradation near the erosion-deposition boundary, upstream of uplifts in the Mahabharat range and Sub Himalayas.

A parallel is drawn between the Himalayas and New Guinea based on the hypothesis that continent-arc collision, of the type occurring in northern Australia, preceded continent-continent collision in the Himalayas. The present sedimentary/tectonic phase in New Guinea resembles the Subathu (Paleocene-Eocene) phase in the Himalayas. Incipient counterparts of the major Himalayan structures, including the MCT and the MBT, are recognized in New Guinea. The drainage patterns in the Himalayas and in New Guinea bear a similar relation to major structures. This suggests that (1) the tectonic evolution of the Himalayas has been rather uniform since early stages of collision, and (2) the Himalayan drainage was also formed at these early stages and is therefore antecedent to the rise of the High Himalayas.

S/156. Seeber, L. & Pêcher, A., 1998. Strain partitioning along the Himalayan arc and the Nanga Parbat antiform. *Geology* 26, 791-794.

Shortening along the Himalayan arc of continental convergence is approximately in the radial direction. If the underthrusting foot-wall block (India) is not deformed, the hanging-wall block (Tibet) needs to stretch along the arc, as suggested by radial grabens in southern Tibet. In contrast, the Nanga Parbat–Haramosh massif and the western Himalayan syntaxis are part of a 250-km-long antiform that strikes in the radial direction (northeast) and verges northwest. The Nanga Parbat antiform is the structural and topographic expression of arc-parallel shortening that compensates for arc-parallel extension in southern Tibet. This shortening is predicted to be as high as 12 mm/yr.

S/158. Seeber, L., Quittmeyer, R.C. & Armbruster, J., 1980. Seismotectonics of Pakistan: A review of results from Network data and implications for the Central Himalaya. *Geological Bulletin, University of Peshawar* 13, 151-168.

Microearthquakes detected by two telemetered seismic networks in northern Pakistan reveal a decollement style of tectonics for the Hazara and northwest Punjab region. The three-dimensional distribution of seismicity and sediments and metasediments is decoupled from the basement. Below the decoupling surface major faults trend northwest. These faults are recognized as basement structures that are associated with the Himalayan arc, but that extend towards the northwest beyond the Hazara-Kashmir syntaxis. During the last six years, the period of network observations, the seismicity is mostly associated with the basement faults. Seismic activity within the decollement is generally low and the decoupling surface is either aseismic or associated with very low seismicity.

The results from northern Pakistan, together with recent seismicity along the Himalayan arc and information on great Indian earthquakes, are combined to derive a general model of Himalayan tectonics. A shallow thrust of gentle dip, termed the Detachment, underlies the Indo-Gangetic plain and the Lower Himalaya. Rupture of this fault, which separates the low-strength sedimentary wedge from the basement, results in great earthquakes that cause devastation over a wide area, but occur only infrequently. Down-dip from the Detachment, beneath the higher, the thrust assumes a steeper dip and juxtaposes basement material of similar properties. Earthquakes occur more frequently on this portion of the fault, termed the Basement Thrust, but are smaller than the Detachment events. They can, however be damaging locally. The model suggests that much of the Indo-Gangetic plain underlain by the Detachment has a high seismic hazard. In the Hazara arc region of northern Pakistan the Detachment is associated with a thick layer of Infracambrian salt. In this region the Detachment may slip aseismically; however, slip by large infrequent earthquake cannot be ruled out.

Results from a seismic network centered on Quetta show that the Chaman fault, and the fault associated with the Quetta earthquake of 1935, are currently active. The segments that ruptured during the most recent large earthquakes on these faults, 1892 on the Chaman fault and 1935 on the Quetta fault, are relatively quiet at present. On both faults the current seismicity is concentrated near the ends of the ruptures associated with these earlier events, and indicates left-lateral strike-slip. In analogy with the San Andreas and Alpine fault system, in California and New Zealand, respectively, two distinct portions of the Chaman fault system are recognized. One, north of approximately 31°N, trends obliquely to the regional slip vector and is probably characterized by infrequent great earthquakes. The other, south of 31°N, has a strike subparallel to the regional slip vector and consists of a broad zone of faults that rupture in large, but not great, earthquakes.

Locations of earthquakes that have occurred between 1970 and 1988 in the northwest Himalaya of Pakistan, as computed by the ISC, were analyzed to improve knowledge of the spatial distribution of seismicity near the Nanga Parbat-Haramosh Massif (NPHM). A set of 15 earthquakes were relocated using the multiple-event relocation

technique of Jordan and Sverdrup (1981). Earthquake located using records from at least 25 to 30 stations tend to be well-located in the ISC database: smaller error ellipses and shorter distance of relocation. These analyses indicate that earthquakes with magnitudes $m(\text{sub } b)$ greater than 4.0 have occurred since 1970 along the NPHM.

The Murree Kohala road one of the most important road of the country which provides facilities of communication between Pakistan and Azad Kashmir, crossing over the Jhelum river at Kohala. This road is also important for defence point of view. The slopes along the Murree Kohala road are very unstable, especially kassari to Phagwalai village. The condition of the Murree -Kohala road is satisfactory where a good driver can drive every type of vehicle at the speed of 40-50 kms/hour, except for the landslide areas. At Murree Kohala road three major slides were selected for study namely Kasseni (K_0, K_1, K_2, K_3), Norgali (N_1, N_2) and Eliot (A_1, A_2). These are between lower topa to Eliot which are also marked on the map. The second road which join Kohala is starting from Jhikkagali via Burban which meet the Murree Kohala road near phagwani Village. There is also a slide near Kashmiri Bazar which is shown on the map. The project area is lying in the Murree Formation which is mainly composed of Shale, mudstone and sandstone. The detailed geological mapping of the active landslides area were carried out on, the map, sandstone, mudstone and shale with specific symbol on the map. The samples were collected

Acidic microporphyries of Late Paleozoic age are intimately associated with appreciably larger volumes of acidic plutonic rocks of alkaline igneous province of Peshawar Plain. Field evidences and their partial intercalation in the metasedimentary sequence of Jaffar Kandao and Baroach Formations suggest an Early Carboniferous age.

Very coarse to fine-grained felsic phenocryst in fine-grained to glassy felsic groundmass clearly imparts a porphyritic texture to these rocks. On the basis of modal and chemical composition, majority of these rocks are classified as rhyolites on one side and basalt (now greenschist) on the other. Variables and their ratios based on major and minor elements classify these rocks as A-type, mildly alkaline and peraluminous in character. On various tectonomagmatic discrimination diagrams, these rocks show a within plate continental rift environment, and this character is also supported by Hf/Th, Hf/Ta and concentration in Zr and Ta. Sensitivity of Th, Hf and Ta due to crustal contamination is seen in tectonomagmatic discrimination triangular diagrams based on these three elements.

Eu-anomaly displays fluid-solid rock interaction confirming soda metasomatism due to late magmatic phases in these rocks.

Hand-panning survey in an area of about 1083 square miles in the lower part of Kohistan bordering Swat district was carried out to study the distribution of heavy minerals in the alluvial of Ushu and Gabral rivers.

The area under examination is underlain by various types of plutonic, volcanic and metasedimentary rocks. The plutons are represented by norites, diorites and the associated rocks of the Kohistan Basic Complex. Metasedimentary suite is represented by quartzite, various types of schists, phyllites and semi crystalline limestone of the Kalam Group. Whereas volcanics are represented by rhyolite and dacite of the Utror Group.

Microscopic examination of heavy suite reveals hornblende, opaque minerals, garnet, biotite, hypersthene and augite. These constitute bulk of the detrital heavy minerals. Whereas sphene, silliminite, cassiterite, leucosena and tourmaline are present in some slides. Among the opaque minerals magnetite, titanomagnetite, pyrite, chalcopyrite, arsenopyrite, limonite and ilmenite were tentatively diagnosed. Radiometric analysis of the hand-panned concentrates reveals presence of no radioactive mineral. Search for valuable fluorescent minerals has also been carried out and except zircon no other mineral has been detected under UV-lamp of short waves lamp.

S/170. Shah, K., Shahabuddin, Hassan, B. & Ahmed, M.S.A., 1967. Studies on Resin from Makerwal Coal. Pakistan Journal of Scientific & Industrial Research, 10(3), 212-215.

Makerwal coal is known to contain a high percentage of resins which are recoverable by solvent extraction. Alternative methods of recovery reported earlier show a wide degree of variation in the yield of resins and the quality of coal residue. An attempt has been made to evaluate these methods, by studying separately the behaviour

of original coal, solvent extracted resins and the coal residue from solvent extraction, on superheated steam treatment and carbonisation.

It was found that on superheated steam treatment at 300-330°C these resins were only partially recoverable while on carbonisation extensive cracking of the resins was observed. The experimental data from the present work and critical review of the earlier work in this direction has clarified some of the hitherto reported anomalies of the behaviour of Makerwal coal.

The geological and mineralogical characteristic of Rara limestone has been investigated to evaluate the properties of limestone as concrete aggregate. The Crushing Value, Impact Value, Loss Angle 'S', Specific gravity, water absorption and shape of the particles are comparable to recommended B. S standards with few exceptions. At places rocks are highly crushed and deleterious material in the rock aggregate is very high. Mineralogically the iron content (25%), muscovite (7%) and dolomite (2%) are unacceptable. The alkali concrete aggregate reaction involves argillaceous dolomitic limestones, clays, argillites and very far in south expansive cherts were found. It is common in the gravel derived from various limestone formations in the area. Siliceous limestones are investigated from lower plain and Majuhan and in some instances, appear to be a major factor in concrete deterioration. The classical areas of alkali carbonate reaction occur in lower plain and Darwana Nalah. The iron content in the presence of water, argillites and clays associated with alkali expansive reactions in concrete have been described.

S/172. Shah, M.A. & Anwar, J., 1981. Regional geology of Chili Bagh west of Kohat, N.W.F.P., M.Sc. Thesis, Department of Geology, University of Peshawar, 41p.

The rocks of the area range in age from Eocene (represented by the Panoba Shale, Kuldana Formation, and Kohat Formation) to Miocene (represented by the Murree Formation) with a disconformity between them. The Panoba Shale has a varied lithology of clay, shale, and marl and was deposited in deltaic environments.

The Kohat Formation is divisible in a lower Kaladhand Limestone Member, a middle Sadkal Shale Member and an Upper Habih Rahi Limestone Member. These were deposited in moderately deep to shallow marine environments. The Murree Formation is represented by clay and sandstone in the area, and was deposited in the lacustrine environments.

The area exhibits remarkable deformational structural features the study of which revealed a series of symmetrical and asymmetrical, cylindrical and non-cylindrical folds. A fault with major strike slip components, joints and other major structural features, were also observed, studied, and marked on the map. The cross bedding is characteristic of Murree Formation.

The rocks of the area have been subjected to intense chemical weathering and rapid rate of erosion in the geological past. Deep erosional work of the various agencies in the past have cut most of the intensely folded anticlines, the cores of which are now exposed.

S/177. Shah, M.R., 2001. Paleoenvironment, sedimentology & economic aspects of the Hangu Formation in Kohat-Potwar & Hazara area. Ph.D. thesis. NCE Geology, University of Peshawar.

The Hangu Formation of early Paleocene age is widely distributed in the hill ranges of Kohat-Samana, Surghar, Attock-Cherat, Hazara and Salt Range areas of north Pakistan. The formation is comprised of thin to thick-bedded sandstone, siltstone with thin interbeds of limestone and shale. The rocks are characterized by horizontal lamination, graded bedding, cross stratification and bioturbation.

The formation occupies a significant stratigraphic position as it marks the Cretaceous-Tertiary (K-T) boundary. This stratigraphic boundary is in the form of a major unconformity at the base of the Paleocene in north central Pakistan and adjacent north western India, defined by laterite, ferruginous pisolites, and bauxite or local erosional unconformities. The lower contact of the formation marks varied erosional phases in different parts of the north Pakistan. Stratigraphically it overlies the Cretaceous Kawagarh Formation at Samana, Kalachitta and Hazara, whereas in Surghar Range it overlies the Lumshiwal Formation. The hiatus is even more pronounced in the Salt Range area, where it overlies the Lumshiwal, Samanasuk, Datta, Mianwali, Chhidru, Wargal, Amb, Sardhai formations and Warchha Sandstone of Cretaceous, Jurassic, Triassic and Permian ages respectively. In Cherat and Balakot area the formation rests over the Dakhner Formation of Precambrian and Abbottabad Formation of Cambrian age. This indicates a major unconformity in these areas progressively increasing eastward.

From the study of different stratigraphic sections the formation can be subdivided into a number of lithostratigraphic units and lithofacies based on the lithological variations and sedimentary structures. The important lithofacies recognized in these areas are; 1) Lateritic/Bauxitic lithofacies. 2) Cross-bedded sandstone lithofacies. 3) Bioclastic limestone lithofacies. 4) Coal, carbonaceous shale lithofacies. 5) Bioturbated quartzose sandstone lithofacies. Lithofacies analysis and petrographic studies of the Hangu Formation indicate that transgressive shoreline environments deposited the formation, which is partly represented by terrestrial to coastal swampy conditions and partly by shoreface to offshore (shelf) environments of deposition.

The upper and basal parts of the formation contain economic minerals like coal, laterite, bauxite, silica sand and fairly good source rock potential for hydrocarbon generation. The coal is found in the Samana Range, Surghar Range and Attock-Cherat Range but is missing in Salt Range, Kalachitta and Hazara areas. The coal is dull to shining black in colour, grades from high volatile B to C bituminous in rank and is in the form of lenses, stringers and lenticular beds. The laterite and bauxite developed at the base of the formation in the study area is found as discontinuous beds, lenses, sheets and pockets. The laterite is found in Samana Range, Surghar Range, Attock-Cherat, Kalachitta, Salt Range and Hazara while bauxite is confined to Salt Range area. The silica sand, which is present in the upper, middle and lower parts of the formation, is well developed in the Samana Range, moderately developed in the Surghar Range and is poorly developed in the western Salt Range. Source rock potential for hydrocarbon generation is developed in Surghar, Salt Range and Attock-Cherat Ranges.

S/180. Shah, M.R., Abbasi I.A. & Haneef, M., 2001. Facies and paleoenvironment of the Hangu Formation (Paleocene), N. Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, 29-30.

The Hangu Formation of Early Paleocene age is widely distributed in N. Pakistan. It is comprised of thin to thick-bedded sandstone, siltstone with thin limestone/shale interbeds and thin coal seams, containing a wide variety of sedimentary structures (Shah et al., 1993). The thickness of the formation varies from 97m at the stratotype to 1m in the Eastern Salt Range.

As a part of this study, 19 stratigraphic sections of the formation were studied and described along the entire belt of the outcrop in the Salt Range, Attock-Cherat Range, Kohat-Potwar and Hazara areas. The purpose of this study is to establish the stratigraphic relationships, identify lithofacies and interpret the depositional environments. Five lithofacies of the formation are recognized on the basis of lithological variations and distinct depositional fabric (Shah et al., 1999). These lithofacies include; FILF-1 (Laterite/Bauxite Lithofacies): This lithofacies marks the base of the formation and is comprised of laterite, lateritic clay, shale, bauxite and bauxitic clay, as discontinuous bodies, pockets and lenses. The laterite is well developed through out, while bauxite is confined to the Central Salt Range.

HLF-2 (Cross-bedded Sandstone Lithofacies): This lithofacies is dominantly comprised of sandstone in Kohat-Samana area and sandstone, siltstone, clay and limestone in Surghar Range and Salt Range. The lithofacies is cross-bedded. HLF-3 (Bioclastic Limestone Lithofacies): This lithofacies is represented by skeletal wacke packstone and is only present in the Surghar Range and Salt Range. It is interbedded in siltstone and shale. FLLF-4 (Coal/Carbonaceous Shale Lithofacies): Coal, carbonaceous shale and sandstone lithofacies is restricted to Hangu, Makarwal and Cherat areas. This lithofacies is found in the upper part at the Hangu section, while at Makarwal and Cherat it is found in the lower and middle parts.

HLF-5 (Bioturbated Quartzose Sandstone Lithofacies): This is the topmost lithofacies of the formation and is comprised of highly bioturbated sandstone, siltstone and clays. The lithofacie occurs widely in the study area.

The lithofacies interpretation of the Hangu Formation reveals that the formation represent deposition in near-shore, beach-barrier environments. HILF-1 represents non-marine terrestrial (sub-aerial exposures) environments. HLF-2 represents beach/foreshore environments deposition. HLF-3 is deposited in paralic (back-barrier) environments. HLF-4 is interpreted to deposited in shallow marine/lagoonal environments, while HLF-5 represents shoreface environments of deposition.

S/182. Shah, M.R., Abbasi I.A., Haneef, M. & Khan, A., 1993. Nature, origin and mode of occurrence of Hangu-Kachai area coal, district Kohat, NWFP, Pakistan: A preliminary study. Geological Bulletin, University of Peshawar 26, 87-94.

Coal showings are known from the Hangu Formation of Paleocene age in the Hangu-Kachai area, northwest of Kohat. The Hangu Formation is well developed in this area and is comprised of quartzitic sandstone with minor intercalations of shale. The coal seam is developed near the upper contact of the Hangu Formation with the overlying lockhart limestone. Preliminary exploratory drilling of the Hangu Formation in the area have revealed the presence of coal. The coal is dull to shining black and ranges from high volatile B to C bituminous in rank. The Hangu area coal occurs in the form of discontinuous stringers and lenses and is less than 2 meters thick.

The average analytical results on as received basis indicate, the coal bed contains 0.52 % moisture, 14.2 % ash, 4.2% sulphur, 53 % fixed carbon and 32.64 % volatile matter. Based on the average BTU/lb and fixed carbon content of the Hangu-Kachai coal samples collected from the field, with minor exception of variation in color, the Hangu coal is analogous to the known coals of the Balochistan and the Salt Range areas. On the basis of its stratigraphic position, mode of origin and structure, the Hangu-Kachai coal is comparable with the Makarwal coal of the Surghar Range. Detailed exploratory studies are proposed to evaluate the nature and extent of the Hangu-Kachai area coal.

S/183. Shah, M.T., 1986. Petrochemistry of the rocks from Shergarh Sar area, Allai Kohistan, Northern Pakistan. M.Phil. Thesis, University of Peshawar, 221p.

The Shergarh Sar area in Allai Kohistan is located at the junction between the Indo-Pakistan plate and the Kohistan island arc block. Rocks of the area are distinguished into three petro-tectonic units: (1) The Kohistan island arc sequence, (2) The Indus suture mélange zone, and (3) The Indo-Pakistan subcontinent sequence.

Amphibolites are the most abundant rocks in the Kohistan island arc sequence. These are distinguished into epidote-amphibolites and garnet epidote-amphibolites. The Indus suture mélange zone mainly comprises ultramafics (clinopyroxenite, peridotite and serpentinite), pillow lavas, greenschist rocks, and blueschist facies metagraywacke. The Indo-Pakistan subcontinent sequence includes granite gneiss, thin bedded crystalline limestone, and schists. In the present work, the field features, petrography, and chemistry of the constituent rock units are discussed in detail.

The potential usefulness of the observed petrochemical indices from the constituent rocks in the studied suite is elucidated as tectonic finger prints and genetic indicators in this thesis. The major and trace element constraints of amphibolites, suggest their derivation from a basic igneous parent of tholeiitic character developed in an island arc type environment. The intimately associated igneous and metamorphic rocks within the Indus suture mélange zone owe their development to different processes in varied tectonic environments. The chemistry of the ultramafics suggests the comagmatic nature of the constituent rocks, and their development by the partial melting of mantle of peridotitic composition. Lavas in the Indus suture mélange zone are compact, mostly glassy or very fine grained. These are characterized by pillow structures, and frequently show incorporation of angular to rounded fragments and blocks of carbonate rock. Their major and trace element analyses closely correspond to tholeiitic rocks produced by partial melting process in an island arc type environment. Chemistry of greenschist rocks, occurring in north western part of the studied area, suggests their derivation from a basic parent through metamorphism. Assessment of the chemical data in related chemico-tectonic systems favour origination of their parent material in typical oceanic environments.

Petrography and mineral chemistry of the blueschist facies metagraywacke from the studied area are compared with that of the equivalent rocks occurring in Shangla (Swat) and Ladakh. P-T conditions of metamorphism are calculated. Details of thin section and chemical study oppose oscillatory transition in metamorphic conditions, as noted in Shangla, or retrogression as found in similar rocks from eastern Ladakh.

metal deposits in Besham area, northern Pakistan. Geological Bulletin, University of Peshawar 25, 67-71.

Regionally metamorphosed sediment-hosted stratiform exhalative type base metal deposits are exposed in the Lahore and Pazang properties of Besham area at the northern margin of the Indian plate. Sphalerite geobarometer and garnet-biotite geothermometer were used calculate the P-T conditions of metamorphism. These geothermobarometer yielded most convincing results for the studied deposits. These deposits and the host meta-sediments were subjected to amphibolite facies metamorphism with a metamorphic temperature of $585 \pm 250^\circ\text{C}$ and a pressure of 8 ± 2 kb.

S/186. Shah, M.T., 1992b. Tourmaline as an evidence of exhalative origin for Besham base metal deposits in northern Pakistan. Geological Bulletin, University of Peshawar 25, 123-126.

Tourmaline occurs as an accessory phase in the metaquartzite/meta-arkose unit of the Pazang group in Besham area. The chemistry of different tourmaline grains varies within the same sample but there is no change in composition within a single grain. These tourmalines have an intermediate composition between schorl and dravite. This composition along with FeO/FeO+MgO ratio for the studied tourmaline grains is unlike those of granitic terrain and can be comparable to that of the tourmaline found in association with submarine exhalative massive sulfide deposits.

Proterozoic sediment-hosted massive sulfide ores occur in the highly deformed and metamorphosed rocks of the Pazang group in the Besham area, District Kohistan. The massive sulfide ores and associated rocks of the Pazang group were subjected to skarnization after their deposition. Both magnesian and calcic skarns were formed. As a result, the Mn-rich skarn minerals (i.e. clinopyroxenes, pyroxenoids, garnet, olivine and serpentine) have been developed within these rocks. The chemistry of these minerals suggest that the protoliths for both calcic and magnesian skarn were probably impure limestone and dolomite respective with intercalations of umber, chert and clays.

S/189. Shah, M.T., 1994. A note on the bornite-chalcopyrite intergrowth texture in the volcanic-hosted copper mineralization in the Dir area, northern Pakistan. Geological Bulletin, University of Peshawar 27, 125-126.

Various experimental studies have been carried out to understand the possible bornite-chalcopyrite intergrowth texture. The bladed and lenticular shape intergrowth of chalcopyrite in the studied bornite can be termed as widmstätten texture of Schwartz (1931) and Durazzo and Taylor (1982). This type of intergrowth texture can possibly be the product of either: 1. Replacement of bornite by chalcopyrite or 2. Exsolution from anomalous bornite during heating in a temperature range c. $200-2500^\circ\text{C}$. In this case the chalcopyrite exsolution lamellae in the bornite matrix of the studied rocks may have probably been produced due to the rapid growth of chalcopyrite in a highly supersaturated bornite matrix with chalcopyrite $> 25\%$.

S/192. Shah, M.T., 1997a. Mineralogy, texture and geochemistry of the volcanic-hosted hydrothermal copper mineralization in Dir area, Kohistan arc terrane, northern Pakistan. In: Wijayananda, N.P., Cooray, P.G. & Mosley, P. (Eds), Geology in South Asia-II, Geological Survey and Mines Bureau, Sri Lanka, Professional Paper 7, 263-280.

Copper mineralization in the Dir area is related to a hydrothermal activity, which is mainly confined to the metavolcanic sequence within the Kohistan island arc in Pakistan. The sequence is composed predominantly of basaltic-andesite and andesite with subordinate basalt, dacite, rhyolite and pyroclastic breccia. Chalcopyrite is the main copper-bearing phase. Subordinate Cu-phases are bornite, chalcocite and covellite. Electron microprobe analysis indicates the pure nature of these ore phases. Malachite and azurite showings are conspicuous along the shear zones. A variable gain and loss of MnO, Na₂O, K₂O and P₂O₅ are noticed in the mineralized metavolcanics, which show an enrichment of Cu, Zn, Mo, Cd, Ag and Au. Both mineralized metavolcanics and mineralized quartz veins have a high $\delta^{18}\text{O}$ signature. This suggests the involvement of isotopically heavy or-forming fluid in the alteration and copper mineralization in these volcanics. This fluid has an estimated $\delta^{18}\text{O}$ isotopic composition of 5.1 per mil, which could be the magmatic water introduced by the granodiorite or diorite intrusion below the metavolcanic sequence.

S/194. Shah, M.T., 1997c. Mineralogy, chemistry and genesis of the Proterozoic base metal deposits at the northern margin of the Indian plate in Besham area, Himalaya, Northern Pakistan. In: Hussain, S.S. & Akbar, H.D. (Eds.), Proceedings, National Symposium on Economic Geology of Pakistan, 1997, Islamabad, 11-57.

The Himalayan mountain range is a geological manifestation of the collision of northward moving Indian plate with the Asiatic plate. Kohistan arc terrane is sandwiched between these two plates and is bounded by two major thrust faults. Rocks of the northern margin of the Indian plate have a complex tectono-metamorphic history with poly-phase deformation and metamorphism. These are mainly composed of the Proterozoic basement gneisses and schists, which are overlain by several sequences of metasediments of Phanerozoic age. These rocks have been

divided into Besham, Pazang and Karora groups. The first two groups are a part of the basement complex and the third one is composed of a cover of metasediments that unconformably overlie the basement complex.

Base metal mineralization in the rocks of the Indian Plate occurs along its northern margin in the footwall of Main Mantle Thrust (MMT) around Besham and is confined to the Pazang group. The rocks of the Pazang group are distinguished into Pelitic formation, Sulphide formation and Meta-quartzite/Meta-arkose formation from bottom to top. The Sulphide formation having Zn-Pb mineralization constitutes the distinct portion of the Pazang group and is the subject of present research.

Mn-rich clinopyroxenes, pyroxenoids and Mn-rich garnets are the common skarn minerals. Quartz, feldspars, biotite, muscovite, hornblende, phlogopite, epidote and carbonates are present in variable amount in each rock unit. Tourmaline, zircon, apatite, sphene and pyrophanite occur as accessories. Olivine, serpentine and phlogopite are commonly developed in the magnetite-rich carbonates. Among the ores, sphalerite, pyrrhotite, pyrite and galena are the main sulphides with minor amount of chalcopyrite and melnikovite. Magnetite is the major oxide present in these rocks. Mineralogy and chemistry of various silicates and sulphides and the whole rock major and trace elements geochemistry provided some clues regarding the paragenesis of massive sulphide ores.

Lead isotopic gave model ages of 2120-2199 Ma (Proterozoic) for both the Pazang and Lahor deposits. These deposits are more primitive in terms of ages and have lower μ values relative to the well-known sediment-hosted deposits elsewhere in the world. The non-radiogenic isotopic composition and the homogeneity of the ore lead in both Pazang and Lahor ores suggest a well-mixed common source and similar processes for the formation of these ores.

Zn-Pb stratiform mineralization in Besham area occurs in a highly deformed and metamorphosed terrane. Most of the textural features suggest that the mineralization predate the deformation and metamorphism. Both deformation and metamorphism have caused remobilization and crystallization of various ore phases to the present situation. Igneous metasomatic skarn has played an important role in the formation of Mn-rich clinopyroxenes, garnet and pyroxenoids along with Cu, Mo and W mineralization, within the rocks of the Pazang group. Massive sulphide ores and the host rocks are subjected to the upper amphibolite facies metamorphism with a metamorphic temperature of $583 \pm 35^\circ\text{C}$ and pressure of 8 ± 2 Kbars.

The mineralogy, petrology and geochemistry of various ore bodies and their lead isotopic ratios, lack of volcanic rocks and lack of footwall hydrothermal alteration favor a distal submarine exhalative origin for the Besham Zn-Pb ore bodies. These deposits can be classified as sedimentary exhalative stratiform zinc-lead.

S/198. Shah, M.T. & Hamidullah, S., 1994. Field and mineralogical constraints of the Dir metavolcanic sequence, Kohistan arc terrane, northern Pakistan. *Geological Bulletin, University of Peshawar* 27, 43-55.

The Dir metavolcanic sequence, a part of the Dir group, constitutes a NE-SW trending belt within the northwestern portion of the Kohistan island arc in the western Himalaya of northern Pakistan. This sequence is dominantly composed of basaltic-andesite and andesite with subordinate basalt, dacite, rhyolite, and pyroclastic breccia. These rocks are foliated and sheared along local faults and also have small intrusions at places.

Porphyritic textures are dominant, with less common aphyric and seriate textures. Plagioclase (An 10-42) is ubiquitous in all the members of the sequence and occurs as phenocrysts and in groundmass. K-feldspar and quartz predominate both as phenocrysts of the dacites and rhyolite. Chlorite, epidote, and actinolite are the most common metamorphic phases; hornblende, muscovite, biotite, kaolinite, sericite, carbonate, and opaques occur rarely. Phase assemblages and chemistry suggest predominant greenschist facies metamorphism with epidote-amphibolite facies conditions attained locally.

Key words: Metavolcanic, geochemistry, metamorphism, Dir group, Kohistan arc.

S/199. Shah, M.T., Haq, I. & Hamidullah, S., 2000. Geology and geochemistry of the rocks of Yushiri valley, District Dir, Northern Pakistan. *Geological Bulletin, University of Peshawar* 33, 53-78.

The study area is lying in the north-western portion of the Kohistan arc terrane. This terrane is bounded by two suture zones of regional extent at its northern and southern sides, believed to be formed by obliteration of ancient oceanic basin. This arc experienced its first collision at its northern margin with the Karakorum plate at 90-80 Ma, and its second collision at the southern margin during Early Eocene with the Indian plate. Rocks of the study area are distinguished into two main lithological units: (1) Amphibolites and (2) Metadiorites/metagranodiorites. The amphibolites occupy the southern part of the studied area while metadiorite/metagranodiorites are exposed in the northern part of the study area. Both these rock units have intrusive contacts and exhibit local faulting and shearing. The amphibolites also host small patches of slightly metamorphosed gabbro-norites. The amphibolites are generally massive but also exhibit banding at places. They are intruded by quartz and quartzo-feldspathic veins especially in areas where shearing and faulting are intense. They are also intruded by the metadiorite / metagranodiorite in the form of small plugs. The metadiorites / granodiorites are medium to coarse-grained, massive in character and have xenoliths of amphibolites. Copper mineralization in the form of disseminated grains of tetrahydrite and chalcopyrite and supergene enrichment in the form of malachite and azurite occur within quartz veins in limited areas. Amphibolites are mainly composed of hornblende and plagioclase with subordinate amount of quartz and alkali feldspar. Biotite, muscovite, chlorite, epidote, apatite, sphene, rutile, calcite and opaque occur as accessories. The metagabbro-norites contain plagioclase, orthopyroxene and clinopyroxene as the dominant mineral constituents. The metadiorite, quartz-diorite and metagranodiorite are dominantly composed of plagioclase with variable proportion of quartz and alkali feldspar. The other minor constituents include biotite, hornblende, muscovite, apatite, sphene, zircon, garnet and opaque.

Chemically the amphibolites and metagabbro-norites are comagmatic. Their chemical characteristics favor the igneous parentage (i. e., host gabbro-norite) for the studied amphibolites. The major and trace elements study of these rocks suggests that these are of calc-alkaline nature and are formed by the arc magma within the subduction related environment. The chemical characteristics of the granitoid rocks (metadiorite/metagranodiorite) suggest that these are comagmatic and have close affinity towards the calcalkaline rocks, developed in island arc type of set up. Both the amphibolites and gabbro-norites could be related to either Kamila amphibolites belt or Chilas Complex. The studied granitoids are, however, correlated with the stage II pluton of the Kohistan batholith.

S/201. Shah, M.T., Ikramuddin, M. & Shervais, J.W., 1994. Behaviour of Tl relative to K, Rb, Sr and Ba in mineralized and unmineralized metavolcanics from the Dir area, northern Pakistan. *Mineralium Deposita* 29(5), 422-426.

Copper mineralization in the Dir area of northern Pakistan is confined to the quartz veins and associated with hydrothermally altered metavolcanics. Chalcopyrite is the main copper-bearing phase with subordinate amounts of bornite, chalcocite, covellite, malachite and azurite. Both mineralized quartz veins and associated unmineralized (least altered) and mineralized (strongly altered) metavolcanics have been analyzed for Cu, Au, Ag, Tl, K, Rb, Ba and Sr. An increase of Cu, Au, Ag, Rb/Sr and Tl/Sr, and a decrease of Sr and K/Rb is observed in both mineralized metavolcanics and mineralized quartz veins. Thallium shows lithophile behaviour in the Dir metavolcanics and no chalcophile behaviour was observed. The Tl/Sr ratio might be an indirect guide for the exploration of volcanic-hosted hydrothermal copper deposits.

S/202. Shah, M.T. & Jan, M.Q., 1993. Mineralogical constraints of the Shergarh Sar amphibolites, Allai Kohistan, northern Pakistan. *Geological Bulletin, University of Peshawar* 26, 59-73.

Shergarh Sar amphibolites, a part of the southern amphibolite belt, widely exposed in the area around Bana in Allai Kohistan. Epidote-amphibolite is the main unit with scattered patches of garnet-bearing variety. Amphibole, epidote and, in some, garnet are the main phases with minor amount of quartz, plagioclase, clinopyroxene, opaque oxides and rutile. Amphiboles range in composition from tchermakitic-hornblende to actinolite with magnesio-hornblende as an intermediate phase. This transition is marked by decrease in Al/Ti, alkalies and Fe^{2+}/Mg ratio and increase in Si. Epidote occurs as large crystals (both zoned and unzoned) with low Ps contents (9-15) and as small granular aggregates with high Ps contents (17-27). Garnet occurs sporadically in the form of porphyroblasts and is found in association with leucocratic veins. It is chemically unzoned and is predominantly made up of almandine-grossular-pyrope solid solution. Plagioclase ranges from An₂₇ to pure albite and clinopyroxene is chemically homogenous diopside.

Petrographic observations and thermobarometry suggest that the rocks were initially equilibrated under amphibolite facies with overprinting of greenschist facies assemblage. This retrogression may have been facilitated by shearing during the obduction (uplift-cooling) of the rocks along the Indus suture following their Eocene collision with the Indian plate.

S/204. Shah, M.T. & Khan, A., 1999. Geochemistry and origin of Mn-deposits in the Waziristan ophiolite complex, North Waziristan, Pakistan. *Mineralium Deposita* 34, 697-704.

The Waziristan ophiolite complex is located along the western margin of the Indian plate in northwestern Pakistan. The Mn-deposits in the Saidgi and Shuidar areas are part of this ophiolite complex. These deposits, both banded and massive in nature, are hosted by metachert and are generally overlying metavolcanics. Braunitz and cryptocrystalline quartz are the main constituents of the manganese ores in both areas. Hematite occurs in the Shuidar deposits as a minor phase. Metacherts are microcrystalline quartz, chalcedony, and lesser hematite. Chemically, the studied Mn-deposits and associated metacherts are very similar to those formed by submarine

hydrothermal effusive processes. The deposits originated along sea-floor spreading centers (mid-ocean ridges) within the Neo-Tethys Ocean and were later obducted as part of the Waziristan ophiolite complex.

S/205. Shah, M.T., Latif, A. & Aurangzed, 1980. Major element abundances in volcanic rocks from Kalam volcanic zone, Swat. M.Sc. Thesis, University of Peshawar, 56p.

Andesite and salic eruptives of calc-alkaline affinity in the Kalam volcanic zone constitute the upper part of the Kohistan sequence (Tahirkheli et al., 1970) developed in the western branch of the Himalayan syntaxis between 71°E and 75° E. The sequence is interpreted as a complete cross section of a mature island arc formed by subduction during Mesozoic in the southern part of the Neotethys and obducted onto the Indian plate in Upper Cretaceous time (Bard et al., 1980). The Kohistan sequence includes a thick complex of amphibolites, hypersthene gabbros, pyroxene diorites, hornblende diorites, granodiorites, metasediments and volcanic rocks.

The potential usefulness of the geochemical parameters of the extrusive rocks from the Kalam area, Swat as tectonic fingerprints and genetic indicators is discussed in this paper. There is a close correspondence between the available petrochemical indices of genetic significance of the studied suite to the calc-alkaline volcanics in western and southwestern Pacific regions, which substantiates earlier workers' designation of an island arc environment in the Kohistan Himalaya during Mesozoic time.

S/207. Shah, M.T. & Lechler, P.J., 2002. Gold anomalies in the Dir and Swat Kohistan, northern Pakistan. *Journal of Science & Technology, University of Peshawar*, 26, 1-6.

The major portion of the study area is comprised of rocks of the Kohistan Island arc while the rest of the area is composed of the rocks of the Indo-Pakistan plate. Both these terrains are separated by the Indus suture mélange zone, which represents the collision suture between the Indo-Pakistan and Eurasian plates.

Geochemical exploration for gold has been carried out by collecting heavy mineral panned- concentrates and stream sediment samples from various drainage basins of the study area. Mineralogical studies of the panned-concentrates suggest the presence of gold in the form of piece, speck and color in certain drainage basins, however, no nugget of gold has been found. The characteristics of these gold particles suggest that these have been transported from nearby source. The concentration of gold, obtained in various drainage basins, has been processed through geo- statistical map analysis technique, which has delineated anomalous areas of most interest for further

S/208. Shah, M.T. & Majid, M., 1985. Major and trace element variations in the lavas of Shergarh Sar area and their significance with respect to the Kohistan tectonic anomaly. *Geological Bulletin University of Peshawar*, 18, 163-188.

A belt of dark-green volcanics along with serpentinite, peridotite, pyroxenite and greenschist marks the spatial disposition of the Indus suture zone in Allai Kohistan of Hazara division. Major and trace element analyses of selected lava samples are used to investigate geochemical variations in the Shergarh Sar Pashtu village section of the volcanic belt. The lavas are mostly glassy but occasionally show phenocrysts of plagioclase, clinopyroxene and, very rarely, brown hornblende. On the basis of normative mineralogy, two compositional groups, e.g. olivine tholeiite and quartz tholeiite, are identified. Fractionation control of the observed phenocrysts over the major and trace element distribution in the lavas is established through the solutions of chemical data in the C.M.A.S. model and conventional two-dimensional plots.

The major and trace element constraints of the studied lavas are corresponding more closely to tholeiites developed in the island arc type environments and substantiate, through a chemical comparison, the assumed prevalence of

such structure(s) in the Tethys ocean before the complete closure as proposed in the tectonic models of the Himalayan development.

S/209. Shah, M.T. & Majid, M., 1992. Petrology and chemistry of the ultramafic rocks from the Allai Kohistan section of the Indus suture zone in Hazara, Northern, Pakistan. *Acta Mineralogica Pakistanica* 6, 73-84.

Rocks of the Shergarh Sar area, a part of the Allai Kohistan are divisible into three petroectone units: (1) Kohistan Island Arc sequence, (2) Indus Suture Zone, (3) Indo-Pakistan subcontinent sequence. The Indus Suture Zone in this area comprises an elongated belt of ultramafic rocks, pillow lavas, greenschists, blueschists and metasediments that have been obducted onto the Indo-Pakistan plate. Ultramafics (clinopyroxene, peridotite and serpentinite) exhibit strong shearing or cataclasis. Clinopyroxene and olivine are the dominant primary phases and are partially or completely altered to serpentine, fibrous amphibole, chlorite, magnetite and chromite. Among serpentine, both antigorite and chrysotile of syntectonic and post tectonic behavior have been distinguished. The effects of serpentinization on the whole-rock chemistry is indicated by the release and introduction of certain elements during the process. The constituent rocks are comagmatic and probably represent a dismembered ophiolite suite.

Shergarh Sar Area, a part of the Allai Kohistan is located at the closure of the Indo-Pakistan and Kohistan island arc block. Rocks of the area are distinguished into three petroectonic units. 1-the Kohistan island arc sequence 2-the Indus mélangé zone and 3-the Indo-Pakistan subcontinent sequence. Amphibolites are the most abundant rocks exposed in the area and are considered to be a part of the southern amphibolite attributed to the metamorphic segregation processes. Mineralogically these rocks are distinguished as epidote amphibolite and garnet epidote-amphibolites. Amphibole + epidote + clinopyroxene + actinolite + chlorite+ quartz + opaque is the main mineral assemblage. Garnet occurs sporadically in these rocks. The textural features are indicative of retrogression from epidote-amphibolite to green schist facies conditions. The major and trace element constraints of these amphibolites, suggest their derivation from basic igneous parent of tholeiitic character developed in the island arc type of environment.

Key words: Petrography, amphibolites, tectonics, geochemistry, Allai Kohistan.

S/212. Shah, M.T. & Sarwar, A., 1998. Litho and stream sediments survey for gold and base metals in areas around Timargara and Samarbagh, District Dir , northern Pakistan. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 180-181.

The area of study (about 900-km²) is lying within the Kohistan arc terrane in the northern part of Pakistan. It is located immediately north of the Main Mantle Thrust (MMT) in Dir district. It has a complex geology and is mainly composed of amphibolites, metadiorites, metagabbro-norites, metagranodiorites, metagranites and metavolcanics with subordinate amount of hornblendites, ultramafites and tonalites. The area has already been investigated for preliminary geology, however, no detail geochemical investigation has been carried out for precious and base metals

mineralization. This study is mainly based on rocks and stream sediments (both pan-concentrates and -80 mesh fine fraction) geochemical survey for gold and base metals in order to delineate areas likely to contain mineralization and be worthy of follow-up work.

The area has been divided into 56 drainage cells ranging from 2-50 km² with an average density of about one site per 15 km². From each cell a pan concentrate and -80 mesh fine fraction were collected for mineralogical and geochemical studies. The visible gold as piece (>0.5mm), speck (0.5-0.3mm) and color (<0.3mm) was identified in the pan concentrates of certain streams, mainly in the north eastern and north western portion of the study area. However, no nugget of gold has been noticed in the pan-concentrates. The specks and colors are generally angular to subangular, sometime irregular to rectangular in shape and bright yellow in color. The pan concentrates are dominantly composed of magnetite whereas zircon, quartz, pyroxene, garnet, hornblende, feldspar, tourmaline, chromite and rock fragments occur as minor constituents. The floats were also examined for alteration and other geological phenomenon at each site.

Samples of Rocks and stream sediments (both pan concentrates and fine fraction) have been analyzed for Au, Ag, Cu, Zn, Pb, Co, Ni, and Cr. The geochemical data have been displayed and evaluated by considering various geostatistical methods. Geochemical maps have also been prepared on the basis of single and multi-elements consideration in order to pin point areas of most interest. These studies show that pan-concentrates have higher concentration of base metals as compared to that of fine fraction and are, therefore, silicate-bound rather than sulfide-bound in stream sediments. The higher concentration of Cu, Pb, Zn, Ni, Cr, Co and Ag could be related to the bed rock rather than to specific mineralization in the area. The anomalous gold, however, could not be directly related to the bed rock but it could possibly be related to the existence of gold-bearing mineralization, most probably in the form of quartz veins, in the north and north-eastern part of Samarbagh. Further detail geochemical survey is, therefore, recommended for follow-up in the region.

S/216. Shah, M.T. & Shervais, J.W., 1996. Mafic volcanism and the petrologic evolution of the Dir-Utror metavolcanic sequence, Kohistan arc Terrane, Northern Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 133.

The Dir-Utror volcanic series forms a NE-SW trending belt within the northwestern portion of the Kohistan island arc terrane in the western Himalayas of northern Pakistan. The Kohistan arc terrane comprises a diverse suite of volcanic, plutonic and subordinate sedimentary rocks of Late Mesozoic to Tertiary age, developed prior to and after suturing of the Indo-Pakistan and Asiatic continental blocks. The Dir-Utror volcanic series near Dir is dominated by basaltic-andesite and andesite, with subordinate basalt, high-Mg basalt, dacite, and rhyolite. Porphyritic textures are dominant in the lavas, with less common aphyric and seriate textures. Pyroclastic breccias are common locally and may represent near vent facies. Plagioclase is the dominant phenocryst in mafic to intermediate rocks, K-feldspar and quartz phenocrysts predominate in the dacites and rhyolites. Chlorite, epidote, albite and actinolite are the most common metamorphic phases; blue-green amphibole, andesine, muscovite, biotite, kaolinite, sericite, carbonate, and opaques are widespread but less abundant. Phase assemblages and chemistry suggest predominant greenschist facies metamorphism with epidote-amphibolite facies conditions attained locally.

Whole rock major element compositions define a calc-alkaline trend: CaO, FeO, MgO, TiO₂, Al₂O₃, V, Cr, Ni and Sc all decrease with increasing silica, whereas alkalis, Rb, Ba, and Y increase (Figure 1). MORB-normalized trace element concentrations show enrichment of the low-field strength incompatible elements (Ce, La, Ba, Rb, K) and deep negative Nb, P, and Ti anomalies – patterns typical of subduction related magmas. Mafic volcanic rocks plot in fields for calc-alkaline volcanics on trace element discrimination diagrams, showing that pre-existing oceanic crust is not preserved here. All rocks are LREE-enriched, with La=16-112*chondrite, La/Lu=2.6 to 9.8*chondrite, and Eu/Eu*=0.5 to 0.9 (Figure 2). Dacite and rhyolites have the lowest La/Lu ratios and highest Eu/Eu* ratios, reflecting the dominant role of plagioclase fractionation of the more mafic lavas; chondrite-normalized REE patterns for these andesites cross those of the basaltic andesites, indicating that these lavas cannot be related to a common parent.

The high proportion of mafic lavas is similar to that observed in the Aleutian arc and rules out involvement of older continental crust. The scarcity of more evolved felsic volcanics (dacite, rhyolite) can be explained by the nature of underlying crust, which consists of accreted intra-oceanic arc volcanic and plutonic rocks, and is mafic relative to normal continental margins. Andesites with high La, La/Lu, K₂O, and Rb may be crustal melts. The REE pattern for some andesites cross the chondrite-normalized patterns of dacites and rhyolites, showing that these rocks cannot be related by fractional crystallization, assimilation, or magma-mixing. The REE systematics of these andesites are compatible with an origin by crustal anatexis, leaving a refractory residue mineralogically similar to high pressure mafic and ultramafic granulites of the Jijal Complex. We suggest that the garnet-rich granulites of the Jijal Complex represent the restites formed during this crustal melting.

S/217. Shah, M.T. & Shervais, J.W., 1997. Oxygen isotope geochemistry of the Dir metavolcanic sequence and associated copper mineralization in Kohistan arc terrane, northern Pakistan. *The Nucleus* 34, 49-55.

Dir metavolcanic sequence constitutes a northeast southwest trending belt within the northwestern portion of the Kohistan arc terrane. This sequence is dominantly composed of basaltic-andesite and andesite with subordinate basalts, dacite, rhyolite and pyroclastic breccia. Copper mineralization in the Dir area is mainly confined to the quartz veins and associated hydrothermally altered metavolcanics. Chalcopyrite is the main copper-bearing phase with subordinate amount of bornite, chalcocite, covellite, malachite and azurite in both mineralized quartz veins and associated mineralized metavolcanics.

Both mineralized metavolcanics and mineralized quartz veins have high $\delta^{18}\text{O}$ signature. This suggest the involvement of isotopically heavy ore forming fluid in the zonation and copper mineralization in these volcanics. This fluid has the estimated $\delta^{18}\text{O}$ isotopic composition of 5.1 per million which could be the magmatic water introduced by the granodiorite or diorite intrusion below the metavolcanic sequence.

Key words: Geochemistry, oxygen isotope, metavolcanics, copper mineralization, Kohistan arc.

S/218. Shah, M.T. & Shervais, J.W., 1999. The Dir-Utror metavolcanic sequence, Kohistan arc terrane, northern Pakistan. *Journal of Asian Earth Sciences* 17, 459-475.

The Dir-Utror volcanic series forms a NE-SW trending belt within the northwestern portion of the Kohistan island arc terrane in the western Himalayas of northern Pakistan. The Kohistan arc terrane comprises a diverse suite of volcanic, plutonic, and subordinate sedimentary rocks of late Mesozoic to Tertiary age, developed prior to and after suturing of the Indo-Pakistan and Asiatic continental blocks. The Dir-Utror volcanic series near Dir is dominated by basaltic-andesite and andesite, with subordinate basalt, high-MgO basalt, dacite and rhyolite. Porphyritic textures are dominant, with less common aphyric and seriate textures. Plagioclase is the dominant phenocryst in mafic to intermediate rocks, K-feldspar and quartz phenocrysts predominate in the dacites and rhyolites. Chlorite, epidote, albite, and actinolite are the most common metamorphic phases; blue-green amphibole, andesine, muscovite, biotite, kaolinite, sericite, carbonate, and opaques are widespread but less abundant. Phase assemblages and chemistry suggest predominant greenschist facies metamorphism with epidote-amphibolite facies conditions attained locally.

Whole rock major element composition define a calc-alkaline trend: CaO, FeO, MgO, TiO_2 , Al_2O_3 , V, Cr, Ni, and Sc all decrease with increasing silica, whereas alkalis, Rb, Ba, and Y increase. MORB-normalized trace element concentrations show enrichment of the low-field strength incompatible elements (Ce, La, Ba, Rb, K) and deep negative Nb, P, and Ti anomalies-patterns typical of subduction related magmas. Mafic volcanic rocks plot in fields for calc-alkaline volcanics on trace element discrimination diagrams, showing that pre-existing oceanic crust is not preserved here. All rocks are LREE-enriched, with $\text{La}=16\text{-}112 \times \text{chondrite}$, $\text{La/Lu}=2.6\text{-}9.8 \times \text{chondrite}$, $\text{Eu/Eu}^*=0.5\text{-}0.9$. Dacites and rhyolites have the lowest La/Lu and Eu/Eu* ratios, reflecting the dominant role of plagioclase fractionation in their formation. Some andesites have La/Lu ratios which are too high to result from fractionation of the more mafic lavas; chondrite-normalized REE patterns for these andesites cross those of the basaltic andesites, indication that these lavas cannot be related to a common parent.

The high proportion of mafic lavas rules out older continental crust as the main source of the volcanic rocks. The scarcity of more evolved felsic volcanics (dacite, rhyolite) can be explained by the nature of the underlying crust, which consist of accreted inter-oceanic arc volcanic and plutonic rocks, and is mafic relative to normal continental margins. Andesites with high La, La/Lu, K_2O , and Rb may be crustal melts; we suggest that garnet-rich high-pressure granulites similar to those exposed in the Jijal complex may be restites formed during partial melting of the crust.

S/219. Shah, M.T., Shervais, J.W. & Ikramuddin, M., 1991. Geochemistry of metavolcanics and associated Cu-mineralization in the Dir area of the Kohistan island arc, N. Pakistan. *Geological Society America, Abstract with Programs, Annual Meeting, Sanfransico, California.*

Key words: Mineralogy, metavolcanics, geochemistry, copper mineralization, Kohistan island arc, Dir.

S/220. Shah, M.T., Shervais, J.W. & Ikramuddin, M., 1994. The Dir meta-volcanic sequence: Calcalkaline magmatism in the Kohistan arc terrane, northern Pakistan. Geological Bulletin, University of Peshawar 27, 9-27.

A variably deformed and metamorphosed NE-SW trending belt of Dir metavolcanic sequence is exposed within the north-western portion of the Kohistan arc terrane. The sequence is mainly composed of massive and sheared volcanics and pyroclastic breccia. The petrochemical indices suggest that they are dominantly basaltic-andesite and andesite with subordinate basalt, dacite and rhyolite in composition.

Whole rock major element compositions define a calc-alkaline trend: CaO, FeO, MgO, TiO₂, Al₂O₃, V, Cr, Ni and Sc all decrease with increasing silica, whereas alkalis Rb, Ba, and Y increase. Mafic to intermediate volcanic rocks show calc-alkaline affinities on petrochemical diagrams. Chondrite-normalized REE patterns are LREE-enriched. Dacites and rhyolites have the lowest La/Lu ratios and highest Eu /Eu* ratios, reflecting the dominant role of plagioclase fractionation in their formation. MORB-normalized spider diagrams show progressive enrichment of the low-field strength incompatible elements (Ce, La, Ba, Rb, K) and a distinct negative Nb anomaly; patterns typical of subduction related magmas.

It is suggested that the high-Mg basalt of the Dir area is primitive in nature and could be the representative of the primary magnesian liquid formed by the partial melting of mantle wedge at the base of the Kohistan arc terrane. This liquid may have fractionated the other members of the sequence especially low magnesia basalt and basaltic-andesite.

Key words: Calcalkaline magmatism, Kohistan island arc, Dir.

S/221. Shah, M.T., Thorpe, R.I. & Siddique, S.A., 1992. Lead isotope signature of the Proterozoic sediment-hosted base metal deposits at the margin of the Indian plate in Besham area, northern Pakistan. Geological Bulletin, University of Peshawar 25, 59-65.

Proterozoic base metal deposits in the rocks of the Indian plate occur along its northern margin at the Pazang and Lahor properties near Besham. These are stratiform exhalative type deposits, which are highly deformed and regionally metamorphosed. Lead isotope studies were carried out on these deposits. Lead isotope ratio yield model ages of 2120-2199 Ma (Proterozoic) for both the Pazang and Lahor deposits. The assumed minimum age of mineralization is 2077 Ma, as suggested by the secondary isochron. These deposits are more primitive in terms of age and have lower μ values relative to the well-known sediment-hosted deposits elsewhere in the world. The non-radiogenic isotopic composition and the homogeneity of the ore lead in both Pazang and Lahor ores suggest a well-mixed common source and similar processes for the formation of these ores.

S/222. Shah, M.Y., 1997. Gold-silver and base metal prospect south of Skardu and part of northern Deosai Plateau, District Skardu, Northern Pakistan. Abstracts, National Symposium on Economic Geology of Pakistan, Islamabad, 1p.

A cost effective geochemical exploration methodology based on panned concentrate and minus 80 mesh samples from contiguous measured drainage cells in south of Skardu. Northern Pakistan have established an area of 613 sq. kms as highly potential target for occurrence of precious and base metals. Based on visual gold counts in the panned concentrate samples and supported by a range of chemical analyses of pan con. and minus 80 mesh samples. a total of 64 anomalous values for gold, silver, copper, lead, zinc, cobalt, bismuth and nickel has been evolved above the threshold values already set for Northern Areas, in individual drainage cell areas ranging from 6-54 sq. kms. Field observations of the alteration types, prevailing mineralization pattern and chemical analyses of a few outcrop chip samples in the prospect area also provide terra firma for detailed exploration to locate source rock/s for precious and base metals.

Key words: Geochemistry, gold, silver, base metals, Skardu, Deosai.

S/228. Shah, S. & Khan, M.S., 2000. Structure, stratigraphy and statistical studies of the Siwalik group of an area between Kotli and Mirpur, Azad Kashmir. M.Sc. Thesis, University of Peshawar, 148p.

A thick sequence of molasse sediments of the Siwalik group, exposed in part of the area between Mirpur and Kotli district of Azad Kashmir are objective of this report. Amongst the major geological aspects, stratigraphy structure, petrography and statistical analysis have been dealt in detail.

Stratigraphically these sediments, ranging in age from late Miocene to Pleistocene are divided into

I Upper Siwalik - Soan Formation (Late Pliocene to early Pleistocene).

II Middle Siwalik

(a) Dhok Pathan Formation (early to middle Pliocene)

(b) Nagri Formation (Early Pliocene)

III lower Siwalik - Chinji Formation, (Late Miocene).

The Siwalik group comprises sandstone, shale, and conglomerate. The Chinji Formation is composed of reddish shale and subordinate sandstone beds. In the Nagri Formation Sandstone is predominant with occasional shale beds. The Dhok Pathan Formation is marked by alternating sandstone and clay bed.

Structurally the area is folded into six anticlines and synclines with same trend of fold axis. These folds are of open type. Brief petrographic study show that sandstone comprises of quartz, feldspar, mica, calcite, hornblend, rock fragments, and minor amounts of apatite garnet, zircon, chlorite, sphene and ore. Kyanite and staurolite are other rare mineral. Sieve analyses of sixteen samples Indicates that dominant clastic fraction in medium to fine moderately sorted, positively skewed and steeply peaked. Average values of various statistical measures obtained are:

Sorting	Skewness	Kurtosis	Mean
0.968	0.246	1.076	2.437

There is no systematic horizontal or vertical variation in different statistical measures but present a rather zigzag pattern which indicates that the material of variable size was brought to the basin between each cycle.

S/232. Shah, S.H., Khan, K.S.A., Khan, N.A. & Khan, M.S.Z., 1987. Geology and mineral investigation of the Thor quadrangle (Topographic Map, 43-E/15; Scale, 1:50,000), Diamir district, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release No. 289, 21p.

The Thor quadrangle lies within the southern portion of the Kohistan island arc sequence, which is bounded by the two megashears, the Main Mantle Thrust (MMT) towards the south and the Main Karakoram Thrust (MKT) towards north. The MMT zone, lies a few kilometres south of this quadrangle (out of map). The major lithological zones within the quadrangle include the southern amphibolite belt (Kamila amphibolites), the pyroxene granulites, the Thurlu ultramafics and Kohistan granodiorite. The Kamila amphibolites, with both banded and massive varieties, trending almost east-west: with southward dips, have sporadic granitoid intrusions related to the Kohistan granodiorite. These granitoid intrusions of both massive and gneissic texture, range in size from small pockets to that of stocks. The pyroxene granulite belt of noritic composition, degranulitized in its southern portion at its contact with the Kamila amphibolites, is believed to have been crystallized from a tholeiitic magma in a continental margin or island arc location, metamorphosed at a depth of more than 40 kms and finally tectonically emplaced in its present position as remobilized crystalline material. The degranulitized portion consists of plagioclase, hornblende, biotite and quartz, formed as a result of the retrograde metamorphism of the previous noritic complex. A small oval - shaped ultramafic body, mainly composed of dunite, troctolite and peridotite with basic dykes, has been tectonically emplaced within the pyroxene granulites after the main metamorphism during the collision of the Indian - Asian landmasses, but before the two uplifted to their present positions. This ultramafic suite is believed to represent a portion of oceanic crust and upper mantle. A syncline trending NE-SW, is present within the pyroxenite granulite. Small exposures of buff coloured micaceous and silty clay are locally present on both banks of the Indus River.

The ultramafic suites although favourable for crystallization and segregation of metallic minerals, because of composition and localized stratiform nature, are almost devoid of any significant mineralization.

S/233. Shah, S.H. & Khan, N.A., 1999. Geochemistry of sulphide bearing zones in Shigar-Skardu area, Skardu District, Baltistan. Geological Survey of Pakistan, Information Release 691.

Key words: Geochemistry, sulphide, Shigar-Skardu.

S/234. Shah, S.H., Khan, N.A., & Khan, M.S.Z., 1987. Geology, geochemistry and mineral investigation of the Skardu quadrangle (43 M/11), Baltistan district, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 290.

Regional geological mapping at the scale of 1:50000, of the Skardu - Shigar area was carried out during the field season 1983-84 as a part of the geological Survey of Pakistan's continuing programme of regional geological mapping of Pakistan, and particularly of the Northern Areas.

The Skardu - Shiga area, covered by topographic sheet 43-M/11 is underlain by the rocks of the Katzarh Formation, the Greenstone complex, the Yasin group, the Burj-La Formation, basic complex, the Deosai volcanics, the Ladakh intrusives, and the unconsolidated deposits of moraines, terrace and recent alluvium & sand dunes.

The Katzarh Formation of Early Cretaceous age consists of various grade schists, phyllites, slates and shale. The greenstone complex of Early Cretaceous age consists mainly of gneiss, marble schist and green tuffaceous slate, intruded by various mafic and intermediate igneous rocks. The Yasin group of Early Cretaceous age consist of massive, dolomitic limestone, limestone, quartzite, and carbonate schists and shale. The Burj-La formation of Late Cretaceous age consist of black slate, phyllites, tuffaceousu slate, argillaceous breccia. The Basic complex of Cretaceous – Eocene age consists of amphibolite, hornblendite, pyroxenite, uralite gabbro, diorite and schists. The Deosai volcanics of Late Cretaceous age consist of green andesite and andesite porphyry, dacite and dacite porphyry, rhyolite porphyry, and tuffaceousu slate. Most of the rocks are metamorphosed in low grades. The Ladakh Intrusives of Early Eocene to Miocene – Pliocene age consists of quartz diorite, diorite, granodiorite, muscovite granite, two mica granite, pegmatite and aplites. Some gabbroic and ultramafic rocks in the form of dykes are also present in places. The unconsolidated rocks in Skardu-Shigar area consists of unsorted glacial morains, river alluvium, and eolian sand deposits in the form of dunes.

The Greenstone complex has faulted contacts both with the underlying Katzarh formation and the overlying Yasin group. The Deosai volcanics are faulted against the underlying Burj-La formation. Folds and faults of varying scales of magnitude are common in the mapped area.

Copper showings in the form of crack fillings and disseminated grains are present in the Deosai volcanics, located in the Shagari Kalan Lung, Shagari Bala Lung and Irgilun Lugma. Marble bands are exposed at the base of the Greenstone complex on both banks of the Shigar River, and continued eastwards beyond the Shigar Lungma. A bed of quartzite within the yasin group is present on both banks of the Mustafabad Lungma.

Key words: Mapping, stratigraphy, Cretaceous, Miocene, Skardu quadrangle.

S/235. Shah, S.H., Khan, N.A. & Latif, M., 1986. Geology and pegmatites of the Gilgit-Jaglot-Hanuchal area, Gilgit District, Northern Areas. Geological Survey of Pakistan, Information Release 273.

A large number of pegmatites were checked physically in the field. In most cases grab, samples were taken, but channel samples of some zoned pegmatites were also collected.

The pegmatites are generally scattered but there is a large concentration of them from Parri upto Shuta along the Skardu road. In the investigated area about 1200 pegmatites have been observed, which range in dimensions from mere one centimetre stringers and veinlets to about 9 metres in thickness and from a few metres to about 175 metres in length. Pegmatites run both along and across host rocks but they mostly occur as dykes. Their general trend is east-west. The host rocks for the pegmatites are meta tuff, diorite, granodiorite, para- amphibolite, ortho-amphibolite and the meta-sedimentary schistose rocks

Most of the pegmatites are simple but some are zoned. The zoned pegmatites mostly consist of wall zone, intermediate zone and core. In some pegmatites, intermediate zone can be further subdivided into two subzones. The zones are not essentially symmetrical with each other, some heterogeneous pegmatites were also found, viz. hornblende pegmatites in Shuta area.

Most of the pegmatites are intrusive in nature whereas around Parri the recrystallized pegmatites are also developed from the acidic intrusive rocks mostly from granodiorite and aplite under the action of volatiles. Most of the pegmatites are barren, except a few in which some economically important minerals are noted, viz, microcline, biotite, beryl, radioactive mineral and amazonite. Beryl has been found in the biotite-bearing pegmatites only. Such economically important minerals are found only as surface traces in pegmatites which seem to be uneconomical except the beryl-bearing pegmatites at Konadas, Station (Sn, 13), Jalalabad (Sn.37) and amazonite-bearing pegmatites at Jaglot (Sn. 46) which are worth further exploration. Low radioactivity in some samples from Parri, Skardu road, and Jaglot area was noted which measures from 434 to 2,774 counts per hour.

Key words: Geology, pegmatites, Jaglot, Gilgit.

S/236. Shah, S.H. & Khan, R., 1998. Geology and mineral investigations of the Jaglot–Bunji quadrangle (43 I/10), Gilgit- Diamir – Skardu Districts, Northern Areas, Pakistan, Geological Survey of Pakistan, Information Release 547, 39p.

The investigated area lies towards SE corner of the Kohistan Island Arc sequence, which is bordered by the Nanga-Parbat Haramosh massif of the Indian mass, having remobilized cataclastic metamorphosed and granitized gneisses. Direct collision of the Indian mass occurred with the Eurasian mass, along the Nanga Parbat-Haramosh massif spur, thus dividing the Kohistan-Ladakh island arc in two parts -the Kohistan island arc and the Ladakh island arc. In the investigated area, the rocks of the Indian mass started subducting under the rocks of the Kohistan Island arc, during the Early Eocene, along a megashear the Main Mantle Thrust (MMT). The MMT zone, in the investigated area, generally measures 200 m -300 m in width, while in the Lichar surroundings it is truncated and disturbed by the Raikot fault and also concealed under scree. The subduction of the Indian mass under the island arc, resulted in severe tectonism, thrusting, folding, formation of a cordillera type folded mountain chain, along with profuse intrusion of subduction related granitoids in the island arc sequence.

The Cretaceous island arc volcanogenic rocks were intermixed with the Jurassic to Cretaceous flysch type intra arc metasediments with subsequent multi-phase and diversified type magmatism of granitoids in the Kohistan island arc. The first phase of this magmatism commenced in Late Cretaceous (Albian) while its third and final stage, representing a swarm of acidic dykes and pegmatites, in the Indus-Gilgit confluence area, occurred during Oligocene and even Miocene (Patterson and Windley, 1985). The earlier acidic intrusions were metamorphosed to orthogneisses. Three Himalayan orogenic episodes from Late Paleocene to Pliocene/Pleistocene caused strong diastrophism, resulting in the formation of different sets of foliation and lineation and metamorphism. Large deposit of white, saccharoidal marble is present in Thelichi area. Some metalliferous hornblendites and volcanics, mineralized pegmatites, scattered multi coloured sulphide deposits and placer gold showings, all make the investigated area economically significant.

S/239. Shah, S.H., Khan, R., Khan, N.A. & Latif, M., 1999. Geology of the Satpara quadrangle (43 M/12), Skardu District, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 689, 15p.

The Satpara quadrangle covers the Survey of Pakistan topographic sheet No. 43-M/12 and lies in the Ladakh island arc. The mapped area covers the eastern portion of the gigantic Deosai Plateau having average elevation of about 4,000m above the sea level.

The investigated area is underlain by the flysch type metasediments, the metavolcanics and the plutonics. The calcareous metasediments are exposed as small outcrops within the pelitic metasediments, and supposed to have originated as a result of isolated depositional basin environments. The unconsolidated sediments cover the valley slopes, as well as, have vast exposures over the Deosai Plateau. The intra-arc metasediments and metavolcanics, were subsequently subjected to magmatism of calc-alkaline nature. This magmatism occurred in three phases during Late Cretaceous to Miocene (Petterson and Windley, 1985). The granitoids of the investigated area, cover mostly the second phase magmatism which are subduction related and Andean type in origin.

Three Himalayan orogenic episodes from Late Paleocene to Pliocene/Pleistocene caused diastrophism and tectonism, resulting the formation of different set of foliation, and lineation. Local folding and faulting within metasediments and metavolcanics occurred, but the mapped area lacks any regional controlled megastructure. Ferruginous fault breccia, exposed at the shahtung baihk, resulted the weak zone along which iron rich solutions impregnated the countryrock volcanics. However, iron (Fe_2O_3) content is surprisingly low, from 5.75% to 7.75%.

The sulphide showing at the Shikar Nala mouth, contain stringers, small pods and thin veinlets having mineralization of pyrite, chalcopyrite and manganese dendrites, Such sulphide mineralization is sparse, scattered and as low percentage by volume in the Deosai volcanics, These factors make it uneconomical. Small marble exposures are located in the remote and unapproachable areas, which make it uneconomical due to transportation problems.

Key words: Geology, Satpara quadrangle, Skardu.

S/240. Shah, S.H. & Khan, S., 1980. Geology and geochemistry of part of Hunza area, Gilgit Agency. Geological Survey of Pakistan, Information Release 115, 44p.

Reconnaissance geological mapping and geochemical investigations were carried at 1:250000 scale during September and October, 1975 from Bulchi das to Khunjerab in the Upper Hunza Valley, lying in topographic sheets 42 L and 42 P. during this field season, the reconnaissance mapping was done mostly along the Karakoram Highway.

Two mountain ranges running approximately east-west Karakoram in the south and Hinduraj in the north. These mountain ranges consist of acidic igneous rocks viz. granite/granodiorite. The region between these ranges consists of sedimentary and metasedimentary rocks including limestone, slate, gneiss, schist and quartzite of probably Upper Carboniferous to Jurassic age. Fossils in the limestone and the slate are not common. Folding within sedimentary and metasedimentary rocks can be seen at some localities.

The contact of the Karakoram granodiorite with the Pasu slate is faulted, but with the metamorphic rocks of the Baltit group it is intrusive. The high grade metamorphic rocks garnet-mica schist, and coarsely crystalline marble, probably indicate thermodynamic regional metamorphism caused by the intrusion of the two huge silicic batholith (Karakoram & Hinduraj) composed mainly of biotite-granodiorite.

Key words: Geology, geochemistry, Hunza, Karakoram, Hinduraj.

S/241. Shah, S.H. & Shah, S.S., 1984. Geology and mineral investigation of Parri quadrangle (43 I/9), Gilgit district, Northern Areas, Pakistan. Geological Survey of Pakistan, Information Release 224.

The investigated area lies within the Kohistan island arc sequence, bordered by two megashears viz. the Main Mantle Thrust (MMT) on southern side and the Main Karakorum Thrust (MKT) on northern side. Towards eastern extremity of the quadrangle, the bedded variety of Kamila amphibolite is exposed, which was considered a part of the Salkhalas, by previous workers. The rocks of the Greenstone complex are developed on the northern periphery of the Kohistan island arc; while the Kamila amphibolite, which form the base of the arc is the product of an intraoceanic subduction in the fore-arc basin. The Nanga Parbat-Haramosh massif which lies towards southeast of the quadrangle, is largely composed of more or less intensely metamorphosed metasediments of the Salkhala formation.

The area around the Gilgit-Indus Rivers confluence is composed of hornblende granodiorite, melanocratic diorite, inclusions and xenoliths of amphibolite, hornblende para gneiss and ortho-amphibolite bodies of various dimensions. These rocks are perhaps the result of assimilation and hybridization processes occurring along the

marginal zones of the Kailas granodiorite batholith. The effects of dynamothermal metamorphism are more pronounced along the marginal zone of the batholith and resulted the formation of paragneiss and granite gneiss. Such rock types are common in the neighbouring Nanga Parbat. Tectonically, the area has been greatly disturbed which resulted a number of anticlines and synclines associated with faults. Due to proximity with the Main Mantle Thrust (MMT), the Hurban area has been severely affected by tight folding and faulting.

The intrusions of pegmatites along with the granitic and aplitic dykes and sills are quite profuse from Jalalabad along Gilgit River, and Shuta along Indus River, down streamwards upto Jaglot (out of the quadrangle). The pegmatites are mostly uneconomical, with the exception of some showings of beryl near Jalalabad alkali feldspar near Aftab camp, which may prove to be of economic significance by later detailed exploration. Significant stratified sulphide zones alongwith a gossan, have been observed in the Bilchhar and Cinnakar areas, which need further prospecting. Workable marble deposit is present in the Hurban -Shahbatot area, within the metasedimentary rocks of the Kamila amphibolite. The reserve estimation has been calculated with the following formula (Mc Kinsty, 1968, p.60). Reserves (in metric tons) = Volume in m³ x Sp. Gravity. (The specific gravity for marble taken to be 2.7).

Key words: Geology, mineralogy, Parri quadrangle, Gilgit.

S/242. Shah, S.H., Zaidi, M.M. & Shafique, M., 1986. Reconnaissance geology of Tangir–Darel–Khanbari area, Diamir district, Northern Area, Pakistan. Geological Survey of Pakistan, Records, 78.

This is a detailed mapping of some the most inaccessible area in the Kohistan terrane, namely, the valleys of Tangir, Darel and Khanbari. Theses valleys cross the boundary between the Chilas Complex and the Kohistan Batholith. The map shows that screens of metamorphosed volcaosedimentary rocks, biotite-feldspar gneisses and schists occur in a terrain mainly occupied by gabbro, olivine gabbro (minor), varieties of quartz diorites and monzonite. Field features and petrographic characteristics for the rocks are given.

Key words: Geological mapping, norite, diorite, granite, Central Kohistan, Diamir.

S/243. Shah, S.H., Zaidi, M.M. & Shafique, M., 1987. Geology of Tangir-Darel Khanbari area, Diamir District, Northern Areas, Pakistan. Geological Survey of Pakistan, Record 78.

The area contains metamorphosed volcano-sedimentary rocks and norite. The former comprise migmatized amphibolite, gneiss, schist and quartzite derived from argillaceous/ tuffaceous material. These have been intruded by mafic to felsic rocks, olivine gabbro (oldest), the diorite, quartz diorite, quartz monzonite, granodiorite dykes and felsic pegmatites. Pyroxene-quartz diorite seems to be a product of hybridization of meta-norite by quartz diorite magma. The pegmatites contain radioactive and tungsten minerals in trace amounts. There are eight tables, three maps and three cross sections.

Key words: Metavolcanics, paragneisses, Tangir, Darel, Khanbari, Chilas complex, Kohistan arc.

S/245. Shah, S.H.A., 1984a. Stratigraphic observations of laterites in Pakistan and oscillation and movement of the Eurasian and Indian Blocks. Geological Bulletin, University of Peshawar 17, 101-108.

The laterite beds in Pakistan are found in isolated zones of outcrops but are spread a wide area in the country. They can be divided stratigraphically into four age groups: Upper Devonian of Chitral district; Jurassic of Punjab and Baluchistan; Cretaceous –Paleocene of Punjab, Baluchistan and Sind; and Oligocene of Sibi. Laterites are also found as thin layers or ferrogenous coating in the Siwalik group of rocks.

The mode of formation of the laterites indicates conditions of sub-aerial weathering or oxidation. It has been observed that rocks rich in ferromagnesian minerals on oxidation gave rise to thicker beds of laterites having higher percentage of iron. Some interesting information regarding the movement of plates have been provided by these laterite layers when studied on regional scale.

The authors have described the petrography of the dolerite intrusions in the Palaeozoic formations of the Attock slate series, and the Nowshera Reef Complex.

The intrusions are in the form of lensoid sills except a few dykes in the Nowshera Reef complex. They measure from a few feet to as much as 10 feet in thickness. Mineralogically they are composed of plagioclase, pyroxene, ilmenite and Magnetite. The constant accessories are quartz, calcite, chlorite, epidote. The rare accessories are hornblende and apatite. From this study the authors have concluded that the rocks crystallised from a tholeiitic magma. Mineralogically they are the same and may be correlated to the Cretaceous ultrabasic intrusions.

S/250. Shah, S.H.A., Malik, M.A. & Ahmed, S., 1997. Neogen molasses sediments of Potwar Plateau, Pakistan their implications for petroleum generation and exploration. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. Geological Survey of Pakistan, Records 109, 42-47.

The Potwar Plateau lies in the northern Pakistan and is confined by the Kala Chitta and Margalla Hills to the north and the Salt Range to the south. It is bounded by the Jhelum River to the east and the Indus River and Kohat Plateau to the west.

The Potwar Plateau is part of the Himalayan foreland fold- and thrust-belt system formed due to the ongoing collision between the Eurasian and Indian Plates that started in Early to Middle Eocene time (Stoneley, 1974). This is the principal oil producing province of Pakistan. Oil is produced from pre-Neogene carbonates and sandstones.

The Neogene molasse sediments which are the focus of this study are represented by the Miocene Rawalpindi Group and Pliocene-Pleistocene Siwalik Group. The Neogene rocks are as thick as 6400 m (Fatmi et al., 1984). The stratigraphy of the Neogene molasse sediments has been studied extensively (Burbank and Reynolds, 1988; and Johnson et al., 1986). These sediments which comprise conglomerate, sandstone, siltstone and shale were derived from the southward advancing upthrust Himalayan mountain ranges and were deposited in a network of fluvio-deltaic system in the adjoining foredeep area. Rapid rates of sedimentation ranging from 20 to 50 cm/ 1,000 years have been established (Reynolds and Johnson, 1985).

Drilling in the Potwar Plateau has revealed abnormally high formation pressures in the Neogene molasse sediments. These abnormal pressures in the Neogene rocks are in cases as high as lithostatic. Pressure gradients above lithostatic have been reported in the Adhi area (Malick, 1979). Undercompaction and tectonic stresses have been considered the main causes of these abnormal pressures in the Potwar Plateau (Malick, 1979; Sahay and Fertl, 1988; and Kadri, 1991). But the possibility of structural deformation as being one of the causes cannot be ruled out as well. Based on the mudweight and drilling exponent data, formation pressures in the Neogene sediments increase from the north to south. In the north Potwar drilling has revealed pressure gradients in the range of 0.5 to 0.65 psi/ft. (Fig 2), whereas pressure gradients approaching lithostatic have been found in the central and eastern Potwar regions (Fig.3). These overpressured zones seem to be widely distributed in the Potwar area. They constitute severe drilling and safety hazards thereby significantly increasing drilling costs and in some cases they also have resulted in the abandonment of the wells prior to reaching the target reservoirs.

On the contrary, the Neogene molasses sediments have played a vital role in the hydrocarbon generation in the Potwar region. Maturity modeling (Fig. 4) suggest that the Neogene molasse deposits have provided the required depth of burial to bring about the maturation of the source rock to generate and expel hydrocarbon to the traps. These overpressured Neogene molasses sediments have also provided effective sealing mechanism for the entrapment of oil in the Potwar region. A major part of the Potwar oil is sealed below the Neogene molasses deposits.

S/252. Shah, S.M.A. & Wahabudin, M., 1976. Study of the waterlogged and saline land of Kafur Dehri area, N.W.F.P., M.Sc. Thesis, University of Peshawar, 41p.

This report covers field work, and comparison of data obtained by the authors with data achieved by the WAPDA during session 1974-1975. It has been established from lithologic-log of the test wells drilled in the Kafurdheri area that the sub-surface geology of this area is very complex and great variation can be expected from place to place. But generally the area is underlain by unconsolidated deposits of Quaternary age comprising of gravels, sand with silts, and clay.

The analysis of shallow-water and soil samples show that the shallow-groundwater of the area is generally of calcium-magnesium-bicarbonate type and cover about 70 percent of the total area (30,031 acres). The soils in the thesis area are mainly developed from the material contributed by the adjoining hills of Khyber Agency and are medium to fine texture with very weak to moderate

Structure. The soil salinity is localised and mainly confined to the area around Palam-dhari, Kafurdheri and Shahi Bala villages. The affected area is non-alkali-saline soil and are not supposed to present any difficulties in reclamation.

The main objective of the present work of WAPDA is to remove the constraint of water-logged and salinity, for this purpose it is proposed to remodel the present drainage system and to install about 73 tube - wells of capacity 1 - 2 cubics to the Kafur-Dheri area, so that the water table would be established at 15 feet below natural surface.

S/266. Shah, S.M.I., Raza, S.M. & Sheikh, K.A., 1985. Field Guide to the Siwalik Hominoid Sites, Potwar Plateau. Geological Survey of Pakistan, Information Release 248.

The uplift and erosion of the Himalayas during the Neogene has resulted in an extensive apron of freshwater sediments deposited in the sublatitudinal foredeep developed at the margins of the mountain front. These clastic sediments of fairly homogenous composition are generally known as the Siwalik Group. The area where they are defined and are best known is the Potwar Plateau of Pakistan.

The Siwalik rocks of the Potwar Plateau and the adjoining regions of Jammu and Himachal Pradesh have remained the focus of intensive studies for the last more than 100 years. Because of the continuity of sedimentation spanning over much of the Neogene time and for the reasons that these rock units contain diverse and important assemblage of fossil vertebrates, the Siwaliks of Pakistan are ideally suited for the collection of late Tertiary vertebrate fauna. During the past hundred years these deposits have attracted most of the celebrated vertebrate Paleontologists of the world. Although large and small mammal taxa recorded in the Siwaliks are also found in the Neogene of Africa, Europe, Central Asia and North America, but the Siwaliks are unique to provide fossiliferous strata forming long and continuous stratigraphic sequences and offer clear superposition of the fossil localities. The Siwaliks, therefore are key to the land-mammal stages of Southern Asia and subsequently the recent studies are proving to be critically important for refining the Neogene vertebrate chronology of the Old World.

Since 1973, various aspects of the geology, paleontology and paleoanthropology of the Siwaliks of Potwar Plateau have been studied by research groups from the Geological Survey of Pakistan, Peshawar University, Harvard University, Dartmouth College, Lamont-Doherty Geological Observatories, and the University of Arizona. The studies have been done in three separate areas - the Chinji-Nagri area, the Hasnot -Tatrot area, and the Khaur area. Each area contains the type-section of one or more of the classic Siwalik formations.

Material collected in Pakistan from 14 to 8 Ma B.P., greatly expanded our knowledge of this group; previously unknown parts are now represented, in particular post cranial remains which are so important in the post cranial anatomical studies and even for precise taxonomical emplacement of these species. New finds of hominoids from other parts of the world have greatly enhanced the phyletic knowledge and understanding of the stages of hominoid evolution after about 5 million years ago, prior to that time, an enormous gap still exists; i. e. the time between 8 to 4 m.y. spans this gap. Fortunately a large area in Pakistan is occupied by the continental sediments of this age.

Provided the said stock did not extinct after 8 m. y. in Pakistan; it is believed, that a thorough search in the Siwaliks, where so many reasons combine to indicate greater probability of success, will hopefully yield material so crucial to the understanding of the critical phases of hominoid evolution.

S/267. Shah, S.M.I., Siddiqui, R.A. & Talent, J.A., 1980. Geology of the eastern Khyber Agency, North Western Frontier Province. Geological Survey of Pakistan, Records 44, 31p.

Geological investigation of the eastern part of the Khyber Agency has shown that four major stratigraphic units can be identified and mapped. The youngest, the Khyber Limestone of Carboniferous to Permian age, overlies the Ali Masjid Formation of Late Devonian age. Shagai Limestone of Silurian Devonian age underlies the Ali Masjid Formation and the oldest unit is the Landi Kotal Formation of ? Ordovician-Silurian age.

All the formations have wide spread exposures in the eastern part of the map area, Detailed search for fauna indicated that sections of these formations along the Khyber highway proved barren while those of the western part of the map area are fossiliferous. This being the case the upper two formations are richly fossiliferous while the lower formations are rarely fossiliferous. Structurally the area is very complex, frequent folding followed by faulting complicates stratigraphic interpretation of the area.

Key words: Khyber Agency, stratigraphy.

S/269. Shah, S.R.A., 1990-92. Geological mapping and evaluation geotechnical properties of decorative stones of Nauseri-Muzaffarabad and Garhi Habibullah area Neelum valley, Azad Kashmir. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 1-116.

The geotechnical properties, dynamic and static test results are presented for three types of rocks ranging in age from pre-Cambrian to Permian. Attention was drawn to the different geotechnical properties of these rocks and hence, the variation in their stability as decorative stones. Comparison was made between a number of the static properties of the rocks and the geotechnical performance. The study emphasizes the importance of those properties relevant to particular application as building or decorative stones. An indication is given of the suitability of these rocks to the main construction geomaterial uses, building stones, riprap, decorative, stone, roadstone, aggregate dressing and concrete. The geotechnical properties like compressive strength, crushing strength, water absorption, water content, soundness, Abrasion resistance, Porosity and specific gravity evaluation suggest that the rocks are suitable for decorative purposes.

S/270. Shah, S.S. & Khan, S., 1970. Geology of part of Swat between Khwaza Khela and Lillunai. M.Sc. Thesis, Peshawar University.

This is a report of the geological, work, covering about 20 sq.m of Khwaza Khela area. The purpose of this work is to study the nature of the contact between the Upper Swat Hornblendic Group and the lower Swat-Buner Schistose Group of Martin et al (1962), and to study the Hornblendic Group in some detail. Most of the area is covered by the Hornblendic Group, which is classified into: -

- 1) Banded Gneisse
- 2) Amphibolite
- 3) Diorite
- 4) Minor alpine ultramafics and pegmatites

The rocks are regionally metamorphosed, hornblende and Epidote are very common minerals (along with feldspar). The schistose group is represented by:-

- 1) Green Schist
- 2) Phyllite schists
- 3) Garnet-mica schist

The Hornblende Group strikes North-East and dips North-West, whereas the Schistose Group strikes North-South. Close to the contact, variations are common in the dip and strike due to thrusting. The area is a continuation of the western part of the Himalayan mountain. Age of the Hornblende Group is so far not certain but mostly agreed upon Precambrian, while the Schistose Group is proposed to be Silluro-Devonian age.

S/271. Shah, S.Z., Muhammad, T., Shafiq, M. & Wais, M., 1997. Structure and stratigraphy of a part of Kohat Plateau, northeast of Mittha-Khel, District Karak, N.W.F.P., Pakistan. M.Sc. Thesis, Department of Geology, University of Peshawar, 53p.

The exposed rocks of the area under study range in age from Eocene to Pliocene and belong to the Chharat, Rawalpindi and Siwalik groups. The Chharat Group is represented by the Jatta Gypsum, Kuldana and Kohat formations. The Kohat Formation is unconformably overlain by the Kamli Formation of Rawalpindi Group which is in turn overlain by the Chinji and Nagri Formations of the Siwalik Group. The proposed structural model which is based on detailed field traverses shows large scale south-verging folds and a series of hinterland dipping fore thrusts and foreland dipping back thrusts, emerging from a basal decollement located within the Jatta Gypsum. The structural geometry of all these faults have resulted in the development of imbricate structure in the eastern part of the mapped area and a pop-up structure in the western part. The imbricate structure comprises of two fault-bounded horses which repeat the stratigraphic units of the area. The pop-up structure is bounded by a fore and back thrust with opposing vergence directions. The structural geometry of the area is typical of the foreland fold and thrust belt and the sequence of faulting is from interior to exterior i.e. break forward sequence of faulting.

S/273. Shahid, M., 1995. Depositional environments of the Misri Banda and Panjpir Formation, Peshawar Basin, NWFP. M.Phil. Thesis, University of Peshawar, 44p.

The Early to Late Ordovician Misri Banda Formation of Peshawar basin is an approximately 280 meters thick siliciclastic sequence of interbedded fine to medium grained quartz arenites and shales. On the basis of sandstone to shale ratios, bed thickness and characteristics, sedimentary structures, five lithofacies are recognised. These are lithofacies MB1, basal conglomerate and sandstone lithofacies; MB2 cross laminated sandstone lithofacies; MB3 medium grained quartz arenite lithofacies MB4 laminated shale lithofacies and MB5, sandstone interbedded with shale lithofacies. These lithofacies are interpreted to have been deposited in foreshore (intertidal) to shelf below the storm wave base. Lithofacies MB1 was essentially deposited on beach to foreshore environments. The lithofacies MB2 was deposited in a shoreface set up and lithofacies MB3 on foreshore. Lithofacies MB4 and MB5 were deposited in shelf environment. The forinerone in deeper and below storm wave base while the last one in a comparatively shallow set up. The deposition of these lithofacies when viewed in a chronological order indicates transgressive regressive trends of the sea at the time of their deposition.

Similarly five lithofacies were identified in about a 800 meters thick Panjpir Formation of Silurian age. These are lithofacies PF7, argillite; PF2, papery laminated shale with sandstone lensoid bodies; PF3, argillite with interbeds to sandstone; PF4, bioturbated quartz arenite and PF5, calcareous sandstone and sandy limestone with dark grey shale. These lithofacies are interpreted to have been deposited in shelf to foreshore set up. Lithofacies PFJ was deposited in shelf with partially restricted environments which prevailed up to the deposition of lithofacies PF2. However, the

environments became open and shallower during the deposition of lithofacies PF3 and PF4 which were deposited in shallow shelf and foreshore set up respectively. The deposition of lithofacies PF5, as interpreted, in restricted shelf indicates another deepening episode. The overall stratigraphic arrangements of the lithofacies of Misri Banda Formation and Panjpir Formation with MB1 the oldest and PF5 the youngest lithofacies, suggest several transgressive and regressive episodes and therefore several parasequence boundaries are identified within these formations.

S/274. Shahid, M., Tanoli, S.K., Haneef, M. & Jaswal, T.M., 1997. Lithofacies and depositional environments of Misri Banda Formation (Ordovician), Peshawar Basin, Pakistan. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p.60.

The Early to Late Ordovician Misri Banda Formation of Peshawar basin is an approximately 280 meters thick siliciclastic sequence of interbedded, fine to medium grained, quartz arenites and shales. On the basis of sandstone to shale ratios, bed thickness/geometry and sedimentary structures, five lithofacies are recognised. These are lithofacies MBI, basal conglomerate and sandstone; MB2, cross laminated sandstone; MB3, medium grained quartz arenite; MB4, laminated shale and; MB5, sandstone interbedded with shale. These lithofacies are interpreted to have been deposited in from foreshore (intertidal) to shelf environments. Lithofacies MB 1 was essentially deposited on beach to foreshore environments. The MB2 was deposited in a shoreface set up and MB3 on foreshore. Lithofacies MB4 and MB5 were deposited in shelf environment. The former one in deeper and below storm wave base while the last one in a comparatively shallow set up. Lithofacies MB2 and MB3 are repeated several times in Misri Banda Formation. The deposition and repetitions of these lithofacies, when viewed in a chronological order, indicates several transgressive/regressive trends of the sea at the time of their deposition.

About 800 meters thick Panjpir Formation (Silurian) of Peshawar basin is dominantly argillite and shale with crinoidal limestone and arenite. Five lithofacies are identified on the basis of lithology, bed thickness/geometry and sedimentary structures. These are lithofacies PFI, argillite; PF2, papery laminated shale with sandstone lensoid bodies; PF3, argillite with interbeds of sandstone; PF4, bioturbated quartz arenite and PF5, calcareous sandstone and sandy limestone with dark grey shale. These lithofacies are interpreted to have been deposited in shelf to foreshore set up. Lithofacies PFI was deposited in shelf with partially restricted environments which prevailed up to the deposition of lithofacies PF2. However, the environments became open and shallower during the deposition of lithofacies PF3 and PF4 which were deposited in shallow shelf and foreshore set up, respectively. The deposition of lithofacies PF5, as interpreted in restricted shelf, indicates another deepening episode.

S/280. Shahzad, M.S., 1992-94. Sedimentary petrology/sedimentology of early Paleocene Lockhart limestone of Changla Gali and lithostructural mapping of Barian area Hazara, North West Himalaya, Pakistan. M.Sc. Thesis, Punjab University, Lahore, 96p.

A comprehensive study of Geology and Structure of Barian area (Distt. Abbotabad) is presented with special emphasis on the sedimentology of Lockhart Limestone of Early Paleocene age. Large scale (1:21120) geological mapping of a small segment (50 square km) of Attock Hazara fold and Thrust Belt (AHFTB) of Lesser Himalaya in Barian area within the geographic coordinates: longitudes, 73° 21' 45" to 73° 25' 15": Latitude, 33° 55' to 33° 59' 30" has carried out. The project area comprises nearly 50 sq. km on both sides of the Murree-Khaira Gali road. The Murree Ayubia road passes through the area. The lithostratigraphic units range in age from Middle Jurassic Samanasuk formation to the Murree Formation of Early Miocene age. Structurally, the area is comprised of a number of major fold structures and faults. The core of the Chhumbi Anticlinorium in the extreme north west of the area comprises of M. folds with near vertical tight synclinal in folds of Lumshiwal Sandstone. At Darya Gali, there is an opposing vergence of folds across MBT (Darya Gali fault). A number of closely spaced faults together constitute the Khaira Gali Fault zone in the southeast in the core region of Chhumbi Anticlinorium. A detailed study of sedimentary petrology of Lockhart Limestone of Early Paleocene has been carried out to unravel the environment of deposition and diagenesis of the Lockhart Limestone was deposited on open shelf. It has been divided into lower wackstone and an upper packstone facies which in turn contains sixteen microfacies. However, the lower wackstone indicates lower nutrient supply due to which the biological activity was relatively at lower level. The upper packstone facies marks an increase in the supply of nutrients proliferation of biological activity.

A 35 miles long stretch of Nilum valley road, from Muzaffarabad to Jargi, has been investigated to study landslides, bridge failures, and other problems associated with this important but badly maintained road. A map showing geology on both sides of the road has been prepared and the areas, which are most susceptible to slope failure, are delineated along the road. Also the portions where retaining walls are needed have been marked. Suggestions for improving the present condition of the road are also made at the end of the paper.

S/285. Shakoor, A., 1986-88. Geology and petrology of the Eastern Chilas calc-alkaline complex in the vicinity of Chilas (District Diamar) with special emphasis on petrogenesis of the rock units. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan 105p.

A geological map of 301 sq. km. between Pain Ges Gah Helor Gah in the north of the Indus River and Thuly Gah in the south in Chilas area is presented at the scale of 1:25,000 on toposheet No's 43 E/15, 43 I/9 and 43 I/7 issued by the survey of Pakistan. Most of the project area lies in the vicinity of the north side of the eastern Chilas Complex. The exposed sequence of rocks in the project area is a part of the northern limb of the Chilas Complex, where ultramafic rocks occur in the core of the anticline and is overlain by norite, gabbro-norite and diorites. This is capped by metadiorites of Early Jurassic age which is a part of Kamila Amphibolite. Field and petrographic study show that the rocks of the Chilas Complex are formed within a separate magma chamber and igneous in nature. There is a younger silt like leuco dioritic pluton emplaced in metadiorite. The leuco diorite hosts a small ultramafic body which has probably been formed by a magmatic protrusion of ultramafic composition and is not related to ultramafic rocks in core of the Chilas Complex.

S/288. Shakoor, A., 1994. A Preliminary evaluation of landslide hazard along the Karakoram Highway, Northeastern Pakistan. In: Ahmed, R. & Sheikh, A.M. (Eds.), Geology in South Asia-- I. Proceedings of the First South Asia Geological Congress, Islamabad, 1992. Hydrocarbon Development Institute of Pakistan, Islamabad, 347-353.

The Karakoram Highway, known as the world's highest and the most difficult road ever built, is a 500 mile (800 km) long road that links Islamabad, the capital of Pakistan, to the Xinjiang Province in China. It took 25,000 workers nearly 20 years to construct the Karakoram Highway which first runs along the Indus River from Thakot to Gilgit, and then along the Hunza River to the Chinese boarder. Twenty-nine million cubic yards of rock had to be moved during the construction stage. The highway cuts across three major ranges including some other world's highest mountains, and ascends from an elevation of 5,000 ft (1,515 m) near Thakot to over 16,000 ft (4,800 m) near Khunjerab Pass at the Chinese boarder.

Landslides and other forms of slope failure have been the most serious problem along the Karakoram Highway both during and after its construction. Over 1,000 people died during the construction of this road, mostly due to landslides and rock falls. Since its opening to heavy traffic in 1979, it has seldom been free from, obstruction caused by landslides, many of which resulted in fatal accidents. The presence of a large variety of highly jointed rock types, loosely deposited glacial sediments, extremely high and steep slopes, melt and occasional occurrence of large earthquakes are the important factors that contribute to slope failures along the Karakoram Highway. Rock falls, plane failures, wedge failures, toppling slumps, debris slides, debris flows and mudflows are common along the Highway. The largest and the most devastating failures occur in the glacial deposits. Examples of these various types of slope movement are presented.

S/290. Shams, 1979-81. Lithostructural mapping of Kalapani, Kathwal, Kakul Area, District Abbottabad. M.Sc. Thesis, Punjab University, Lahore, 235p.

The project area (Kakul, Kathwal and Kalapani) lies on the western flank of the Hazara Kashmir syntaxial bend of erosional cycle is of youth stage. The weathering of chemical nature mainly aided by mechanical action of water ice in winters. The valleys are mostly 'V' shaped. On the basis of climatic conditions and other physiographic features, it is concluded that the mapped area is in 'Maritime' morphogenetic region.

The rocks of the area were deposited in the Himalayan part of Tethys geosyncline and range in age from Mesozoic to Tertiary, along with Hazara Formation of Precambrian Era. All the rocks of the project area are sedimentary in origin. The Hazara Formation however, is affectedly metamorphism. The area is interrupted by two disconformities marked by laterite, one between Samana Suk Formation and Chichali Formation and others between Kawagarh Formation and Hangu Formation.

An attempt is made to reconstruct the depositional environments of the formation in detail. For the ancient environmental analysis different factors are brought under consideration.

Petrographic analysis of the rock samples has been made to construct the ancient geological environments of deposition and is also used to determine the economic value of the rocks. The geological history of the area is constructed on the basis of detailed study of structure, tectonics, depositional environments, fossils and sedimentary structures.

The structure of the area is complex. The folds are asymmetric recumbent and overturned with their axis in NE-SW directions. The general strike of the formation is NE-SW, but may change locally. Faults are of reverse and pseudonormal type. A brief description of tectonic behaviour of each rock unit also described. The structure of the area under consideration is the result of Himalayan Orogeny.

S/293. Shams, F.A., 1961. A preliminary account of the geology of the Mansehra area, District Hazara, West Pakistan. Geological Bulletin, Punjab University 1, 57-63.

A preliminary map and a short account of the geology and the regional structures of the Mansehra area are presented. The area consists mainly of regionally metamorphosed arenaceous schists and quartzites; and granites and granite gneiss of varying age. Dolerite intrusions are common; and much of the area is covered by alluvium. Preliminary studies indicate that the older granites were emplaced as sheets and the younger granite intruded as a small cross-cutting plug-like body.

Key words: Maps, structure, metamorphism, granite, dolerites, Mansehra.

S/294. Shams, F.A., 1963a. Reaction in and around a calcareous xenolith lying within the granite-gneiss of Manglaur, Swat state West Pakistan. Geological Bulletin, Punjab University 3, 7-18.

The results of mineralogical and petrographic studies of an inclusion, lying within the Swat granite-gneiss and now composed mainly of skarns, are described in relation to the geological environment. The probable reactions that took place under the influence of the granite are discussed. It is concluded that combined thermal and metasomatic contact action must be assumed to have occurred if the present mineralogy of the xenolith with its skarns is to be accounted for.

The results of a petrographic study of a band of calcareous nodules, situated within the quartz-rich mica schists near the southern contact of the Mansehra granite, are described. Under the thermal influence of the granite, reactions and recrystallizations took place, which are further discussed.

Key words: Petrography, metamorphism, granites, Mansehra.

S/296. Shams, F.A., 1963c. An inky blue beryl from Swat State. Geological Bulletin, Punjab University 3. p31.

Some time ago, three crystals of an inky-blue mineral were sent from Swat State to the writer for identification. The mineral was quickly identified as a species of beryl but its unusual colour suggested further study. Megascopically, all the three fragments of crystal show perfect hexagonal symmetry with occasional unequal development of prism faces. The terminal faces are not present, having been broken off during extraction from the rock. The fresh interiors show traces of a whitish material, identified microscopically as quartz, zonally distributed and extinguishing simultaneously. In plane-polarised light, the beryl is markedly pleochroic from colourless to bluish. Under crossed polars a very fine cross-hatched twinning of the microcline type is seen. Also seen is a haphazard, non-uniform and patchy extinction; the areas with weaker illumination yield perfect uniaxial interference figures while the others show a distinct biaxial nature with a 2V of 10° to 15°; this feature was also noted in the green beryl (emerald) of Swat by Davies (1962). In the present example, the dual optical character may mean, either that the hexagonal symmetry is simulated by means of a fine polysynthetic twinning of aragonite type (Winchell, 1951), or that the higher symmetry originated at a higher temperature and broke down on cooling. Refractive index measurements on these crystals, in white light, gave; $w=1.607$ and $\epsilon = 1.599$ (both ± 0.001), while the majority of beryls have w values within the range 1.568 to 1.602 (Winchell, 1951). This inky-blue beryl is similar to one described by Schaller et al.

(1962), from Arizona, U. S. A., which was reported to contain an unusually high cesium content and to be low in lithium. The mineral is being further studied.

S/299. Shams, F.A., 1965a. Mineral differentiation in crenulated schists. *Geological Bulletin, Punjab University* 5, 48-50.

A kind of metamorphic differentiation of quartz and mica in crenulated schists has recently been explained by Rast (1965 p. 89-90) on the basis of migration of mica minerals towards areas of maximum flexure. On the other hand, Nicholson (1966) p. 209-210 has attributed mobility of silica towards less strained areas of the fold hinges, thus leaving behind a mica enrichment in the flanks. In addition to these minerals, silicates containing iron, magnesium and aluminium also show noteworthy behaviour. Rast (loc. cit. p. 90) has commented that "The siting of porphyroblasts containing iron, magnesium and aluminium is strongly influenced by phyllonitic minerals. The common over-growth of garnet on the limbs of flexures suggests a common nucleation on the biotite (or muscovite) of the flexures". Thus it is suggested that the crystallization of garnet, and presumably of other such basic silicates, is determined only by the pre-location of biotite etc. and that they themselves do not show any particular behaviour while the rock is suffering crenulation folding. The writer's observations are based on work in the Mansehra-Amb State areas of northern West Pakistan, do not lend support to this idea. The present note is intended to draw attention to certain interesting pieces of evidence which have a bearing on the problem. In the Mansehra-Amb State areas, regionally metamorphosed pelitic to psammitic schists had suffered refolding during a tectonic phase connected with the Himalayan orogeny; syntectonic growth and neocrystallization of garnet, staurolite and chlorite being common. Due to their somewhat equidimensional porphyroblastic nature, the pre-existing garnet crystals appear to have suffered rotation with continued growth and are mostly located near or in the crestal regions of the folds, as if the old schistosity had flowed around them. The garnet crystallization that took place during crenulation led to the growth of distinct shells around the pre-existing crystals; the shells enclose inclusions of groundmass minerals in the helicitic fashion. In addition a new generation of garnets arose within similar regions of the folds.

Key words: Schists, metamorphic rocks, differentiations.

S/300. Shams, F.A., 1965b. An occurrence of kyanite pseudomorphs after andalusite from Amb State, West Pakistan. *Mineralogical Magazine* 35, 669-670.

The Amb State area makes part of the western limb of a regional syntaxial arc of the north-western Himalayas. It consists of pelitic and psammitic schists and quartzites, intruded by granitic gneiss, while the whole area is cut sporadically by doleritic minor bodies. The highest grade of metamorphism reached by the schists is marked by almandine garnet while andalusite and cordierite-bearing hornfels are developed at the granite contact. Nothing has yet been published on this area although a preliminary account on the adjoining Mansehra area has been published (Shams, 1961). Recently, during field investigation of the aureole rocks near Choian (grid 896394 1" topographic sheet No. 43B/15, Survey of Pakistan), certain hornfels were found in which the andalusite had

suffered transformation into kyanite in such a manner that the original shape and twinning of the andalusite are remarkably well preserved. These rocks are heavy, tough and dark coloured and, in addition to pseudomorphs, consist of quartz, muscovite, biotite, garnet, and tourmaline etc. The pseudomorphs lie preferably within weak foliation planes of the rock and show rough parallelism of their longer dimensions, although all orientations are present (fig. 1). Their size varies from very tiny to as big as 2"X ~"X a., and rarely even bigger individuals are present. Their surface is generally coated with a brownish micaceous material while the freshly broken surfaces show the typical bluish colour of kyanite. Inside the pseudomorphs the kyanite blades are arranged in completely haphazard manner, minor amounts of quartz and muscovite are also present, the latter being at, least partly of alteration origin. The kyanite gave: a 1"713, 3 1"720, F 1"725 (all • measured in filtered white light), 2Va -- ~ 82 ~ sp. gr. = 3"43. The shape and the interpenetration twinning of the andalusite is so well preserved (fig. 2) that shearing stress, in the sense of Harker (1939), does not appear to have played any significant role during pseudomorphism. On the basis of field observations, it is concluded that the inversion took place when the hornfelsed meta-sediments were acted upon by confined hydrostatic pressure that had developed during the FIGS. 1 and 2 : fig. 1 (left). Sketch of a rock bearing kyanite pseudomorphs after andalusite. Note a broken crystal at the top. FIG. 2 (right). Photograph of kyanite pseudomorph after twinned and Musite expansion of the granite body. This mode of formation compares well with that of the Southern Rhodesian pseudomorphs (Workman and Cowperthwaite, 1963) and proves that Harker's theory of stress dependence of the transformation, andalusite to kyanite, is not of universal application. This inversion can take place under the influence of pure hydrostatic pressure as well.

S/303. Shams, F.A., 1967a. The petrology of some chloritoid and staurolite-bearing schists from the Mansehra-Amb State-area, Northern West Pakistan. Geological Bulletin, Punjab University 6, 1-9.

Petrographic description is given of some chloritoid and staurolite-bearing pelitic schists from the Mansehra-Amb State area, Northern West Pakistan. Textural evidence suggests possibility of the following reactions:

Petrochemistry of the rocks is discussed. The ratio FeO+MnO/FeO+MgO for the co-existing chloritoid and staurolite is 0.89 and 0.87 respectively, which suggests that there can be only a very narrow P – T range of co-existence of these minerals.

Key words: Petrology, chloritoid, schists, Amb state, Mansehra.

S/304. Shams, F.A., 1967b. A note on radiometric ages of the micas from granites of Mansehra-Amb State area, northern West Pakistan. Geological Bulletin, Punjab University 6, 89-90.

One of the controversial aspects of Himalayan geology is age of the granitic intrusions that form voluminous outcrops along almost all the Himalayan belt. Right from the beginning of geological work in the Himalayas, it was generally felt that these intrusives bodies could be grouped into two types (Pascoe, 1963:

(i) dominantly foliated calc-alkaline granites, with essential biotite and/or hornblende and subordinate muscovite, and accessory ore, garnet, apatite, tourmaline and zircon. This was called the Central Gneiss or the Himalayan Gneiss. It occurs as sheet-like bodies which form continuous outcrops over long areas and show remarkable parallelism between their strike and dip and that of the foliation of the enclosing strata, and (ii) dominantly unfoliated sodalite granites with essential muscovite, tourmaline and some-time hornblende, and subordinate biotite and accessory garnet, epidote and ore minerals. In the field, they occur as small plutons or sheet-like bodies that are rather sporadically distributed and frequently intrude the Central Gneiss.

Perusal of the literature shows that there has never been any major difference of opinion about the age of second group of granites; assuming their essentially unfoliated nature, they are believed to have been emplaced during the period of waning Himalayan orogeny, and are loosely called Tertiary granites, although as Pascoe (loc cit.) writes "the actual evidence- of such so far found is not as widespread as it was at first supposed" (p. 420). The controversy turned upon the question of the-age of the Central Gneiss. The proposed ages range from Palaeozoic (Carboniferous, Auden (1932); Infra-Triassic, Middlemiss (1896) to Tertiary (Tertiary, Hayden (1907); early Miocene, MacMahon (1833). These ideas were based on the general concepts of the writers rather than direct evidence. On record, however, is an important discovery, made by Auden (op.cit.) of a granitic pebble in the breccia at the base of the "Purple Series" of Garhwal.

Lithologically, this pebble was found to be identical to the Arwa granite, a member of the Central Gneiss, and therefore Auden claimed that the Central Gneiss cannot be younger than Carboniferous. According to Wadia (1939) there are three types of granites in Kashmir Himalayas : (i) A biotite granite, most widespread from Kashmir to Assam, (ii) A hornblende granite, less common than (i) but similar in structure and composition. It is thought to be post-Cretaceous, as it was found to be intrusive into an orbitolina limestone at the head of the Burzil valley.

No age is suggested for the biotite granite, but it is considered to be earlier than the hornblende granite; it will be pre-Cretaceous anyway, and (iii) Tourmaline granite, more recent than (i) and (ii) as it intrudes them. Misch (1949) has been concerned with the Nanga Parbat granites. He claims that the various types, as described by him and earlier recognized by Wadia (1939), have so close affinities that no real age sequence can be found. According to him the granite of Nanga Parbat is a product of syntectonic granitization while the tourmaline granites are the product of the continuation of this process in the post-tectonic period. It follows from this that the main granite is post-Cretaceous and the tourmaline granites are much younger.

S/308. Shams, F.A., 1969. The geology of the Mansehra-Amb state area, northern West Pakistan. Geological Bulletin, Punjab University 8, 1-32.

About 600 square miles of area, covering large part of Mansehra sub-division of the Hazara District and the adjoining Amb State, in northern part of the West Pakistan, has been mapped and an original geological map, on the scale of 1 inch to 1 mile has been prepared.

The area constitutes the hard crystalline core of a major syntaxial loop of the northwest Himalayas and is composed of semi-pelitic to psammitic schists and quartzites that have suffered regional metamorphism up to kyanite grade of the Barrovian type. These schists bound a large granitic complex composed of an older group of gneissic (the Susalgali gneiss) to granitoid rocks (The Mansehra granite and the andalusite-bearing granites), ranging from granite to granodiorite, and a younger group of sodic granites (The Hakale granite, Karkala granite etc.). In addition, there are a large number of aplites and pegmatites, and a few porphyry dykes are met with. Dolerites cut the entire plutonic complex and are met with as ophitic dolerites, epidiorites and amphibolites, depending upon their age of emplacement. Details of field observations and laboratory studies are given as far as the general geological aspects of the area are concerned.

S/313. Shams, F.A., 1980a. Origin of the Shangla blueschists, Swat Himalaya, Pakistan. Geological Bulletin, University of Peshawar 13, 67-70.

Chemical analyses of two metasedimentary and one meta-igneous type blueschist rocks from Swat suggest that the former type is hypersodic as compared with many of the world occurrences. The blue amphibole is crossite of

appropriate chemical composition. The rocks are believed to be of metasomatic origin, having suffered soda activity of pore fluids. A yet younger phase of soda activity originated from serpentinization of the Alpurai ultramafic mass and was responsible for growth of the albite prophyroblasts that contain helicytic trails of the blue amphibole.

The blueschist zone is taken to make a typical fossil trenchplate subduction suture in terms of theories of global tectonics. Radiometric age of muscovite from a metasedimentary blueschist type is 84 ± 1.7 m.y. or upper Coniacian, which compares suitably with other ages obtained from the region. The presence of this early Alpine subduction zone of the Swat Himalaya is taken to represent the continuation of the Indus Suture Line.

A general review is given of the mode of occurrence, lithological subdivision, mineralogical and geochemical compositions of major granitic complexes of the NW Himalayas in Pakistan. Variation and comparative studies are utilized to interpret origin and mutual relationship among the granites. It is concluded that regional granitization

leading to anatexis had been a repeated cycle in the evolution of the granitic complexes starting with the Caledonian upheaval. Dominant are the pre-Himalayan granites while true Himalayan granites are subordinate. Pegmatitic phases are important elements in correlative petrology and shows regional application of the petrogenetic scheme proposed herewith. The process of granitisation and tectonic mobilization had been active within zones of decreased pressures due to up-warping produced as a result of northwards drift of the Indo-Pak plate. Besides internal homogenization, pre-existing rock formations suffered addition and exchange of material with the environments and the mantle-derived fluids. A special lineage of this process lead to the formation of alkaline complexes. The phenomena of reversed metamorphism is explained and the status of granitic areas as thermal highs and capable of originating tectonics is presented. Comments are made on mineral potential of granitic complexes of the Himalayas. Absolute age data are utilized in support.

S/323. Shams, F.A., 1984b. Do the Dir-Swat volcanic zones indicates split in Indo-Pak plates? Abstracts, First Geological Congress, Lahore, p.72.

In the western part of the so called Kohistan Zone in Dir and Swat, there are the belts of volcanics that do not extend eastwards over the entire length of the Kohistan Zone, although most of the other lithologies do so, such as amphibolites, norites-gabbros, diorites etc. The origin of the volcanics in Western sub-zone indicates great depths reached by the subducting Indo-Pak plate, leading to fusion of rocks and generation of magma. The eastern sub-zone no such occurrence of volcanic rocks in may indicate that eastern portion of the subducting plate reached shallower depths. If true, then the Indo-Pak plate is considered to have split, with western portion reaching greater depths as compared with the eastern portion that attained shallower depths on subduction. The line of split may coincide with the Indus re-entrant and this may also explain the restricted occurrence of blueschists and the nature of obducted Jijal block. Implications are commented upon.

S/324. Shams, F.A., 1986a. The Indus-Kohistan suture zone and blueschist metamorphism in N.W. Pakistan and its implications. Abstracts, Symposium/Workshop on Plate Tectonics and Crust of Pakistan. Institute of Geology, Punjab University, Lahore, 24-25.

Blueschist metamorphism along the Indus-Kohistan Zone was discovered in 1971 (Shams, 1972) from Swat Himalayas, while many more occurrences are now known from other parts of IKS-IS-ITS zone of the Himalayas. This unique phenomenon is believed to confirm the activity of a subduction zone. Although many plate tectonic models have been proposed regarding the origin of the Himalayas and many sutures have been suggested in northern Pakistan yet petro-structural importance of the blueschists have not been well recognized so far. It is noteworthy that such rocks have not been discovered from the Karakorum (or Northern) Thrust zone or from the Main Boundary Thrust (MBT) which has been claimed as a Palaeozoic suture recently (Nawaz and Ghazanfar, Abs. 24). This may mean that blueschist metamorphic conditions were not prevalent along these tectonic zones. On the other hand, Permian absolute ages from Chilas and Dras (in Kashmir) basics hint towards rift status of the IKS-IS, comparable in age to the Panjal rift that is referred generally to Hercynian epirogenic movements.

On the basis of field, petrochemical and age data, it is tempting to propose that northern Pakistan (and its geologic-tectonic extensions) represents a region of tectonic piling up of rifted longitudinal slices of Indo-Pak plate. It was only along the IS that subduction occurred while other narrow zones of longitudinal seas closed by compressional movements. The 1KB (and IS~ITS) appears to have been reactivated during Jurassic-Cretaceous, like the MBT which is now claimed being reactivated. Although the sequence of closure of various sutures is disputed and views differ even diametrically yet the subduction-zone status of the 1KB-IS-ITS is accepted by all. Therefore, the principle of pregradation of tectonic sutures southwards is not violated even in view of complex history of evolution of orogens North of the Indo-Pak plate. Various evidence and views are critically reviewed.

The dolerite members of the basic minor intrusives, of the Mansehra-Amb State Area, have been subjected to detailed petrographic and mineralogical investigations. In addition to modal variation of various constituent minerals, pyroxene minerals have been studied to understand their relationship in co-existence. The chemical nature of the dolerites and their trend in mineralogical phase variations are comparable to those of the well known tholeiitic provinces of the world. An outstanding feature of pyroxenes of these dolerites is that their maximum magnesian content is higher than most of the known cases of similar origin.

This is the first detailed study of dolerites of the Mansehra-Amb State Area.

S/341. Shams, F.A., Jones, G.C. & Kempe, D.R.C., 1980. Blueschists from Topsin, Swat District, NW Pakistan. *Mineralogical Magazine* 43, 941-942.

BLUESCHIST rocks, the first to be found in Pakistan, were reported by Shams (1972) from near Topsin (34° 53.5' N.; 72° 34-5' E.) and also by Desio (1977) from Shangla, a nearby locality also in Swat District, northern Pakistan. Recently, further occurrences were reported from the area by Tahirkheli (1979). The rocks form part of the so-called Lower Swat-Buner Schistose Group of Palaeozoic age (Martin *et al.*, 1962). To the north the blueschists are bounded by an amphibolite zone which is succeeded by a basic complex, considered to have suffered regional metamorphism up to the granulite facies (Jan and Kempe, 1973; Jan, 1979a, b). On the north-east is an alpine-type serpentinite mass thought to be a tectonically emplaced block (Jan, 1979c). Phyllite and quartzose mica schists outcrop to the east and

west, also belonging to the Lower Swat-Buner Schistose Group. To the southwest, the blueschist rock body thins out and disappears under alluvial cover. A major regional thrust immediately to the north of the Schistose Group, the so-called Patan Line, has been accepted as marking the edge of the subduction zone related to the suturing of the colliding Indian and Eurasian lithospheric plates (Desio, 1977). This thrust has since been renamed the Main Mantle Thrust by Tahirkheli *et al.* (1979), who regard it as the zone of obduction of the basic complex (the Kohistan Sequence) on to the Indian plate. This has increased the importance of the discovery of the blueschists and warrants an account of their petrology. One type of rock (14348; Table I) is schistose, greenish grey in colour, and strongly foliated with shiny, slickensided surfaces. The blue amphibole is associated with micaceous folia, along with quartz, albite, muscovite, garnet, chlorite, epidote and traces of tourmaline, rutile, sphene and apatite. A younger phase of albite (0.03% CaO) forms porphyroblasts which contain trails of matrix minerals as well as of the blue amphibole. The other type of rock (14363) is a heterogeneous, dark bluish black metadolerite, variously composed of a granular aggregate of epidote, chlorite, garnet, quartz, and minor sphene and rutile, with blue amphibole forming clusters of large crystals. The chemical compositions of the two rock types are given in Table I, along with their amphibole compositions and structural formulae. Plotting of the amphibole compositions in the $Mg/(Mg + Fe^{2+})$ versus $Fe^{3+}/(Fe^{3+} + Al^{VI})$ diagram (fig. 1) for the glaucophane-riebeckite group shows them to be crossites comparing closely with four compositions from Deer *et al.* (1963). Thus, the blueschist rocks from Topsis illustrate typical assemblages such as are taken to mark plate subduction or obduction zones in fold mountain belts (Ernst, ~1975), as in the Himalayas (cf. Farah and DeJong, 1979). Their discovery shows that the anomalous status attributed to the Himalayas as collision-type mountains lacking blueschist metamorphism (Powell and Conaghan, 1973) is no longer applicable.

Key words: Blueschists, geochemistry, mineral chemistry, Swat. .

S/342. Shams, F.A. & Mahmood, A., 1984. Plate-tectonic model for northern Pakistan and mineralization regims. Abstracts First Pakistan Geological Congress, Lahore, p.73.

Key words: Plate tectonics, mineralization.

S/343. Shams, F.A., Mahmood, A., Mirza, K.J., Mirza, Z.A., Ahmad, Z.A. & Siddiqui, M.A., 1983. Petrology of Shamozaï area, District Dir and Swat NW Pakistan. *Kashmir Journal of Geology* 1, 55-60.

The first detailed description of the Shamozaï area, districts Dir and Swat is given on the basis of 1: 10,000 mapping of about 206 km² North of the River Swat and including Southern edges of the Hornblende Complex, Kohistan Zone. Petrographic and mineralogical details of various units are given. The structural features of the area and problems of metamorphism are briefly discussed.

Key words: Petrography, metamorphism, Shamozaï, Swat.

The granitic complex of the Mansehra-Amb State area is composed of an older group of granitic gneisses and granitoid granites, and a younger group of tourmaline-bearing granites; in addition, a large number of aplitic and porphyry bodies are also associated. Representative specimens of each rock type have been analysed chemically and the petrochemical data is interpreted in conjunction with the results of field and petrographic investigations.

Key words: Petrography, chemistry, granites, Amb, Mansehra.

S/346. Shams, F.A. & Rehman, F., 1967. An estimation of temperatures of formation of some granitic rocks of the Mansehra-Amb state area, Northern West Pakistan, and its bearing on their petrogenesis. *Geological Bulletin, Punjab University* 6, 39-43.

Temperatures of formation of some granitic rock of the Mansehra-Amb State area have been estimated on the basis of mineralogical reactions and transformations, and by Barth's method of two-feldspar geothermometry. The estimated temperatures range from 580°C to 670°C and therefore, are in the range of granitic magmas both as products of differentiation as well as that of anataxis.

Key words: Temperature estimation, chemistry, granites, Amb, Mansehra.

Field evidence of metasomatism of the metamorphic rocks had the contact with a facies of the Mansehra granite has been followed with laboratory investigations and the results are discussed.

Key words: Metasomatism, Mansehra granites.

S/348. Shams, F.A. & Rehman, F., 1973. A note on copper mineralization near Baldher, Haripur, District Hazara, North West Frontier Province, Pakistan. *Geological Bulletin, Punjab University* 10, 95-96.

Rare copper staining of the Hazara Slates has been known for some time but only in 1971 worth- while zone of mineralization was located near Baldher (Long. 73°6'; Lat. 33°59') about 9 miles N-E of Haripur (Fig. 1). The place was visited by authors in April, 1972. The mineralized zone represents a belt of fault breccia in the Hazara Slate Formation of Palaeozoic age. The latter are represented by khaki to steel grey coloured fine-grained slates that texturally show a status near to phyllites. Thin bands of greenish and purplish slates are sporadically present. Mineralogically, these are composed of varying proportions of quartz, muscovite, bleached biotite, chlorite, feldspar, tourmaline and ore grains etc. No detailed account of petrography of these rocks is available in literature, nevertheless, it is of no direct bearing to present problem in its restricted sense.

The fault breccia zones are recognisable due to the presence of rock rubble and conspicuous ochery colour of limonite. The angular rock fragments are strongly fractured and stained by limonite while the central portion of the breccia zone is occupied by greyish white, coarse quartz-rich material; copper mineralization is generally associated with the latter rocks. In thin section, the quartz rich breccia-zone rocks show strong cataclastic texture, composed of large strained quartz grains bordered by fine-grained strain free quartz. Wherever fractures run through the rock, quartz shows growth outward from its margins; the fractures themselves are generally healed by limonite. In addition to dominant quartz, irregularly distributed angular fragments of slate are present, which show a weak preferred orientation in specimens sampled near walls of the breccia zones. General coarsening of the rock fragments along fractures running through them is frequently seen. Such fractures, both in quartz-rich areas as well as in rock fragments, are quartz grains; occasionally intergranular spaces occasionally filled by bright green malachite, lined as well carry malachite. 111 frequent cases, galena outwardly by limonite is associated although it shows tendency to occur separately from copper mineralized areas of the breccia zone rocks.

The elemental copper content of 5 representative specimens ranges from 0.34% to 2.35% (determined by dithizone method). The primary copper mineral is chalcopyrite which alters to cuprite to malachite. Pyrrhotite is generally associated and makes veins and bands that contains tiny chalcopyrite grains. The chalcopyrite areas show boxwork alteration to reddish limonite with a thin marginal zone of pyrrhotite around chalcopyrite.

The malachite is associated with ore minerals in such a manner that its thin veins appear issuing from alteration zones and penetrating the host material. The malachite preferably fills openings in slate fragments parallel to foliation and fractures in large It appears that chalcopyrite is the primary ore and its content will increase with depth, as has been supported by exploratory digging to a vertical depth of about 10 feet. Further work is in progress.

S/351. Sharma, K.K., 1991. Geology and geodynamic evolution of the Himalayan collision zone: a synthesis. *Physics and Chemistry of the Earth* 18, 431-439.

The great mountain ranges of the Himalaya and the Karakoram and the highest plateau of Tibet are the earth's unique features which according to general consensus came into being due to the successive accretions of various isolated continental and arc terranes with the converging Indian and Eurasian land masses during Late Mesozoic-Early Tertiary. The regions which were terracognita till seventies aroused global interest to generate field and laboratory data for the better understanding the geological history and the geodynamic evolution of these spectacular features. The data generated in the past two decades suggest that four major terranes Kun-lun, Qiangtang, Lhasa and Himalaya have accreted successively with one another along Litian-Jinsha suture, Banggong-Nujiang suture and Indus-Zangbo suture, respectively (see Inset Map-1 of the compiled geological map). More detailed studies of these collision zones are likely to provide information to reconstruct the chronology of various events, as has been possible to some extent in the case of the Himalayan collision zone. A number of micro-terranes, such as the Kohistan island arc, the Ladakh island arc and the Gangdise continental arc, evolved and sutured in different stages and at different times, resulting in the Himalayan collision zone. The information on other collision zones occurring to the north of this zone is also increasing and a multi-disciplinary effort by Chinese (Academia Sinica) and British (Royal Society London) scientists during June, 1985 (Chang Chengfa et al., 1988) has further added to our knowledge of these collision zones. This attempt followed the successful endeavour of the Chinese and French scientists who carried out joint studies during 1981 in the southern Tibetan region of the Lhasa sector of the Himalayan collision zone. In the classical concept of the plate tectonics and orogeny, the rifting of the continental lithosphere initiates under a hot convecting column which ultimately drives the rifted continent blocks apart with opening of the sea and creation of the oceanic crust in-between the separated blocks. At some stage of its growth, the oceanic crust starts subducting to give rise to an island arc or a continental arc depending upon Mariana or Chilean type subduction.

S/357. Sheikh, A.A., 1988-90. Geological mapping and economic geology of the metamorphic rocks (Gokdarra-Ghaligai), Swat District. M.Sc. Thesis, Punjab University, Lahore, 84p.

The detailed geological map of the project area has been prepared. The project area has been mapped on a scale 1" = 12500' = 12,500'. This thesis consists of two sections. Section No.1 deals with the general geology of the project area. Introduction, Physiography, Structural Geology & Tectonics and the lithologic units of the project area have been discussed in this part. In Section No.2, Petrography, Chemical analysis, Petrogenesis, Discussion on Petrogenesis, Economic Geology and SOME THING, NEW ONE (Dolomite/Wollastonite Skarn) in the project area is discussed. The project area is consisting upon the metasedimentary and metamorphic rocks which lie in the Higher Himalaya Crystallines of the MMT Zone. The rock units belong to Lower Swat Buner Schistose Group and are of Lower Palaeozoic age.

Key words: Mapping, metamorphic rocks, economic geology, Swat.

S/358. Sheikh, A.M., 1983-85. Litho-structural studies of Fitni-Bhirina-Paniali and Haddo Bandi Area, District Mansehra. M.Sc. Thesis, Punjab University, Lahore, 162p.

There is a specific relationship between the geological structures, landforms and the climate. This relationship can be worked out by qualitative as well as quantitative analysis of the topographic map. The most commonly exposed lithologies in the project area are schists from chlorite to garnet grade, Susalgali granite gneiss, Mansehra granite, quartzites and hornfels. The rocks of the project area have been classified into nine lithologic units for the sake of mapping purposes at a scale of 9.2 Cm. to a kilometer on 5.8 inch to a mile. The area is deformed by different deformation phases, among which three are recognized on mesoscopic as well as microscopic scale and area is characterized by heterogeneous deformation. The rocks have been folded isoclinally and later being refolded into open folds. The area lies in the zone of brittle deformation and show extensive fracturing instead of folding. Mesoscopic and microscopic deformational features are well developed in the area. The rocks exhibit effects of polymetamorphism. The thermal metamorphism is superimposed on the regional metamorphism.

S/359. Sheikh, I.A., 1973-74. Engineering geology of Muzaffarabad-Tithwal, Azad Kashmir. M.Sc. Thesis, Punjab University, Lahore.

Field mapping of about 200 miles² of the Neelum Valley area from Muzaffarabad area to Jari have been done on a scale of 1"=0.263 miles. Nauseri granite gneiss has been identified and mapped for the first time. A description of

the location, aerial extent, contact relationships, lithology and petrography, structural features and engineering behavior of each of the rock types shown on the map is given. This is followed by separate chapter on the structure of the area.

A detailed study of the existing Muzaffarabad-Tithwal road has been made with respect to its alignment and the problems associated with it such as those of landsliding, bridge instability and poor drainage. The rocks exposed at the proposed Nurseri bridge site have been studied and engineering tests have been performed on the samples taken. A careful study of the slopes at this site was also made. On this basis the proposed site has been evaluated and its feasibility is worked out. In the end a summary of the whole study recommendations is given.

(Eds.), Paleomagnetism of Collision Belts. Geoscience Laboratory, Geological Survey of Pakistan, Islamabad, 129-141.

Magnetic polarity stratigraphy and sedimentology of the lower part of the Middle Miocene Chinji Formation at its stratotype is discussed. The area lies on the southern flank of the Soan Synclinorium, south of Chinji village between Chittaparwala section in the east, to Huch Nala section in the west, some 16 km apart along the strike. The Chinji Formation is composed dominantly of red to reddish brown siltstone and mudstone with subordinate light grayish green to gray sandstone. Two laterally continuous sand body units, namely the Rainbow Sandstone and the Obstacle Sandstone were traced in the lower part of Chinji Formation to correlate Chittapanwala section to Huch Nala section. In order to check the isochroneity of these trace units, seven short lithostratigraphic sections each 150 m thick on average, spanning over the interval bracketed by the two sandstone bodies were measured and paleomagnetic sites were chosen at an average of 7 m in each section. Magnetic reversal timelines and polarity zones in each section were established and correlated with the Chittaparwala magnetic polarity section. Reversal timelines (named T1 through T7) were traced between the Chittaparwala and Huch Nala section, i.e., 13.88 to 12.33 Ma. The Rainbow Sandstone throughout its lateral extent in the area remains within the reversal timelines T2 and T3 (13.88 to 13.46 Ma). The upper sandbody, the Obstacle Sandstone, lying about 120 m above the Rainbow Sandstone, gives a much complex history of fluvial system spanning between T4 to T7 (13.21-12.33 Ma). The sedimentary details and isochron of the Rainbow and Obstacle sandbodies indicate different channel belts and floodplain mosaic. It can be postulated that the fluvial system represented by the Rainbow sandbody was dominated by coexistence of more than one major river draining the area. The Obstacle sandbody suggests perhaps switching of the same river system westward through time. The mean sedimentation rate for the Lower Chinji Formation is 0.13 d y r . The mean rate of lateral migration of the river system w k h deposited the Obstacle sandstone is 1.7 cm/yr approximately.

S/364. Sheikh, K.M., 1985-87. Geology of Dunga Gali-Barian Area, District Abbottabda. M.Sc. Thesis, Punjab University, Lahore, 103p.

This report incorporates a comprehensive geological study of nearly 25-km² area between Dunga Gali and Barian on the Murree-Abbottabad road. The study includes stratigraphically the rock units range from Upper Jurassic to Eocene and represent the sequence of the Hazara Province of the Kohat-Potwar Basin. It is primarily a limestone-shale sequence reflecting a stable shelf facies. Structurally, the area shows the development of a few synclinoria and anticlinoria, within which a generally tight parallel to similar asymmetric to overturn style of folding predominates. A number of dip-slip-strike faults both of the normal and reverse type is present. A petrographic study of all rock units, based on fairly representative field sampling, is also present.

S/370. Sheikh, W.A., 1985-87. Geological studies of Khanspur Dewal Area with special emphasis on mineralogy and petrology. M.Sc. Thesis, Punjab University, Lahore, 94p.

This report gives an account of geological studies of Khanspur and Dewal Area with emphasis on mineralogy and petrology. The prescribed area lies to the north of Murree in extreme east of Abbottabad and southeast of Muzaffarabad. The area is approximately 56 sq. km. for which geological mapping was done on lithostratigraphic basis, at the scale of 1:10,000. The stratigraphic succession ranges from Datta Formation to Murree Formation (From Jurassic to Miocene). The lithology is mainly limestones, shales, and sandstone with intercalations of marl and clay. Extensive sampling of the rocks was done and studied afterwards in laboratory. In the Chapter of Petrography, the microscopic and megascopic studies of each formation are given. The percentage of each mineral content is also given. Sedimentary structures, tectonics and economical mineral deposits of project area have been discussed in separate chapters.

S/380. Shroder, J.F., 1984. Batura glacier terminus, 1984, Karakorum Himalaya. *Geological Bulletin, University of Peshawar* 17, 119-126.

Batura Glacier in northwest Karakorum Himalaya has received considerable attention in the past decade because of some unusual characteristics and its effects on the Karakorum Highway between China and Pakistan. Chinese glaciologists found evidence that the Batura terminus would advance in the present decades and retreat in the 1990's. The predicted advance has not begun and instead the frontal ice cliff has downwasted and the cliff above the main meltwater channel has backwasted.

Key words: Glaciers, Batura, Karakoram.

S/381. Shroder, J.F., 1989a. Geomorphic development of the western Himalayas. *Geological Bulletin, University of Peshawar* 22, 127-151.

Evolution of the drainage system of the western Himalayas was controlled by antecedence, superposition, capture, ponding, avulsion, and faulting following collision and suturing of the Kohistan-Ladakh island arc between the Indian and Eurasian Terranes. The Indus River arose sometime in the middle Tertiary from an area of eroded volcanics near Mt. Kailas in Tibet and established a course to a ancestral "Sindh estuarine" embayment about 300 km north of the present delta. Neither the old idea of a northwest-flowing "Indobrahm" river in the Himalayan foredeep, nor the newer postulate of an east-flowing ancestral diverse drainage directions. Instead the Indus River seems to have established itself along the axis of the island arc system, and in the Haramosh-Nanga Parbat area is was deflected south in an apparent sinistral sense along the Main Mantle Thrust. Subsequent reversal of motion produced a later dextral offset along the Raikot fault. The river was deflected similarly as it crosses the Kalabagh fault through the Salt Range.

Consideration of relations between uplift rates and erosion shows that the Himalayas are at least six times lower than the theoretical maximum, indicating that balance is achieved by discontinuous pulses of rapid uplift alternating with longer periods of quiescence, as well as by variable rates of channel incision and slope processes of erosion. Calculation of long-term sediment deposition in the Indian Ocean equates to a denudation rate of 0.2 mm/yr. Short-term present day rates are 1-1.8 mm/yr. Present uplift of Nanga Parbat is about 5 mm/yr. and is nearly balanced by denudation at Raikot Glacier of 4 mm/yr.

In Pleistocene at least three episodes of glacial advance left thick valley-fill sections that allow definition of Quaternary events. The early stage is indurated lower Jalipur tillites that lack clasts from Nanga Parbat and show that uplift had not yet exposed the massif. Overlying heterogeneous upper Jalipur valley-fill sedimentary rock is younger than 1-2 mm/yr and is overturned or overridden by basement faulting in places. The middle stage is two or more tills intercalated within variable sediments, including thick lacustrine deposits at Gilgit and Skardu. The last stage consists of three or more separate advances that retain moraine topography. At Nanga Parbat and several other places, transverse glaciers at this time blocked the Indus to produce prominent lake deposits. Some of these ice dams failed and produced catastrophic floods and emplacement of the Punjab erratics at the mountain front. In Holocene time numerous glacial fluctuations and surges have occurred and are being monitored. Both glacial advances and major slope failures across rivers have occurred throughout the western Himalaya in historic time and have produced large impoundments, the dams of which failed subsequently and produced catastrophic floods.

Pakistan is characterized by a highly varied geomorphological landscape. Caught up in continental collision both in the north and west, the area of Pakistan consists of 1. the Karakoram, Hindukush and Himalayan ranges in the North, 2. Suleman and Kirthar mountain range in the west and southwest, 3. Makran coastal ranges in the south along the Arabian sea, 4. Indus plain in the East, and 5. Thar desert in the southeast. Much of the plane area of the country belongs to the Indus river drainage system. This paper describes geomorphology and Quaternary sediments of the country.

S/387. Shroder, J.F. Jr., 1984a. Comparison of tectonic and metallogenic provinces of Afghanistan to Pakistan. Abstracts, First Geological Congress, Lahore, p.20.

Different ideas of tectonic and metallogenic zonation, and difficulties in communication between geologists working in Pakistan and Afghanistan over the last twenty years have limited exchange of information. Detailed work in Afghanistan shows 21 metallogenic zones with 37 associated ore districts. Also recorded are 1432 mineral resource locations classified as: (1) large and medium deposits; (2) small deposits; (3) occurrences; (4) showings; as well as 306 broadly defined mechanical mineralogical haloes. This comprehensive resource analysis was organized around the geosynclinal concepts of Russian work with metallogenesis but is herein adjusted to a plate-tectonic framework and compared to the new tectonic zonation of Pakistan. Cross-border correlation of tectonic zones and metallogenic provinces could be useful in exploration strategy in Pakistan.

S/389. Shroder, J.F., Jr., 1998. Slope failure and denudation in the western Himalaya. *Geomorphology* 26, 81-105.

Slope failures, glaciers, and rivers constitute the three main agents of denudation in the Himalaya. Failure of slopes is strongly controlled by bedrock geology, especially at plate terrane boundaries, although climatic and seismic controls of failure also occur. Slope-failure complexes in the western Himalaya studied for this report include the Pakhar, Kaghan, Nanga Parbat, and Atabad Hunza areas, with 23 different slope failures reported within all the complexes. Quantification of denudation by mass movement requires measurement of volumes and determination of timing of sediment emplacement and removal where possible, to obtain better data on recurrence intervals and total geomorphic work performed in formation of the landscape. The relation of mass movement to overall denudation by glaciers and rivers, and its role in catastrophic floods and debris entrainment is assessed.

Key words: Slope failure, denudation, Himalaya.

S/390. Shroder, J.F., Jr. & Bishop, M.P., 1995. Denudation of Nanga Parbat Himalaya, Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, ETH Zurich, Switzerland.

Conflicting ideas about cause and effect of uplift and erosion of the Himalaya require careful assessment of a variety of tectonic and isostatic uplift mechanisms, coupled with detailed studies of associated denudation. Thermobarometric and geochronologic work by others shows that uplift and unroofing of the Nanga Parbat massif along peripheral faults have accelerated through the Quaternary to over 5 mm yr⁻¹, perhaps even to twice that rate. Climate fluctuations and rapid denudation have also been suggested as a cause of decompression melting, high grade metamorphism and injection of young leucogranites. Erosion of Raikot, Buldar, Astor, Sachen, Rupal, Tarshing, Diamir, and Patro valleys is being assessed by us to determine present-day and past denudation rates. Mass movement, glacier and river erosion are regarded as the chief denudation agents, but catastrophic flood-flushing of sediments from behind multiple glacier and slope-failure dams is thought to have been an efficient and major contributing factor in several valleys as well. Erosion of the Raikot valley (8125 - 1125 m altitude; 128 km² area) on the immense north face of Nanga Parbat is being analyzed most extensively using: (1) erosion surfaces reconstructed from several surviving remnants; (2) most probable durations of erosion; (3) geomorphologic mapping of landforms, sediment transfers, and sediment stores, and (4) measurement of modern process rates. Glacial erosion in middle altitudes dominated in later Pleistocene, but perhaps less so in earlier Pleistocene, possibly before the mountain had achieved its present altitude. The Silver Saddle ice cap on an erosion surface at upper altitudes (~7500 m), and basal ice several thousand meters downslope, are cold based and relatively nonerosive. During Pleistocene colder periods this zone of reduced erosion may have extended to lower elevations than today, but the Raikot Glacier also then extended down into the Indus valley, either as a glacier out of phase with other ice expansions, or as a tributary to trunk valley ice. At present the Raikot Glacier terminus ends at ~3200 m, and little terminal moraine exists there, which suggests efficient transfer of glacial debris load to riverine transport. Below the active Raikot River has eroded a deep gorge across the Raikot Fault and into the Indus River. Present-day denudation rates of warm-based ice at the modern Raikot glacier terminus have been measured by others at ~4.6-6.9 mm yr⁻¹. Also, cosmogenic isotope exposure ages by others on nearby Indus strath terraces show incision rates of 6-8 mm yr⁻¹. Erosion-rate variation in the Raikot and other basins in late Quaternary was most probably episodic, but our time-averaged hypsometric analyses give varying average rates of 3-7 mm yr⁻¹, with an overall rate of 4-5 mm yr⁻¹ as the most consistent with the evidence. Ongoing comprehensive field measurements are expected to produce more detailed and robust measure of denudation for the entire massif.

S/391. Shorder, J.F.Jr. & Bishop, M.P., 1998. Mass movement in the Himalaya: new insights and research directions. *Geomorphology* 26, 13-35.

Ongoing studies that relate tectonics to the processes at the surface of Earth show that many more sources of information about agents of shallow denudation, such as mass movement, are required to comprehend the long term erosion that leads to deep denudation over geologic time. Mass movement in the Himalaya is scale-dependent, from

the massive extension of whole mountain ranges (gravity tectonics), through the sacking failure of single peaks, to the smallest slope failures. Generally, denudation of the Himalayan orogen begins with slope failure onto glaciers and into river valleys and continues by glacial and fluvial transport. The maximum size of stable slopes and mean angles of slope that are produced by these failures are complex and controlled by a variety of factors, including mass strength of the rocks, stress fields, angles of internal friction controlled by rock type, cohesion that includes the control of rock temperature, bulk unit weight of rock, and discontinuities. The processes of mass movement in the Himalaya have been described many times for the past two centuries. Recently, developments in a variety of fields have been introduced to assess the character of mass movement. Geomorphometry, remote sensing, digital elevation models, and geographic information system technology are revolutionizing the study of mass movement in the Himalaya.

S/392. Shroder, J.F.Jr. & Bishop, M.P., 1999. Indus to the sea: evolution of the system and Himalayan Geomorphology. In: Meadows, A. & Meadows, P. (Eds.), *The Indus River, Biodiversity, Resources Humankind*, Linnean Society of London, 231-248.

The Indus River originated more than thirty million years ago, shortly after the collision of the Indian and Eurasian plates, on the slopes of the Mt. Kailas massif, itself a remnant of debris eroded from igneous rocks produced by the collision. Thereafter the river was caught and entrained across the Ladakh and Kohistan island arcs between the rising edges of the colliding plates. Lateral motions on faults formed along the plate boundaries later caused the river to be offset significantly at several locations. As the plates continued to converge, the ancestral Indus eventually broke out to the south at the Nanga Parbat-Haramosh syntaxis. Large quantities of sediment were deposited by the river in foreland basins in front of the range; a vast braidplain was spread out between the Indus and its five tributaries in the Punjab, and the river extended its delta progressively south into the ocean. During the world-wide glacier increases of the Pleistocene, lower sea levels led to entrenchment of the lower Indus into its delta and braidplain. Resedimentation of these entrenchments after the Pleistocene allowed numerous lateral channel migrations, one of which apparently isolated Mohenjo Daro. Water withdrawals upstream now reduce sediment carried to the river mouth so much that the delta is being degraded through erosion.

The Indus sediment cascade, produced by extreme erosion rates that are among the world's highest, has progressively unroofed the range since collision and uplift. This deep exhumation was caused mainly by long term mass wasting, glaciation, and river erosion which mobilized and removed sediment from the Himalayas via the Indus River. The high mountain geomorphology, produced by fluctuating earth surface processes throughout the many climate changes of Quaternary time, is being studied actively to further our understanding of the upper and middle Indus watershed. The Batura Glacier area of Hunza, the Raikot Glacier area of Nanga Parbat, and the Baltoro Glacier area of K2 mountain are the special focus of our ongoing denudation research.

S/393. Shroder, J.F. Jr. & Bishop, M.P., 2000. Unroofing of the Nanga Parbat Himalaya. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 163-179.

The rapid erosional unroofing of the Nanga Parbat Himalaya in late Cenozoic time is thought to have initiated when the Indus River, initially flowing somewhat north and well to the west of its present location, was captured and diverted south close to the massif of today extensional structures and downfaulted topography across the Kohistan-Ladakh island arc terrane. It is hypothesized that the Nanga Parbat pop-up structure was initiated at c. 12-10 Ma, as tectonic aneurysm caused by rapid incision by the Indus River and other surface processes. Because of this subsequent rapid unroofing of the region, however, the oldest sediments to record erosion in the immediate region of Nanga Parbat are <200 ka old: most sediments and our cosmogenic and ISRL exposure dates are more than five times younger. Diverse field measurements of rate of local incision and areal denudation for mass movement, glacial, river and catastrophic floods for the past c. 55 ka are highly differential but internally replicative and externally consistent with research indicating long-term, severe denudation. Averaged rates of maximum incision at more than 15 points around the massif are $22 \text{ mm} \pm 11 \text{ mm a}^{-1}$. Late Pleistocene surface processes at Nanga Parbat were capable of erosional unroofing of the massif sufficiently vigorous to produce the pronounced relief of today.

S/395. Shroder, J.F. Jr., Bishop, M.P., Quade, J., Phillips, W. & Maston, R., 1995. Denudation of Nanga Parbat Himalaya. Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, p.15.

Recognition of rapid uplift of Nanga Parbat (8125m) has led to new understandings of associated casual mechanics of deep crustal processes in fact, it has even been suggested that denudation processes have produced rapid unroofing, decompression melting at depth, injection of Lecucogranites, and metamorphism. Thus high frequency – high magnitude earth surface processes of slope failure, glaciation, river flow, and catastrophic flooding active for only about a million years in middle to late Quaternary time may have caused these lithologic and structural effects. An international group of scholars, headed by Peter Zeitler, original discoverer of rapid uplift of Nanga Parbat, will analyse the mountain range over the next three years. The denudation research group expects to continue to use standard techniques of geomorphologic mapping, remote sensing, geographic information system, quaternary stratigraphy, and new methods of cosmogenic radionuclides dating to analyse the amounts, rates and chronology of denudation of the Nanga Parbat Himalaya through the quaternary.

S/396. Shroder, J.F., Jr., Bishop, M.P., Quade, J., Phillips, W., Nieland, P.H. & Schmidt, A.M., 1996. Dendrogeomorphology and denudation efficiency, Nanga Parbat Himalaya. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 135-136.

Denudation of the Nanga Parbat Himalaya throughout the Quaternary period has been extremely rapid, perhaps enough to produce decompression melting, injection of leucogranites and high-grade metamorphism. Elucidation of magnitude and timing of denudation provides constraints upon these bedrock processes. Denudation processes of many kinds occur on Nanga Parbat but those of chief interest here are mass movement, glaciation, rivers, and catastrophic flood flushing of sediment from ice- and slope-failure-dammed lakes. Remote sensing and geographic information system mapping and analysis of modern process distributions and measurement of rates enable establishment of contemporary sediment fluxes from which to better estimate past denudation quantities. Assessment of these past denudation amounts is constrained temporally through cosmogenic radionuclide dating, carbon-14 dating, soil development, and the principles of dendrogeomorphology. Nanga Parbat is well suited to the use of tree ring dating, mainly in its middle elevations (200-4000m), where geomorphic processes are most diverse and most active, and there coniferous and birch forests can provide standard process-event-response chronologies. Mass movement and glacial processes have affected hundreds of trees on the mountain, particularly in the Diamir, Patro, Raikot, Buldar, Astor, and Sachen valleys.

We report here our results from the Sachen and Raikot valleys where we have analyzed the distribution, timing, and volume of debris flows, several kinds of catastrophic breakout floods, glacier downwasting events, the backwasting of glacier termini, and glacial advances. These data enable better understanding of the transfer of sediment of one process-mechanics regime to another; especially the transfer efficiency of sediment from glaciers to rivers. Depending upon various topographic and geomorphic conditions, the glaciers of Nanga Parbat are moderately to highly efficient in transferring their sediment load to rivers. Raikot glacier is highly efficient, whereas Sachen glacier has a lower efficiency. Other things being equal, more efficient transfer occurs in those glacier valleys where: (1) there is a high ratio between plentiful cold-based, protective ice, and limited warm-based, erosive ice so there is not as much sediment; (2) firn-field glacier nourishment is dominant, which provides maximum ice flux; (3) debris sources and feed limited; (4) supraglacial loads are thinner; (5) outburst floods that remove sediment are more common; (6) the steep terminus zone increases sediment transfer energetics; (7) ice velocity and glacier sediment

discharge are relatively lower at the terminus; (8) there is a laterally migratory subglacial drainage portal at the terminus; (9) high meltwater discharge occurs; (10) a narrow valley occurs in the glacier terminus zone which restricts the moraine and enables its removal. Less efficient sediment transfer occurs: (1) where a low ratio occurs between the more limited cold-based, protective ice, and the more plentiful warm-based, erosive ice so that there is a significant increase in debris; (2) where ice- and snow-avalanche glacier supply predominates so that not as much total glacier ice forms; (3) where debris supply is so enhanced by ice- and snow-avalanches that fluvial regimes are overwhelmed; (4) where plentiful source slopes of mass movement and avalanche rock debris exist; (5) where there is a thicker supraglacial debris load; (6) where outburst floods are restricted; (7) in valleys with a gentler gradient, hence with less potential process-systems energetics; (8) with a fixed drainage portal at the terminus so that material accumulates in other areas; (9) with generally low meltwater discharge; and (10) in wide valleys at the glacier terminus where the ice can spread out moraine. In some cases, dendrogeomorphology in those areas of different transfer efficiencies enables determination of relative and absolute magnitudes of denudation quantities.

Dendrogeomorphology was used to study denudation in the Raikot basin in the north and south Biale debris flow basin, as well as on both sides of the terminus of highly transfer efficient Raikot glacier. The Biale basins on the West Side of the Raikot glacier have experienced catastrophic precipitation events on a ~67-year return cycle, with major tree-corroding events in 1923 and 1990. In the approximately 5000 years since the Neoglacial moraines were emplaced at the base of these basins, some 75 of these events can reasonably be expected to have occurred; less when the monsoon was restricted, more when it was dominant. It can be seen in these cases that although the debris does not leave the mountain directly because it tends to be trapped in the ablation valleys behind the lateral moraines, still it is initially mobilized into these temporary storages that are more easily removed by ice and water late. Recessional moraines of the Raikot glacier occur as thin loops of rocky debris around the front and sides of the terminus. The timing of emplacement of these landforms is defined by tree-ring succession dates and historical records. Our data on glacier velocity and supraglacial debris load proved estimates of the total volume of debris that should have been imported in the time allotted into the open space between the recessional moraine and the present terminus. That total amount of debris, less that of the remaining moraine constitutes missing debris transferred into the Raikot River and generally entirely off the mountain.

In late 1993 or early 1994, the subglacial drainage system of the Raikot glacier became blocked and stopped the Raikot river. After a number of months of restricted water discharge, a catastrophic breakout flood burst from four new portal; three on the west side and one on top of the ice near the terminus, before returning to the original portal on the west side of the terminus. This event mobilized considerable supraglacial debris at the terminus, as well as debris form along the west side of the glacier, the ablation valley, the Neoglacial (NG) and Little Ice Age (LIA) moraines, and a small portion of the most distal of the Biale debris flow sediment. All this sediment was transported into, and flushed from the mountain in, the main Raikot River that became re-established close to its original position. In aggregate our data from the Raikot basin on the huge and active north face of Nanga Parbat suggest that denudation on this portion of the mountain is highly active now and has been even more so in the past. For example, we see from our preliminary cosmogenic dates on the high older moraines of >125,000 years age, that the ancestral Raikot glacier was eight times wider and thicker than it is now. Although we are as yet uncertain about the fluctuating altitude of the cold-based/warm-based transition zone that would have controlled the cold, protective ice zone above the warmer, erosive ice zone underneath, still we can see that with the high ice activity of the recent past, a proportional scaling upwards of denudation values in the past is reasonable.

Sachen glacier on the east side of Nanga Parbat has no firm accumulation zone in direct contact with the terminus, unlike that of the huge Raikot system on the north side of Nanga Parbat, and instead is almost entirely fed by ice avalanches from high up the mountain. The lower efficiency of Sachen glacier is exemplified by the huge lateral and recessional NG and LIA moraine storages and the last glacier is maximum (LGM) in its valley. These moraines are tree-covered and deal for dendrogeomorphologic work. For example, event-response chronology shows that a minor ice advance and catastrophic breakout flood are known to have occurred on the north frontal lobe in the late 1920's but the volume of sediment moved was small. The data suggest that significant denudation from this area could only be accomplished in times of major glaciation and through major catastrophic flood flushing at those times. Otherwise sediment tends to accumulate in long term storages. In terms of the overall denudation of the Astor valley to which the Sachen valley is tributary, more efficient removal of sediment would have occurred when LGM ice was in the Astor valley below Sachen, or when large breakout floods occurred from a Sachen ice dam across the Astor river valley. In sum, facilitated by dendrogeomorphology as a part of the full analytical package being applied to this interesting problem.

S/397. Shroder, J.F., Jr. & Khan, M.S., 1990. Quaternary glaciation of Karakoram and Nanga Parbat, Himalaya. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 17-18.

Controversy and agreement between Pakistani, American and British workers on the extent and timing of Pleistocene glaciation in the western Himalaya are highlighted or resolved in our work through recognition of three main glacial stages, and several glacial stages. The early glaciation, or Shanoz stage, includes glaciated high-level erosion surfaces, the Bunthang till in Skardu and perhaps other tillites. The Jalipur tillite is glacially and tectonically indurated and deformed. We judge it evidence of an oldest glaciation and equivalent to Shanoz and Bunthang, but British workers consider it to be youngest only. The middle glaciation, or Yunz stage, includes a number of tills, perhaps had two major stages, and extended the farthest down the Indus of any glaciation. The last glaciation is subdivided into several stages, the most important of which is the Borit Jheel. We consider it to have terminated in the Dak Chautk or Dianyor moraine at Gilgit, whereas the British workers think it terminated near Chilas and to be equivalent to the Jalipur. A problem has been their lack of acknowledgment of our prior work to which they have had access directly from us. Proper reinterpretation of these contentious issues is critical because of the importance of ongoing studies of absolute uplift rates. In as much as uplift rates are commonly calculated as a function of cooling rates as minerals pass through annealing isotherms at depth, the paleo-configuration of the isothermal surfaces of this region is required for assessment. With present-day relief in the Karakoram and Nanga Parbat Himalaya on the order of 6-7 km, the descending cool waters in fractured and faulted glacial valleys; the rising thermal waters along the Raikot and other faults; the paleotopography, and the glacial and non-glacial histories all have controlled the paleo-isothermometry which is the focus of our present research.

S/398. Shroder, J.F. Jr., Khan, M.S., Lawrence, R.D., Madin, I.P. & Higgins, S.M., 1989. Quaternary glacial chronology and neotectonics in the Himalaya of north Pakistan. In: Malinconico L. & Lillie, R.J. (Eds.), *Geology and Tectonics of the Western Himalayas*. Geological Society of America, Special Paper 232, 275-294.

Thick deposits preserved in deep valleys in the Indus, Gilgit, and Hunza River Basins, and a variety of dates, allow new definition of Quaternary events in the Karakoram and Nanga Parbat Himalaya. An unusually long record for an actively eroding high mountain area is recognized in three major episodes of glaciation during Pleistocene time. An early glaciation is represented by the indurated lower Jalipur tillites and heterogeneous upper Jalipur valley-fill sedimentary rock younger than 1 to 2 Ma, which are folded, overturned, or overridden by rapid movement on the dextral-reverse Raikot fault. This is associated with high overall uplift rates of the Nanga Parbat-Haramosh massif during late Cenozoic time. The middle glaciation is represented by two tills intercalated within variable sediments, including thick lacustrine units dipping as much as 43° along the fault. The Indus -Shatial till of the early middle glaciation records the farthest advance of Pleistocene glaciers down the Indus River valley. The last glaciation apparently occurred after about 140,000 yr ago and consists of three to four or more separate advances, as recorded by moraine topography. The most prominent of these is the Dianyor moraine near Gilgit, which was produced by a major longitudinal glacier. Near Haramosh and downstream at Nanga Parbat, Shatial, and elsewhere, transverse glaciers blocked the Indus River to produce lake deposits now dipping as much as 6° near the fault. Catastrophic floods from failure of the ice dams, and possibly landslide dams as well, emplaced some Punjab erratics and sediments that may have been re-worked into loesses and other sediments at the mountain front.

The Karakoram mountain ranges and the adjacent Nanga Parbat of the Northwest Himalaya to its south constitute one of the most glaciated areas in the world. This area is drained by the Indus river system, much of which is fed by the glaciers. The geomorphology of the area is essentially controlled by exhumation, rapid erosion and glaciation. This has resulted in large quantities of Quaternary sedimentary deposits, the subject of this paper.

Petrographic methods for the determination of joint parameters such as volume density of joints, and joint porosity and permeability have been applied to selected core samples from the Nuryal 1 well drilled in the Potwar region of West Pakistan.

Joint porosity and permeability data from Jurassic variegated siltstone-sandstone and Paleocene Khairabad Limestone from selected core sections of the Nuryal 1 well at depths between 4,662 and 4,751 m indicate the presence of fairly effective reservoir potential in Jurassic variegated siltstone-sandstone and effective reservoir beds in the Paleocene Khairabad Limestone.

S/408. Shuja, T.A., 1984. Role of geothermal energy in Pakistan. Abstracts, First Geological Congress, Lahore, p.6.

Keeping in view the limited reserves of fossil fuels and soaring energy demands, the need has been felt to develop alternate energy resources. Among alternate resources, geothermal energy occupies an important place. Geothermal energy has been developed in 30 countries mainly for generation of electricity. This is cheap and renewable energy resource located in remote areas where poor accessibility hampers development.

Evidence of geothermal activity in the form of hot springs is found in Northern areas, Chagai District (Baluchistan), Dadu District (Sind) and in Azad Kashmir. Geothermal resource studies in Gilgit and Hunza Agencies indicate the presence of high temperature geothermal fluids (1200C— 2000C). Similarly sub-surface temperatures in Chagai have been estimated to range from (1500C - 1750C). Temperature as high as 1600C has been found at Lakhra during drilling. Large concentration of thermal springs in Dadu also Merits attention.

Key words: Geothermal energy.

S/409. Shuja, T.A., 1986. Geothermal areas in Pakistan. Geothermics 15, 719-723.

In this paper an attempt has been made to correlate the tectonic and geologic features with surface manifestations of geothermal activity in Pakistan to delineate prospective areas for exploration and development of geothermal energy. Underthrusting of the Arabian plate beneath the Eurasian plate has resulted in the formation of Chagai volcanic arc which extends into Iran. Quaternary volcanics in this environment, along with the presence of thermal springs, is an important geotectonic feature revealing the possible existence of geothermal fields. Geothermal activity in the northern areas of Pakistan, as evidenced by thermal springs, is the likely result of collision and underthrusting of the Indian plate beneath the Eurasian plate. Numerous hot springs are found along the Main Mantle thrust and the Main Karakorum thrust in Chilas and Hunza areas respectively. The concentration of hot springs in Sind Province is also indicative of geothermal activity. A string of thermal seepages and springs following the alignment of the Syntaxial Bend in Punjab Province is also noteworthy from the geothermal viewpoint. In Baluchistan Province (southwest Pakistan), Hamun-e-Mushkel, a graben structure, also shows geothermal prospects on the basis of aeromagnetic studies.

The area studied is about 80 km². It lies NNE of Muzaffarabad at a distances of 173 km. The mapped area lies between 74° 24' 50"-74° 32' 50" longitudes and 34° 54' 40"- 35° latitudes it covers parts of Survey of Pakistan toposheet No.43 j/5 & 43 j/9. The rocks of the area are of Salkhala Formation. The Salkhala Formation is a metamorphic complex of variegated lithology comprising of schist (chlorite-garnet grade), amphibolites, quartzite

and marble. Granite gneiss is emplaced in Salkhala Formation and is in turn intruded by pegmatites and quartz veins. Regional metamorphism and accompany penetrative deformation, post-date the granite intrusion, because the granite itself is involved in the deformation. Field evidences and Laboratory studies favor magmatic origin for granite bodies.

The area is tectonically disturbed being involved in Himalayan orogeny. The major faults are the Shonthar Nar fault and Daliwala fault. The Shonthar Nar fault trends NE-SE. Shonthar Nar Valley runs more or less along the trace of this fault. Daliwala fault may be considered a dip-slip-strike fault along the eastern margin of Uti Domel granite body. Regional metamorphism and tectonic effect has imparted well-developed secondary foliations and gneissosity in the rocks of the area. Minor folds are numerous. These are close and tight folds and reflect the intensity of forces involved in their formation. Jointing is abundant in the rocks. Tension and shear joints are encountered in granite gneiss, marble and schists. The mineral occurrences in the area under review include Graphite, marble gemstone (Ruby, Topaz, Aquamarine, Quartz etc.) and mica etc.

S/419. Siddiqi, R.A., 1973a. A note on silica sand deposits of Khisore and Marwat Ranges, D. I. Khan Division, N.W.F.P., Pakistan. Geological Survey of Pakistan, Information Release 57, 18p.

Large deposits of silica sand are found in the basal Part of Datta Formation (Jurassic) in Khisore and Marwat Ranges, D.I. Khan Division, N.W.F.P. The total length of the outcrop is 10.5 (4miles in Khisore range and 6.5 miles. Marwat Range). Its thickness vaies from 50 feet to 70 feet. The total reserves upto a workable dip depth of 100 feet are estimated to be 20 million tons.

Silica sand is medium to fine grained. Sieve analysis of grain size from two channels indicate that grains between 20 and 100 mesh, which are necessary for glass making, constitute 57.34% and 75.55% of the two samples respectively.

Chemical analysis of ten channel samples from two sections each from Marwat and Khisore range show that SiO₂ content ranges from 76.61 to 96.99% and Fe₂O₃ from .67% to 4.5%. This shows that silica content and iron, alumina impurities vary a great deal and that quality zoning of the outcrop is unavoidable.

The deposits are easily approachable and at present are being queried near Chunda, 5 miles south of Pezu. The silica sand is being supplied to glass manufacturers of Sind.

The deposit appears capable of meeting the requirements of a modest scale glass industry in N.W.F.P. for the production of ambar and green glass. However, it is recommended that large scale mapping and close interval channel sampling may be carried out for detailed chemical analyses and study of the deposit for possible variation in its quality.

S/420. Siddiqi, R.A., 1973b. Limestone resources of Kohat area, N.W.F.P., Pakistan. Geological Survey of Pakistan, Information Release 58, 21p.

Huge limestone deposits are found in Kohat area. They range in age from Jurassic to Eocene. Chemical analyses show that the most suitable limestone for Cement Industry and for sugar refining is of Kohat Formation, (Eocene). Reserve estimate of Eocene limestone, within a radius of 20 miles from Kohat town is 7000 million tons upto 200 feet above surface. The Outcrops are very close to the communication lines. Plenty of water, power and labour is available. Other raw materials for cement industry, such as gypsum and clay are also available abundantly. Most of the limestone is high grade- and has more than 50% CaO and less than 3% of MgO. Babri Banda, about 5 miles from Kohat on Kohat-Rawalpindi Road, is suggested for setting up a cement factory.

Key words: Limestone, Kohat.

S/421. Siddiqi, R.A. & Saleem, M., 1976. Preliminary report on the discovery of sulphide mineralization in Sawar area, Kotli District, Azad Kashmir. Geological Survey of Pakistan, Information Release 93.

Sulphide mineralization of possible replacement lode type has been found in a shear zone in the Muzaffarabad formation of Permian-Carboniferous age, near Sawar, Kotli District, Azad Kashmir. The metal content of a channel rock sample from the oxidized zone (table-1) is as under:-

Pb	Ag	Zn	Cu	Ni	Au
3.76%	5 gms/ton	0.24%	0.15%	0.003%	5 centigram/ton

An area of 4900 sq. meters was studied and the geochemical anomalies of 224 soil samples, have indicated mineralization covering about 350 sq. meters. The high anomalous areas indicating mineralization are aligned in north west south east direction.

Geochemical values between the median and the threshold, covering an area of about 3000 sq. meters, are also of interest with regard to further work. Further geochemical investigations of a regional nature are in progress and their results would be presented in a final report.

S/424. Siddiqui, F.A., 1967. Note on the discovery of carbonatite rocks in the Chamla area, Swat State, West Pakistan. Geological Bulletin, Punjab University 6, 85-88.

Following the discovery of an alkaline rock complex in Swat (Siddiqui, 1965), detailed mapping of the area was undertaken and presence of some "calcite" veins in the syenite was noticed by A. Shakoor and two M.Sc. students of the Geology Department, Panjab University. This information was passed on to the author who visited the area during August 1966, and found that the veins, mentioned above, contained pyroxene and feldspar in addition to carbonate minerals. Subsequent petrographic work showed that the pyroxene was aegiritic in nature and that apatite was also present in abundance. The field relations and mineralogy of the rock was thus found to have features similar to some known carbonatite rocks. For further confirmation, two samples were submitted to Dr. T. Deans of the Institute of Geological Sciences, Great Britain, who arranged their X-ray fluorescence analysis at his laboratory (Special Report No. 252, 1967). The results showed heavy traces of Ba, Sr and the rare earths Ce and Y, with minor traces of La (See Table No.1). On the basis of these investigations it was concluded that these rocks are in fact carbonatite and an announcement to the effect was made in the Commonwealth Liaison Office Newsletter for October and November 1967. The present note is intended to report further progress on the work being conducted by the author. The rocks have been named as the "Naranji Kandao Carbonatite" in reference to the place where the occurrence was first noticed.

S/427. Siddiqui, F.A., Chaudhry, M.N. & Shakoor, A., 1970. Geology and petrology of the feldspathoidal syenites and pegmatites of the Koga area, Chamla valley, Swat, West Pakistan. Geological Bulletin, Punjab University 7, 1-29.

The feldspathoidal syenites and associated rocks of the Koga area, first reported by Siddiqui (1965), are described in detail. The area lies in the west central portion of a large intrusion of the so-called Ambela Granitic Complex, which occupies much of the Buner, Chamla and Khudukhel areas of the southern Swat.

In the Koga area, three main petrologic types have been distinguished. 1. A calc-alkaline body named Chingalai granodiorite gneiss. 2. Per-alkaline syenites and granites called Babaji Syenites and characterized by granitoid texture and abundance of basic xenoliths. 3. Feldspathoidal syenites called Koga syenites. The contact of type 1 and 2 is occupied by a fault zone. The Koga syenites are intrusive in both 1 and 2 and are similar to Babaji syenites in that both have aegirine, abundance ilmenite, sphene and apatite as common constituents. These minerals occur only as accessories in the Chingalai granodiorite gneiss. Babaji syenites appear to be co-magmatic with the Koga syenites. The Koga syenites occupy a roughly oval shape area with irregular outlines. Field, petrographic and chemical investigations indicate the following sequence of formation: Per-alkaline syenites (with or without quartz)-nepheline syenites-nepheline sodalite syenite- carbonatite. Thus the trend is one of progressive desilication with differentiation. Flow structure is common indication that the under-saturated magma was emplaced as a viscous mush with alkali feldspar crystals suspended in a liquid capable of crystallizing nepheline.

S/430. Siddiqui, R.A. & Shah, S.M.I., 1995. Mineral occurrences in the Eastern Khyber Agency, NWFP. Geological Survey of Pakistan, Mineral Information series 18, 28p.

Preliminary investigation for economic minerals was conducted in the Khyber Agency. Samples were collected and analysed in the Geological Survey of Pakistan. The results obtained are encouraging. Radioactive minerals have been detected in some of the rocks having a considerable extension. Iron mineralization at Misrikhel, good quality dolomite of western LoeShilman, and large quantities of black mica in the eastern Loe Shilman are some among other potential prospects, recommended for detailed exploration. The formations in the Khyber Agency change

facies, some of them rapidly in a short distance. (Change of environment and source, coupled with the episode of metamorphism, makes the entire Khyber Agency worthwhile for detailed mineral exploration.)

S/432. Siddiqui, S.F.A., 1965. Alkaline rocks of Swat, Chamlā. Geological Bulletin, Punjab University 5, 52.

Our field investigations into the origin of certain zircon pegmatites, originally reported in Martin et al. (1962, p. 9) have brought to light the presence of rocks of nepheline syenite and related composition, which may be connected with this occurrence; some of the rocks bear sodalite, aegirite, and other alkaline minerals. This is probably the first recorded occurrence of these rocks in Pakistan. Work is now going on with a view to mapping the area of interest to determine the nature, form and extent of the alkaline bodies and to ascertain whether there is any genetic connection with the riebeckite porphyries of Shewa, Mardan District. The occurrences are located near Ambela, Swat State.

Geological mapping and evaluation of geotechnical properties of Cambrian to Eocene rocks of Nauseri area, Muzaffarabad Azad Kashmir and Garhi Habibullah, Mansehra, Pakistan. Institute of Applied Geology, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, M.Sc. Thesis, 1-78.

The geotechnical, Petrographical, Chemical and lithological characteristics and dynamic and static test results are presented for Cambrian to Eocene Rocks. Comparison is made between a number of static properties of the rocks and their geotechnical performance, particularly during evaluation of different geotechnical properties with changing mechanical, chemical, mineralogical and environmental conditions. The samples (Cambrian) were taken from dolomite quarries near yadgar, Panjal Volcanics (Permian) from Nauseri area and limestone (Eocene) from Yadgar quarries. The Test results presented suggest that the Panjal Volcanics and limestones are suitable as construction raw material for riprap, aggregates, subbase and concrete. The dolomite is fine to medium grained with high magnesium Contents and is useful for industry. The use of dolomite as construction raw material. The Panjal volcanics have high iron content and is harmful to be used as construction raw material in tropical region.

S/435. Sillitoe, R.H., 1976. Metallogenic evolution of a collisional mountain belt in Pakistan (A preliminary analysis). Geological Survey of Pakistan, Record 34, 16p.

Consult the following account.

Key words: Metallogeny, collisional mountain belts.

S/436. Sillitoe, R.H., 1978. Metallogenic evolution of a collisional mountain belt in Pakistan: A preliminary analysis. *Journal of the Geological Society, London* 135, 377-387.

Five post-Palaeozoic metallogenic environments are recognized in Pakistan and adjoining regions: 1. Mississippi Valley-type fluorite, barite and barite-galena deposits generated in Jurassic limestones on the northern miogeoclinal margin of the Indian Shield, perhaps during incipient rifting heralding India's separation from Gondwanaland; 2. chromite deposits in serpentinized dunite, manganese-oxide deposits in layer-1 sediments and a cupriferous massive sulphide occurrence in layer-2 basalts generated within an ophiolite complex at a Tethyan oceanic spreading centre; 3. porphyry copper-molybdenum, manto-type copper, Kuroko-type massive sulphide, vein copper, contact-metasomatic copper and iron, and volcanogenic iron deposits generated in Cretaceous-Cenozoic times by intrusive and extrusive calc-alkaline magmatism along the southern edge of the Iran-Afghanistan microcontinental plate during northward subduction; 4. stibnite occurrences emplaced in the intracontinental Chaman transform fault system during post-early Miocene times; and 5. sandstone-type uranium deposits in Siwalik molasse-type sediments shed during post-early Miocene uplift of the Himalaya. Juxtaposition of the miogeoclinal, ophiolitic and Cretaceous calc-alkaline metallogenic provinces resulted from suturing of the Indian plate with the southeastern margin of the Iran-Afghanistan microcontinent, representing final closure of eastern Tethys. Subsequent renewed northward motion of the Indian plate, causing crustal shortening and uplift along its northern edge, produced the transform-fault and molasse-basin provinces and, along the Makran segment of the plate boundary unaffected by continental collision, the post-early Miocene calc-alkaline province.

Key words: Metallogeny, collisional mountain belts.

S/437. Sillitoe, R.H., 1979. Speculations on Himalayan metallogeny based on evidence from Pakistan. In: Farah, A. & DeJong, K.A. (Eds.), *Geodynamics of Pakistan: Geological Survey of Pakistan*, 167-179.

Sillitoe (1978) recognized five discrete metallogenic environments in Pakistani Baluchistan. They are related to a shelf-carbonate succession, an ophiolite suite, a subduction-related calc-alkaline magmatic arc, an intracontinental transform fault zone, and a molasse basin. None of these environments is well represented further to the northeast, in the Himalayan region. However, minor ophiolitic chromite in the Indus suture zone, molasse-contained uranium in the Subhimalaya, and contact-metasomatic magnetite of probable subduction origin in the north-west Himalaya are recorded. Potential would seem to exist for discovery of other ophiolitic ore types and, in the Lower and Tibetan Himalaya shelf carbonates, of Mississippi valley-type deposits. Subduction-related base and precious-metal mineralization is not likely to be widespread. In much of the Himalaya but may be encountered in the Transhimalaya and, north of the southern branch of the Indus suture zone in the northwest Himalayan region.

Based largely on evidence from the northwest part, post-Palaeozoic mineralization in the Himalaya, including regions immediately north of the Indus suture, is believed to be dominated by minor polymetallic occurrences of Neogene age carrying mainly copper, lead, barite, gold, and antimony of metamorphic origin, and by gemstones, along with some fluorite and possibly rare-earths and minor base metals, generated by anatectic leucogranites. Metamorphic mineralization is attributed to precipitation in dilatant sites by fluids expelled from sedimentary rocks undergoing regional metamorphism, either during thrusting and/or during uplift. The anatectic leucogranites are believed to be poorly mineralized compared with subduction-related intrusives because their source 'magmas, generated by partial melting of basement rocks during continental underthrusting, were water-saturated and therefore consolidated at depths of perhaps 10 km without possessing subvolcanic or volcanic equivalents; the magmas also may have been intrinsically poor in metals. Both these Neogene metallogenic environments were imposed by the process of thrust progradation whereby renewed post-Eocene northward motion of the Indian plate was taken up on a series of major, low-angle thrusts within its leading edge, with activity migrating progressively with time (prograding) southwards from the Indus collisional suture. In Baluchistan, post-collisional northward motion of India was taken up on the Chaman transform fault zone so that thrust propagation was relatively unimportant.

It would appear that the metallogeny accompanying continental collision and its related later effect is on a small scale and that the major ore types, such as porphyry copper, epithermal precious metal and Kuroko-type massive sulphide deposits, found in Cordilleran or island-arc settings above subduction zones, are unlikely to be found.

Exploration programmes should take account of these speculative conclusions and should therefore perhaps concentrate on pre-Mesozoic ore types fortuitously incorporated in the mountain belt, relatively important examples of which are found at Rangpo, Sikkim and Asker, Uttar Pradesh.

S/442. Smith, F.H., 1895. On the geology of the Tochi valley. *Records of the Geological Survey of India* 28(3), 106-110.

This may be amongst the earliest accounts of this part of the tribal Area of present day Pakistan. Following are a few paragraphs from the records.

Bannu District.-One of the four trans-Indus Districts of the North-West Frontier Province, lying between 32° 16' and 33° 5' N. and 70° 23' and 71° 16' E., with an area of 1,670 square miles. The District forms a basin drained by two rivers from the hills of Waziristan, the Kurram and the Gambila or Tochi, which unite at Lakki and flow into the Indus south of Kalabagh. It is shut in on every side by mountains: on the north by those in the Teri tahsil Physical aspects. of Kohat District; on the east by the southern extremity of the Maidani Pahar or Khattak Niazi range and the northern spur of the Marwat range, which separate the District from the Isa Khel tahsil of Mianwali District in the Punjab; on the south-east and south the Marwat and Bhattanni ranges divide it from Dera Ismail Khan; and on the west and north-west lie Waziristan and independent territory inhabited by the Bhattanni tribe. These hills nowhere attain any great height. The highest point of the Maidani range at its centre, near the hamlet and valley of Maidan, has an altitude of only 4,256 feet. The Marwat range culminates in Sheikh Budin, the hill which rises abruptly from its south-west end to a height of 4,516 feet, and forms the summer retreat for this District and Dera Ismail Khan. From these ranges numerous spurs jut out into the Bannu plains, but no other hills break their level expanse. Of the rivers the larger is the Kurram, which, entering the District at its north-western corner close to Bannu town, runs at first south-east, then south, and finally winds eastward through the Darra Tang or 'narrow gorge' which lies between the extremities of the Maidani Pahar and Marwat ranges. The Tochi river enters the District about 6 miles south of the Kurram and flows in the same direction, gradually drawing closer to it until their streams unite about 6 or 7 miles west of the Darra Tang. Between these rivers, and on the left bank of the Kurram in

the upper portion of its course, lie the only tracts which are perennially irrigated. For the first 10 miles of its passage through the District the Kurram runs between banks of stiff clay which rise abruptly to a height of 10 to 30 feet, and its bed is full of stones and boulders; but lower down it spreads over long stretches of marsh land. Its flow is rapid, but it is highly charged with a rich silt which renders it most valuable for irrigation. At the south-east edge the western flanks of the hills bounding Mianwali and Dera Ismail Khan Districts expose Tertiary lower Siwalik soft sandstone and upper Siwalik conglomerates, a thickness of which dips regularly under the alluvium and gravels forming the greater part of the great Bannu plain. On its western side the border area has been examined along one line of route only, namely, the Tochi valley. Here long ridges striking north and south expose upper and lower Siwaliks, Nummulitic limestone, sandstone and shales, some Mesozoic limestone in the ridge east of Miram Shah, and a great mass of Tertiary igneous rocks (diorites, gabbros, and serpentines) west of Muhammad Khel. In the irrigated portions of the District trees abound of the same species as are common in Peshawar; elsewhere there is little but thorny shrubs of the same kinds as are found in Kohat. The more common plants are *Reptonia buxifolia*, *Dodonaea viscosa*, *Capparis aphylla*, *Flacourtia sapida*, *F. sepiaria*, several species of *Grewia*, *Zizyphus nummularia*, *Acacia Jacquemontii*, *Alhagi camelorum*, *Crotalaria Burhia*, *Prosopis spicigera*, several species of *Tamarix*, *Nerium odorum*, *Rhazya stricta*, *Calotropis procera*, *Penriplaca aphylla*, *Tecoma undulata*, *Lycium europaeum*, *Vithania coagulans*, *V. somnifera*, *Nannorhops Ritchieana*, *Fagonia*, *Tribulus*, *Peganum Harmala*, *Calligonum poligonoides*, *Polygonum aviculare*, *P. plebejum*, *Rumex vesicarius*, *Chrozophora plicata*, and species of *Aristida*, *Anthistiria*, *Cenchrus*, and *Permnisetum*.

Bears occasionally come from Waziristan and leopards still frequent the hills, while hyenas are sometimes found where there are ravines. Wolves are common, rewards having been paid for destroying 168 from 1900 to 1904. The Sulaimani markhor is found on all the higher hills, including Sheikh Budin. Uridl are also to be found on the hills, and 'ravine deer' (gazelle) in the neighbourhood of Jani Khel. The general elevation of the plains is about 1,000 feet, and the temperature would be much the same all over the District did not special local causes affect it. Trees, excessive irrigation round the town, and the closeness of the hills combine to make Bannu moist and close in the hot season, and to equalize the temperature throughout the twenty-four hours. The sandy plain of Marwat is hotter by day and cooler by night, and far more healthy in spite of the intense heat. Fevers are common from September to November, and respiratory diseases cause considerable mortality. The annual rainfall averages 12 inches, rarely rising above 16, but at Bannu in 1891-2 less than 5 inches fell in the year. The fall is frequently unseasonable. The population of Bannu is, and has been for many centuries, essentially Afghan. There are, however, remains which tell of an older Hindu population, and afford proof that the District came within the pale of the Ancient Graeco-Bactrian civilization of the Punjab.

S/444. Smith, H.A. & Chamberlain, C.P., 1992. Evidence for late Eocene anatexis within the Indian plate as a result of Eocene Himalayan orogeny. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 84.

Our geologic mapping in the upper Kaghan Valley of northwestern Pakistan has focused on the Indian plate rocks defining the footwall of the Main Mantle Thrust. These rocks exhibit structural and mineralogic changes related to the south-directed obduction of the Kohistan Island Arc onto the Indian plate, thought to originate with the onset of continental collision at approximately 50 Myr (Patriat and Achache, *Nature*, 311:615-621, 1984). As a first step to answering some of the petrologic questions relating to this tectonic event, we sought emplacement ages for a narrow band of leucogranites near the village of Naran that extend for 4-km, cutting across lithologic boundaries within the Indian basement.

Because of the likelihood of xenocrystic components in these melts, we made use of the capabilities of the SHRIMP facility at Australia National University. With the ability to analyze a 20-30 micron spot on an individual grain, SHRIMP U-Pb zircon analyses can avoid obvious inherited cores and instead provide ages for rims presumably grown as a result of the most recent igneous event. We analysed a number of zircons from each of 4 leucogranite

samples in the Kaghan Valley. The youngest ages for each of these 4 samples cluster at 40–45 Myr. These ages are notably older than any leucogranite ages from the greater Himalaya.

Both the structural setting and the mineralogy of leucogranite in the Kaghan Valley are similar to other Himalayan leucogranites. Our leucogranites outcrop in the hanging wall of a pronounced shear zone (the Oghi Shear) which thrust amphibolite-grade basement rocks over low grade, graphitic metasediments of the Salkhala Formation. This structure is thought to be correlative with the MCT, the hanging wall of which hosts other Himalayan leucogranites. However, each of the previous studies of Himalayan leucogranites has used the occurrence of undeformed leucogranites that crosscut the foliation to constrain the minimum age of deformation. In the Kaghan Valley, we find that the leucogranites are deformed.

Thus our relatively old leucogranite ages obviously do not constrain the minimum age of deformation. What they do illustrate is unexpectedly early igneous activity in the Indian plate. That this igneous activity is not simply an isolated, local phenomena is shown by zircon U-Pb ages of 43 Myr, similarly obtained using SHRIMP, from the Malakand Granite near Swat, 300 km to the west.

Taken together, our ages of 40–45 Myr from leucogranites and the Malakand Granite require that igneous activity began within 10 Myr following the onset of Eocene collision between the Indian subcontinent and Asia. While the generation of melts this soon after collision may seem unusual, numerical modeling suggests that water-saturated melts can be expected 0–20 Myr following initial tectonic thickening, given appropriate fluid fluxes.

In the Himalayas, investigators have constrained the timing of metamorphism associated with the Eocene orogeny through the use of cooling ages on a number of minerals. The majority of such studies give minimum metamorphic ages of ~ 30–40 Ma, largely confirming theoretical studies predicting peak metamorphic conditions occurring tens of millions of years after large-scale collision. In northwestern Pakistan, however, the Nanga Parbat-Haramosh Massif (NPHM) exhibits much more recent activity, with rapid and accelerating cooling over the past 10 Ma. The NPHM also exhibits unexpectedly recent igneous activity: three leucogranite dikes give minimum zircon U-Pb ages of 7, 5 and 2.3 Ma. The problem we address in this paper is whether the thermal structure suggested by recent leucogranite production at depth is discernible in the shallower metamorphic rocks of the NPHM. To date metamorphism, we have used the U-(Th)-Pb system in monazite, a common accessory mineral in high-grade metamorphic rocks which can be a viable metamorphic geochronometer, dating the formation of the mineral under moderate metamorphic conditions. Monazite separated from schists and gneisses of the NPHM gives U-Pb ages of 4–11 Ma. We interpret these young ages as evidence for Neogene metamorphism affecting the NPHM, an event heretofore unsuspected in the greater Himalaya and only intimated in the NPHM. This recent metamorphism roughly coincided with leucogranite production at depth and with the onset of high denudation rates. As such, our conclusions offer important constraints on further modeling of similarly anomalous behavior within tectonically active regions, suggesting that any reasonable model should strive to explain the relationship between recent, rapid uplift and coincident recent metamorphism.

Key words: Metamorphism, geochronology, U-Pb, Himalaya.

S/448. Smith, H.A., Chamberlain, C.P. & Zeitler, P.K., 1993. Relationship between deformation and monazite ages-two counter examples in the Himalaya. EOS 74(16), p.123.

Monazite has found use as a geochronometer for metamorphic processes, processes intimately coupled with deformation in developing orogens. While the role deformation might play in initially forming monazite is unknown, the prograde metamorphism of pelites has been shown to result in the genesis of metamorphic monazite. The U-Pb system in such monazite then gives a direct age for onset of metamorphism, as well as offering constraints on the timing of deformation.

In Pakistan, we have used such ideas in two separate regions: the Nanga Parbat-Haramosh massif (NPHM) of the Indian plate and in the Karakorum range of the Asian plate. Although it has been shown that the NPHM is a region of rapid, accelerating uplift and denudation over the past 10 Ma, expectations were that the timing of Himalayan metamorphism would be broadly similar to that shown for the central Himalayas: mineral cooling ages there give younger bounds on the age of metamorphism of ~30-40 Ma. However, metamorphic rocks of the NPHM gives much younger monazite U- Pb ages of 4-11 Ma. We have been able to confirm none of the known scenarios for resetting the U-Pb system in monazite. Instead, we find independent corroborating evidence of Neogene metamorphism: young zircon U-Pb ages from leucogranite dikes and from the metasediments, as well as consistently younger fission-track ages.

Such is not the case for the Karakorum. Undeformed, post-metamorphic igneous units constrain deformation and metamorphism to being older than ~35 Ma, while 2 upper amphibolite facies metamorphic samples give concordant U-Pb monazite ages of 6-7 Ma. Although other geochronologic data are scarce, such young ages are enigmatic. We will use these two counter-examples to speculate on the viability of the U-Pb system in monazite as influenced by thermal and deformational perturbations.

In: Kazmi, A.H. & Snee, L.W. (Eds.), Emeralds of Pakistan: Geology, Gemology and Genesis, 93-123. Van Nostrand Reinhold, New York.

This account has no abstract. It gives a brief of chemical differences between emeralds of Pakistan and Afghanistan. Emphasis is given on chemistry of the emeralds found in these areas. The authors have concluded that the emeralds of Pakistan, like the other emeralds of the world, are green in color due to the substitution of chromium to aluminum in the beryl structure. Pakistan emeralds are unique as they contain large amount of iron, megnisium and sodium. Emeralds from different areas in Pakistan and Afghanistan are chemically different. Swat, Mohmand, Khaltaro, and panjsher emeralds show small but distinct differences in aluminum, magnesium, sodium, chromium, vanadium, and scandium. Emeralds are clearly a reflection of the chemistry of both host rocks and mineralizing fluid.

Key words: Gemology, emerald, chemistry, Afghanistan, Pakistan.

Emerald, the result of the substitution of a small amount of chromium for aluminum in the beryl crystal structure (Deer and others, 1986), is the product of special geological conditions.

Even though beryl is the most common mineral that has beryllium as a major constituent, it is itself rare and is generally found in significant abundance only in late-stage igneous rocks, such as pegmatites. Beryl is rare because beryllium (with an ionic charge of +2) has both a small atomic radius (0.3 Å; Shannon and Prewitt, 1969; hence it is excluded from the crystal structure of most minerals) and a small crustal abundance (less than 5 ppm as estimated by Wedcpohl, 1978, or less than 3.5 ppm according to Beus, 1965). Emerald is even scarcer because chromium, the coloring agent of emerald, and beryllium are geochemically incompatible. Chromium is found only in significant amounts in "primitive" rocks such as ultramafic igneous rocks; in these, beryllium is absent. Thus, special circumstances are necessary to bring chromium and beryllium together and therefore, emerald is one of the rarest and most precious gemstones.

In Pakistan, a series of special geological events resulted in the formation of emerald. In the first three chapters of this book, we summarize the large-scale events. In chapters four through seven, we discuss additional clues on the origin of the emeralds; these clues are revealed in physical and chemical characteristics of the emeralds as well as in the morphology and physicochemical conditions of the formation of tiny inclusions within the crystals. In chapter 8, we review the geology of other known world emerald deposits. In all, an intriguing picture about the general geologic setting and the origin of not only Pakistani, but world emeralds is unfolding. In this final chapter, the characteristics of Pakistani emeralds are summarized and are used to formulate a theory on their origin. Next, a classification scheme based on the general geologic setting of world emeralds is proposed and discussed and is developed into an hypothesis for the origin of all emeralds. Finally, we propose some additional studies that would shed new light on the origin of emeralds.

S/454. Sohail, A., 1987-89. Geotechnical studies for landslide problems along the Murree Kohala Road. M.Sc. Thesis, Punjab University, Lahore, 111p.

Landslides are widespread in many countries and cause great economic losses especially when engineering constructions are designed and erected without knowing the stability conditions of the slopes.

The greater frequency of landslides provoked by construction works, as compared with the past is probably due to several reasons:

- The interference with natural slopes is more intensive because of the rising boldness and extent of structures.
- The mechanization of earthworks accelerates excavation but excludes the possibility of sorting the rock material.
- The selection of building sites is generally restricted to the less favourable ones which were avoided by previous builders etc.

Landslides are closely connected with the geological conditions of the area. Generally speaking Pakistan has a very intricate geological history with active tectonic zones. Frequently occurring landslides, in different parts of the country create problems for government and local people. The area between Murree and Kohala is the site of very diverse sliding Phenomena. (especially along the road). Landslides endanger settlements, high roads, public utilities etc. The Murree Kohala Road has great national importance from strategic and regular communications view point. This shortest possible route between Pakistan and Azad Kashmir is promoting the facilities of communications for development of the linked areas and the supply of basic needs. The Murree -Kohala Road crosses the Jhelum River at Kohala through Kohala Bridge and a stretch of about six kilometers is along the Jhelum River from Basian to Kohala. This road is also important from defence point of view. There is another road which starts from Jhikagali via Bhurban and joins the Murree -Kohala Road near Basian via Bush Road is named as Khaquan Abbasi Road (due

to late Khaquan Abbasi). The entire area through which road passes is the rugged mountainous terrain having sub humid to semi arid climate conditions. As far as the slopes of the project area are concerned, the major part of the road is on the escarpment face and variety of slope conditions exist in the area. The condition of the Murree -Kohala road is satisfactory where a good driver can drive every type of vehicle at the speed of 40-50 kms/hour, except for the landslide areas.

Detailed Lithostructural Mapping and Biostratigraphic study of Barikhel- Bandakha Area (Western Salt Range) District Mianwali, has been done at 1:10,000. Area is exclusively a sedimentary terrain. Stratigraphy along with micropaleontology of certain formations is described. In addition to this macrofauna have been described. Lateral extension of liminic permeable coal is noted. Tectonic style of the area is described with the help of structural details i.e. study of folds, faults and joints etc.

S/462. Spath, L.F., 1934. The Jurassic and Cretaceous ammonites and belemnites of Attock district. Geological Survey of India, Memoirs, Palaeontologica Indica (New Series) 20(4), 1-39.

The ammonites and belemnites described in this paper come from a number of localities in the Attock district, in the extreme north-west of the Punjab, on the borders of the North-West Frontier Province. They were sent to me marked partly Basal Giumal beds (the Jurassic and Spiti shales species), partly Upper Giumal beds (the Albiau forms and some indeterminable belmenites). These cephalopods were accompanied by a number of brachiopods, also pelecipods and gastropods, which are being described by Miss H. M. Muir-Wood and by Mr. L. R. Cox 'respectively. The fauna has already been referred to in my Revision of the Jurassic Cephalopoda of Kachh, hut the publication, in the meantime, of other works, especially on Upper Jurassic successions, makes it desirable to discuss the stratigraphic results afresh and in more detail in a final chapter.

I have to record my grateful acknowledgments to the past and present Directors of the Geological Survey of India in Calcutta (Sir Edwin Pascoe and Dr. L. L. Fermor) for entrusting me with the description of these interesting forms ; also to the Keeper of the Geology Department of the British museum (Natural History), Dr. MT. D. Lang, for giving me all facilities in connection with the study of the collections. I should like similarly to acknowledge the help and continually receiving from colleagues all over the world by consignments of new material, literature or information, even if it may not seem to be directly concerned with the area here discussed. The measurements of ammonites are given in the usual order :--(1) diameter in millimetres, (2) whole-height, (3) whole-thickness, (4) width of umbilicus in percentages of the diameter. The localities are referred to under numbers 1-12 in the specific descriptions to avoid lengthy repetitions, but they are given in full in Chapter 111. Since a number of the species here recorded have been

described from Kachh, the synonymies are also generally condensed. A full list of literature on the subject is given in the last part of my Revision of the Jurassic Cephalopoda of Kachh.

The Upper Kaghan nappe in the NW Himalaya of Pakistan consists of a lower granitoid basement with two cover units: first, a metagraywacke unit of Lower Paleozoic age and second, a Tethyan sedimentary sequence which has at its base the Permian Panjal Traps, which are continental tholeiitic to mildly alkaline basaltic lavas that evolved in the passive continental margin of neo-Tethys. Syn-depositional limestone (new-marble) intercalations occur between

the lava flows. These marbles show extensive extensional structures, associated with the rifting and subsequent extrusion of the lavas themselves. Due to the high grade of metamorphism under which the whole nappe has undergone (eclogite-amphibolite facies metamorphism) only a few fossils were found to indicate the age of the unit. Previous geochemical correlations between the Higher Himalayan-Tethyan Panjal volcanics with known Lesser Himalayan-Tethyan Panjal volcanics in Kaghan Valley revealed that a correlation between the two units could be made. Carbon and oxygen isotope analyses on the marbles between the lavas, as well as those above the analytical groups consist of the Higher Himalayan Panjal Traps (HHPT), Lesser Himalayan Panjal Traps (LHPT), Higher Himalayan Tethyan Triassic series (HHTSS) and the Lesser Himalayan Triassic Rara Formation (LHTRF).

Preliminary analyses show that the marbles from the Panjal Trap units give a marine carbon isotope signature whilst the younger sedimentary series gave a different result. Such stable isotopic correlation is only possible because of the well-defined nature of the units being studied, and that the actual stratigraphic correlations with other documented sections are available. It is therefore considered as a powerful tool in the analysis and reconstruction of similar sedimentary environments that have subsequently undergone different tectonic histories.

S/468. Spencer, D.A., 1991a. Different shortening histories between the 'syntaxial' and 'non-syntaxial' areas of the Himalayan belt. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Grenoble, France, 79-80.

Recent plate tectonic models of Himalayan deformation (e.g. Dewey et al., 1989) are, as yet, the most advanced suggested for the understanding of the collision zone. North of the Indus Suture, they show that shortening accommodation is not homogenous along the length of the mountain chain but varies: crustal thickening and uplift of the Tibetan plateau essentially occurring in north of the Central parts of the Himalaya and indentation with strike-slip faulting occurring in the Karakoram and Pamir region. Similarly, south of the suture, different amounts of shortening by thrusting are suggested to have occurred, although this does not explain how the structurally anomalous syntaxes are formed, their different structural, metamorphic and tectonic histories nor why they are confined to certain area of the Himalaya.

It is suggested that the deformational history south of the suture is primarily influenced by the shape of the Indian plate promontory in the NW Himalaya and the lack of the promontory in the Central Himalaya. The effect of this promontory resulted in the initiation of subduction in the NW parts of the Himalayan belt and reaches the greatest depths for the Indian plate, as evidenced by high pressure eclogite and blueschist facies metamorphism, which are conspicuously lacking in the Central Himalaya. Also, the occurrence of extensional tectonics in the Central Himalaya and its absence in the NW Himalaya probably also attests to differential uplift histories.

The effect of the initial collision of the promontory caused in the Indian plate to rotate anticlockwise in a force field adjustment. This rotation produced a change of tectonic transport shortening direction within the promontory and

subsequently led to large scale superimposed folding which explains syntaxial formation. By contrast, the central Himalayas were more of a 'head-on' collision with shortening easier north of the suture by plateau uplift and then by thrusting south of the suture.

Of fundamental importance in this interpretation is basically the argument about whether the Indian plate promontory actually exists and, if so, its shape. Indentation tectonics in the Pamirs with sinistral faulting on the western boundary and dextral faulting on the eastern boundary, deflection of Asian sutures older than Himalayan age, anticlockwise rotation of the Indian plate, the outline of the Higher Himalayan Crystalline, occurrence of syntaxes and differential rates of collision rates from NW to NE along the belt all attest to presence of a promontory and the subsequent progressive eastward closure of the suture. A 'triangular' shape for the promontory is thought to be the most appropriate.

It is obvious that the promontory did not act as a rigid indenter as thrusting occurred south of the suture. Similarly, during the uplift of the nappes, folding played a major part in the shortening history, in some cases producing a 'Panini' sheet-like deformation in the more internal units. Examples of fold interference are presented from the Hazara-Kashmir, Kaghan and Nanga Parbat-Haramosh Syntaxes, as well as basin and dome patterns in the Upper Kaghan area and are mainly due to a horizontal, anticlockwise translation of deformation, comparable and probably coeval with the movements of the Indian plate. Small-scale structures, as well as the metamorphic and geochronological considerations (Poignant, this volume) correlate well these modifications.

It is therefore suggested that folding is a crucial accommodation feature south of the suture in the syntaxial areas of the Himalaya and has been mainly neglected in shortening history models of the mountain belt. Slight modifications are therefore applicable to explain the deformational features south of the suture, where folding, as well as thrusting, are thought to be of great importance in the understanding of the different shortening histories between the 'syntaxial' and 'non-syntaxial' areas of the Himalayan belt.

S/471. Spencer, D.A., 1992a. Geochemistry of the peraluminous Higher Himalayan Crystalline Granite Basement, Upper Kaghan, Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 126.

The Higher Himalayan Crystalline Basement of Upper Kaghan Valley consists of granites of possible Precambrian (?) age. It is well represented in all parts of the Upper Kaghan nappe due to superposed folding that exposes different structural levels of the unit in both amphibolite and eclogite facies conditions. Major and trace element analysis of a variety of granite types show fairly consistent geochemical analysis, but with a differentiation trend.

Analyses are presented in three chemical mineralogical diagrams (Debon and Le Fort, 1983). In a Q-P diagram, the samples plot on the granite to adamellite sector. Characteristic mineral (A/B) plots show a distinctive trend from granite to granodiorite in the distribution line attitude of the representative points from the association. The slope (ie. the direction of its major evolutionary trend) is negative and in contrast to that seen in the Leucogranite of Upper Kaghan and Zaskar which are vertical (parallel to $A = Al - (K + Na + 2Ca)$, although with a negative trend when plotted together). The Higher Himalayan Crystalline Granites broadly correspond to the 'Cafemic' type of association. Quartz-rich and quartz-poor associations occur with samples plotting above and below the critical line and the colour index ranges from leuco- to mesocratic. Most samples plot in the peraluminous domain and outside the leucocratic field ($B > 38.8$). In the Q-B-F diagram, none of the samples plot in the leucocratic field but occur

between the $Q/Q + F$ of 20-45%. A negative correlation between Na₂O and K₂O occurs with (Na₂O + K₂O) varying from 6.12-9.52.

Major and trace element spider diagrams, with normalizations according to Thompson et al. (1984) and, for comparison, to the Bhutan Leucogranite Mean Standard Deviations, were made. Thompson normalisations show distinctive depletion in Sr, P and Ti with a general negative trend. Bhutan normalisations show rather constant depletion and enrichment amongst the samples themselves, compared to the standard deviation. Distinctive enrichment occurs for Ba, Sr, Sc, Y, Zr, Ti and Zn, whilst depletion occurs for Na, K, Ca, Rb, P, Pb and Co. These patterns may reflect a highly evolved source for the protolith and to generate these concentrations, evolved continental material is needed.

An interesting comparison to the leucogranites of Kaghan can be made. Whilst the characteristic mineral diagrams show distinct differences between the basement and the leucogranite, there are some similarities in peaks between them on the spider diagram. The leucogranites were obviously derived from the basement rocks in Kaghan. A-F-M plots are certainly differentiated ($F/A = 0.12-0.69$) and follow the calc-alkaline differentiation trend, as seen for example in the granitoid rocks of the Trans-Himalayan Batholith. All trace element variation diagrams (Zr, Y, Ba and Rb) with increasing SiO₂ show a magmatic differentiation trend. On the A-C-F diagram, all points plot in the Type 1 field (Al rich) with the most distinguishable feature of these granites being the Al Content Number (Al₂O₃ / Na₂O + K₂O + CaO) all being greater than one (Al content ranges = 1.33 - 1.77). All the granites are therefore peraluminous. By contrast, a Ca-K-Na plot shows a distinctive trend with most having a poor Ca content (Ca < 1.5: range 0.16 - 1.38). Other variation diagrams (Pb/SiO₂: Pb/Ba; Y/Fe₂O₃ and Zr/P₂O₅) also show a distinctive grouping but differentiation of the Higher Himalayan Crystalline Granites compared to the Leucogranite. Further discrimination diagrams (Nb/SiO₂ Nb/Y; Rb/(Y + Nb); Y/SiO₂ and Rb/SiO₂) all put the granites very distinctly into the field of within-plate granites.

The Higher Himalayan Crystalline Granites therefore appear to show very clear geochemical major and trace element characteristics. They were the obvious source of anatectic melting for the Himalayan-aged leucogranite by movement along the Main Central Thrust. Their aluminous content is distinctive and suggests a S-type origin forming in a within-plate environment.

S/472. Spencer, D.A., 1992b. Himalayan eclogite exhumation by fold superposition. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 127.

Superposed folds are common features in orogenic belts that can occur on a variety of scales ranging from micro- to megascopic (e.g. Loch Monar in the Caledonian orogenic belt and the syntaxes of the Appalachians and Himalaya orogenic belt). Their formation is usually accentuated by the occurrence of competence differences between different lithologies, as well as between different units, such as a basement and cover. When the scale of these differences is regional rather than local (as for example in the Higher Himalayan Crystalline of Northern Pakistan and the Lepontine Alps of Central Switzerland), it is possible that the differential local amplitudes of the superposed folds may play an important role in its exhumation history. This is especially so where the interference patterns are thought to be related to formation in an environment of primary origin (such as plate motion) rather than of secondary origin (accommodation features or changes in principal stress directions due to strain localization).

The Upper Kaghan Nappe of the NW Himalaya is of crucial importance for the understanding of the deep-seated orogenic processes associated with the Himalayan collision. Bounded by the Main Central Thrust to the south and the Indus Suture to the north, this Higher Himalayan and Tethyan tectonic unit thus represents exposures of the deepest part of the Indian plate. Evidence of the deep subduction and subsequent differential exhumation of the nappe by thrusting along the MCT, erosion, isostasy and fold superposition is shown by the presence within the nappe of an oval shaped area of eclogite facies metamorphism of some 150 km². Surrounding this high-pressure zone, with decreasing pressure isobar contours, but constant temperature conditions, are found rocks with amphibolite facies. Pressure-temperature estimations, based on microprobe analysis of mineral composition in the eclogites, gives $T = 650 \pm 500^\circ\text{C}$ at pressures of $P = 15$ kbar. This equates to depths of formation of around 55-60 km at Eo-Himalayan times. In contrast, at the southwest front of the nappe, amphibolite facies assemblages of staurolite-almandine with kyanite-sillimanite suggest $T = 550-650^\circ\text{C}$ at $P = 8$ kbar equating to a depth of formation at 30-km. Within the nappe itself, therefore, there seems to exist a relative horizontal pressure gradient that must have formed at different vertical depths in the order of 25 km. taking the minimum possible difference of differential exhumation. Thus, not only was the nappe subducted to different levels, it must have been exhumed at different rates as well. No

internal imbrications (uplift faults), shear zones or major discontinuities. nor extensional structures surrounding the eclogite-amphibolite facies transition have been found within the nappe. An alternative mechanism of exhumation is therefore proposed. The structural evolution of the High Himalayan and Tethyan units in Pakistan show a remarkable similarity to the Pennine style of nappe formation and deformation In the Alps: be. an initial development of large scale recumbent folds followed by complex large scale refolding subsequent to nappe emplacement. In the Higher Himalaya of Kaghan, where ductile deformation was the main process of deformation, evidence suggests that a polyphase ductile - penetrative overprinting occurred after the original nappe forming movement. This led to the development of a system of major post-nappe folds, which were superposed on, and deformed structures related to an earlier Himalayan history of deformation. As with the Pennine nappes of the European Alps, the post-nappe folds can be subdivided into two groups: main Himalayan folds and late Himalayan folds. The late folds are superimposed on the main Himalayan folds with type 1 or 3 interference patterns giving very large scale domes, which are found In the syntaxes, as well as basins and domes In the areas between the syntaxes. such as that in Upper Kaghan. The formation of the second phase basin and domes on the original nappe forming structure is a form of buckling anisotropy, as the earlier formed nappe-style recumbent sheet folds influence the subsequent preferred axes of buckling of the later superposed folds. The refolding is perpendicular to the nappe forming stretching lineation direction and the tectonic shortening direction is parallel to the first main phase Himalayan fold axial planes. The amplitudes of the folds of the latter structures are smaller than those of the recumbent style folds, emphasising that the nappe movements contribute to the overall uplift. However, subsequent horizontal compression on the nappe appears to have been a far more effective uplift mechanism, albeit localised to the amplification of the refolded isobars, than the differential shear accompanying the nappe forming movements. The dimensions of the late stage folds can be derived from their wavelength (W) and amplitude (A). Wavelength determinations between two Inflection points from a cross section parallel to the tectonic shortening direction responsible for their formation, gives a wavelength approximation of 10-km. The tightness of the folds, derived from tangents to the fold surface through the inflection points, gives an average interlimb angle within the close range (70o-30o) of 40o. By using Fourier coefficient analysis, the amplitude of the fold can be derived at 14-km. When the basins and domes are considered together (eclogites are also found in some basin depressions) this figure of 28 km (2 x Amplitude) is certainly within the ballpark of differential uplift within the nappe. Amplification rates of the folds in such an environment were probably not constant and may have been slow during the early continental collision tectonic history. Rather, the eclogite exhumation would be at a maximum during the latter part of the tectonic history. Overall, it may account for some 20-30% of the total vertical uplift, especially in the case of the Upper Kaghan Nappe in the Himalayas where the first confirmed high-pressure metamorphism was found within the Indian Plate of the Himalayan Belt.

The Himalayan collision may have been diachronous from west to east. A promontory collision may have caused the earlier and deeper subduction in the northwest Himalaya and account for variation in initial Collision timing. Earliest collision may have occurred at the KT boundary.

Proceedings of the First South Asia Geological Congress, Islamabad, 1992*. Hydrocarbon Development Institute of Pakistan, Islamabad, 185-202.

The plate motion that is associated with the formation of the Himalayan Orogenic belts has been studied from many different aspects. In general, the collision of the Indian and Asian plates has essentially been described as a “head-on”, north-south collision of India into Asia with virtually no significant component of compression parallel to the plate boundaries. This is generally accepted by many workers to have occurred in Eocene times (55-40 Ma) and very few have argued that collision was significantly earlier by up to 10-25 Ma. Interpretations of strain partitioning in the Himalayan collisional belt have been made by numerous authors who emphasized that the Himalayas themselves only took up some one-third of the shortening, the other two thirds being accommodated in the Asian Plate itself. There are five main methods by which the collision of the Indian into the Asian Plate has been accommodated (extrusion (strike-slip) tectonics, uplift and crustal thickening, thrusting, extension and folding). The structural evidence from a simple “head-on”, south-north collision in the Northwest Himalayan region is not apparently convincing when many of the localized tectonic variations are considered. In view of the localized exhumation anomalies that are now found in the Northwest Himalayan region (Upper Kaghan eclogites, Nanga Parbat granulite facies metamorphism, Shang La blueschists etc.) and their associated basinal depressions (Kashmir Basin, Peshawar Basin, Skardu in intermontane Basin). It is interpreted that this may all attest to differential exhumation and subsidence for different localities in the Himalayas. These occurrences may be localized in space yet they should be explained, on a broader scale, to regional variations in the plate movements. Numerous variations along strike of the Himalayan belt can be documented in the Asian and Indian Plates. These observations, combined with the fact of the remarkable linearity of the units of Himalayan Orogen, suggest that they were diachronous. The diachroneity is suggested to be due to the rather gradual changes along strike of the major Himalayan units. Much evidence suggests a promontory collision in the Northwest Himalayan has occurred. The indentation promontory of the Indian block may have had a “triangular” shape. The promontory would be the first part of the crust to subduct and effectively go to the deepest level and attain the highest pressure for any part of the collision zone. The recognition of the eclogite facies metamorphism is suggested to be an important factor in the understanding of the timing of the Himalayan collision. Upper Kaghan may be the “tip of the iceberg” in terms of the extent of the eclogite facies metamorphism.

S/478. Spencer, D.A., 1994b. Volatile alteration and metamorphic facies: Release of H₂O and CO₂ in the Panjal traps of the NW Himalaya. *Journal of Nepal Geological Society* 10 (Abstract Volume, 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu), 12-129.

Whilst the bulk rock geochemistry of a basalt, subjected to progressively increasing metamorphic grade, may remain on the whole isochemical, it has been long known that volatiles would have to be released and cannot remain constant. Three volatiles which should change through an increase in metamorphic grade are H₂O, CO₂ and O₂. The various metamorphic grades of the Panjal Traps in the NW Himalayas (unmetamorphosed, greenschist, amphibolite and eclogite facies) provide an ideal opportunity to test these ideas and possibly act as chemical indicators of the state of alteration of the rock. Direct and indirect determination of CO₂ and H₂O were made on numerous samples.

Direct determination of CO₂ content in a rock sample has been made by coulometric titration for five main groups: Zaskar Tethyan Shelf - Panjal Trap basalts (Ba); Lesser Himalaya - Panjal Trap Basalts (PJ); Higher Himalaya Second Cover: a -Panjal Trap amphibolites (A); Higher Himalaya Second Cover: a - Panjal Trap Dolerites (D) and

Higher Himalaya Second Cover: a - Panjal Trap eclogites (E). The main observation on the occurrence of % CO₂ in the Panjal Traps with increasing metamorphic grade is that there is a decrease in % CO₂ content that appears to be fairly gradual. This therefore suggests that with increasing metamorphism, CO₂ is being driven off by decarbonation reactions.

Estimation of the volatile content in a sample can be made by the simple weight loss on ignition, and used as a method of indirect determination of H₂O. The loss on ignition and the H₂O(+FeO) in the Panjal Traps show that with an increase in metamorphic grade there is a decrease in the L.O.I and H₂O(+FeO) content that appears to be fairly gradual. This therefore suggests that with increasing metamorphism, volatiles are being driven off by dehydration reactions.

Comparison of the results of this work with the results of some published theoretical calculations are made for the wt. % H₂O of a subducting, and therefore dehydrating, oceanic crust or tholeiitic basalt. Here, predictions were made by combining calculated pressure- temperature paths with a model of metabasalt phase equilibria, where a progression (for the upper parts of the oceanic crust) pass through greenschist to amphibolite to eclogite facies. The agreement between these two independently produced sets of data is clearly apparent.

S/479. Spencer, D.A., 1994c. Where is (Is there a?) Main Central Thrust in the NW Himalayas of Pakistan? Journal of Nepal Geological Society 10, Abstract Volume, 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu, 129-130.

The term "Main Central Thrust" was first introduced into Himalayan terminology by Heim and Gansser in 1939. They described the detachment as a tectonic contact surface between a terrigenous-carbonate autochthon and an overlying metamorphic complex of mica schists and gneisses. It generally dips towards the north and is not a single tectonic discontinuity, but rather a thick shear zone, in places ranging from 5-20 km. It is associated with a strong stretching lineation, strong foliation, and high strains. Still today, much discussion occurs about whether the Main Central Thrust is actually one or two or three thrust surfaces, especially in the Central Himalaya of India and Nepal. As the Main Central Thrust is widely accepted as the intracontinental thrust that separates the Higher and Lesser Himalaya, its recognition is therefore implicit in using these unit names in the Pakistan Himalaya. Any description of the Main Central Thrust must be associated with accompanying structural, metamorphic, stratigraphic and tectonic considerations, which have been well defined in other parts of the Himalayas. For any location of the Main Central Thrust to therefore be accepted, it must comply with all, if not most, of these considerations and not just part of it. Therefore, a description or location of a possible Main Central Thrust cannot be considered without comparing on a regional scale what the implications of this definition mean.

The location of any "Main Central Thrust" in the Pakistan area of the Northwest Himalayan region is likely to remain controversial for some time. This is simply because the area where the Main Central Thrust was last seen, to the south of the Kashmir Basin, was some 100-km away from the next suggested location in Neelum and Kaghan Valleys. This intervening area between the last known location and any new suggested location is only scantily mapped in part. This is due to a border dispute between the countries of Pakistan and India regarding the Kashmir region.

The first occurrence of the Main Central Thrust at Batal, Kaghan Valley, was described by Chaudhry and Ghazanfar in 1986. Since then, ten other suggestions of locations of the "Main Central Thrust" have been made in Pakistan. Whilst it is obvious that not all of these interpretations can be correct, a review of their indicative features is given for discussion. It is also important to note that other workers in the NW Himalayas suggest that the terminology of the "Main Central Thrust" and the associated " Higher- and Lesser Himalaya" be discontinued completely in this region.

Suggested "Main Central Thrust" locations in Pakistan are:

A Main Central Thrust on the western side of the Nanga Parbat Syntaxis

The Shontargali Thrust is an analogue of the Main Central Thrust

The Panjal Fault is, in part, the equivalent of the Main Central Thrust

The Mansehra and Panjal Thrusts are coeval to the Main Central Thrust

The Balakot Shear Zone is the equivalent of the Main Central Thrust

The Oghi Thrust is the equivalent of the Main Central Thrust

The Luat Fault is the equivalent of the Main Central Thrust

Main Central Thrust is located in the lower part of Neelum Valley

Main Central Thrust is the northward continuation of the Batal Fault

Main Central Thrust is folded to form the Kaghan Syntaxis

Only one position of the Main Central Thrust, at Batal in the Kaghan Valley which was the one first recognized by Chaudhry and Ghazanfar in 1986, is generally accepted by the majority of northwest Himalayan workers (who do believe in a continuation of the MCT) as the correct location for a major tectonic contact which might correlate with the Main Central Thrust.

S/480. Spencer, D.A., 1994d. Tectonics of the Higher and Tethyan Himalayan, Upper Kaghan Valley, NW Himalaya, Pakistan. *Journal of Nepal Geological Society* 10, Abstract Volume, 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu, 132-134.

This presentation will aim to summarize the work that has been done in Upper Kaghan over the last few years, to outline existing problems and to attempt to categorise this area in a Himalayan framework (Spencer, 1993). The Upper Kaghan Nappe is tectonically situated in the western syntaxis area of the Northwest Himalaya, NE Pakistan. It belongs to the Higher Himalaya and, as such, it is here delimited by the Main Central Thrust at its base and the Indus Suture at its structurally highest position. The nappe is suggested to be unusual from the generally accepted concepts of other known regions of the Higher Himalaya. Stratigraphically, the Higher Himalaya basement (granite intruding into minor, older metasediments) is overlain by two Tethyan lithological covers (Lower Palaeozoic to Triassic?), which were also metamorphosed during the Himalayan orogeny. Structurally, numerous macrostructural measurements (planar, planar-linear, folds, faults etc.) define at least two major phases of deformation - the first associated with the nappe forming event and the latter deforming the recumbent folds to form a superposed type 1 or 3 interference pattern. Very high strain can be recorded associated with the early ductile deformation. The Indus suture shows only evidence of a late-stage "top-to-the-south" thrust sense of shear, although this is suggested to overprint an earlier extensional movement along the suture zone. This, and the late-stage interference folds (suggested to act as a mechanism for increased erosion by advancing relative uplift), act as the exhumation processes for one of the most unusual features that have been found in Upper Kaghan: the eclogites.

The eclogites of Upper Kaghan show X_{jd} contents of omphacite of up to 0.431, which retrogress to diopside. All garnets are almandine-rich ($X_{\text{alm}} = 0.460 - 0.592$) and coexist with sodic calcic and alkalis amphiboles, phengite and rutile. Garnet-clinopyroxene Fe²⁺-Mg exchange thermometry calculates a mean temperature of formation of $650^{\circ}\text{C} \pm 50^{\circ}\text{C}$. Garnet-phengite (Fe²⁺-Mg) exchange thermometry suggests $658^{\circ}\text{C} \pm 17^{\circ}\text{C} - 676^{\circ}\text{C} \pm 38^{\circ}\text{C}$. The jadeite + quartz and the phengite Si⁴⁺ barometer indicates pressures up to 17.5 kbar, suggesting depths of formation of some 60-km, the deepest known rocks yet to be found that were exhumed by the Himalayan orogenesis. Retrogressive exhumation took place at decreasing temperatures. Three stages of metamorphism are suggested: M1 - rapid increase of pressure and temperature associated with the subducting Indian plate; M2 a decompressional event with decreasing pressure and temperature associated with a stable geotherm; M3 a retrogressive phase associated with overprinted greenschist facies metamorphism. The metamorphic conditions in the nappe are not constant with evidence of isothermic but non-isobaric gradient from the core to the outer sheets of the nappe.

Cathodoluminescence observations on the carbonates of the second Tethyan cover show that at least part of the calcite is not the product of dolomite decarbonation but that tremolite and diopside are closely related to the existing calcite composition. Sedimentary structures only seen in cathodoluminescence suggests a shallow shelf sea environment of formation for the Panjal trap carbonates. XRD calculations of the mineralogical content of the carbonates distinguish between the stratigraphic lower calcite-rich carbonates and the stratigraphic higher dolomite-rich samples, although, the "Permian Carbonates" contain minor calcian dolomite ($\text{Mg}_{39}\text{Ca}_{61}\text{CO}_3$).

Geochemically, the basement feeder and cover flow eclogites and amphibolites (as well as the Lesser Himalaya and the unmetamorphosed Panjal Traps) show remarkable similar element abundances and discriminate to tholeiitic (to sub-alkalic), within plate, continental flood basalts. The Higher Himalayan basement is a peraluminous, "S"-type granite forming in a within-plate environment with signatures that closely correlate to the Mansehra granite. The peraluminous Higher Himalayan leucogranites show many similarities with the Higher Himalayan basement and appear to be derived from the basement granites. $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ isotopes on the carbonates of the Higher Himalaya second cover of upper Kaghan show a distinctive chemo-stratigraphical trend between the known and suggested Permian/Triassic sequences, suggesting stratigraphic affiliation. With increase of the grade in metamorphism, both show a regular successive depletion in the means from a $\delta^{13}\text{C}$ of +2.3‰ to -1.5‰ PDB and $\delta^{18}\text{O}$ of +20.3‰ to +16.7‰ SMOW. Isotope depletion ratios essentially depend on carbonate mineralogical content. Negative shifts of carbon isotopes at the assumed Permian - Triassic boundary of Zaskar are also found. Radioactive isotope ages of

samples from the Upper Kaghan nappe are: $^{147}\text{Sm}/^{143}\text{Nd}$ analysis of garnet and clinopyroxene in eclogite gives an age of 49 ± 6 Ma ($\epsilon_{\text{Nd}} = +2.6$); $^{87}\text{Rb}/^{87}\text{Sr}$ analysis of phengite, garnet and clinopyroxene in eclogite gives an age of 43 ± 1 (initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.70900 ± 0.00004); $^{238}\text{U}/^{206}\text{Pb}$ analysis of rutile in eclogite gives ages of 39 - 40 +1 $^{40}\text{K}/^{40}\text{Ar}$ analysis of hornblende and biotite in amphibolite and eclogite range from 35.2 ± 1.4 Ma to 42.7 ± 1.4 Ma for hornblende and 26.3 ± 0.7 Ma for biotite. $^{39}\text{Ar}/^{40}\text{Ar}$ analysis of phengite and amphibole in eclogite suggests that excess argon was incorporated as they define ages of >106 Ma for amphibole and 81 Ma for phengite. Caution is suggested when using the $^{39}\text{Ar}/^{40}\text{Ar}$ method for high-pressure samples. $^{147}\text{Sm}/^{143}\text{Nd}$ whole rock analysis of basalts, metabasalts, amphibolite, amphibolite-eclogites and eclogites, which pertain to give the extrusion age of the Panjal Traps, are 337 Ma ($\epsilon_{\text{Nd}} = +3.2$) although the M.S.W.D. is high. Whole rock $^{143}\text{Nd}/^{144}\text{Nd}$ analyses of the amphibolites and eclogites of Upper Kaghan (and the Panjal Traps of the Lesser Himalaya and Zaskar) identify them as tholeiitic continental flood basalts. $\epsilon_{\text{Nd}} t = 270$ varies between -9.9 to +4.9 with the more positive values occurring at the higher metamorphic grades. Minor continental crust contamination is present with a mixing curve evolution. Whole rock initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios range from 0.70559 ± 3 to 0.71643 ± 4 (with one exceptionally high 0.73829 ± 3) again suggesting signatures that evolved through the continental crust as tholeiitic, continental flood basalts. Using this new data and published literature data, the cooling history of the Upper Kaghan nappe is determined at $13^\circ - 14^\circ\text{C}/\text{Ma}$. Structural subdivisions of the nappe by core and outer sheet indicate a “rapid - slow - rapid” cooling history rather than a constant cooling history as determined for the nappe as a whole. The cooling history of Upper Kaghan is very different to that of the Nanga Parbat and Besham areas. It is also very different to the East Central Kohistan Island arc.

Fluid inclusion studies on the eclogites and quartzites in upper Kaghan show the presence of three systems of secondary inclusions: $\text{H}_2\text{O}-\text{CO}_2-\text{NaCl}$, $\text{H}_2\text{O}-\text{CO}_2-\text{CH}_4$ and CO_2 . Isochore calculations show that they were all the product of late stage metamorphic retrogression that led to the liberation of CO_2 and H_2O which formed in an early less dense phase followed by a late higher density phase. Tectonically, the Upper Kaghan nappe shows variation in exhumation rates from the outer sheet to the core of 0.75 - 1.3 mm/year. It is related to a model of anti-clockwise change in the tectonic transport direction, which has been earlier ascribed to the structural evolution of the Hazara-Kashmir and Kaghan syntaxis. The finding of this early, high pressure phase of eclogite facies metamorphism renews speculations that an initial Indian plate impingement occurred in the Northwest Himalayan region at around 65 Ma and that successive west - east suturing of the Indian and Asian plate continents occurred subsequently in the Central and Eastern Himalaya.

S/484. Spencer, D.A., 1995d. The Indus suture zone (Northwest Himalaya, Pakistan): Problems of high pressure lithology interpretation. Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, 5-8.

The nature (i.e. structure and lithology) of the Indus Suture in Pakistan is traced. The blueschists (yielding 100±20 to 67±12 Ma) in the suture mélange in Shangla (Swat) and adjacent areas is described, as are 49±6 to 43±1 Ma eclogites from Kaghan valley. The Himalayan deformation play an important role with the evolution of the high pressure rocks, yet these ages are interpreted as resulting from a pre-Himalayan event.

Key words: Indus Suture Zone, blueschists, eclogites, Shangla, Kaghan, Himalaya.

S/485. Spencer, D.A., 1996a. "Collapse folding" as a mechanism of explaining the early ductile extension along the Indus Suture and the subsequent exhumation of the Himalayan eclogites (Upper Kaghan, Pakistan). Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona, 141-142.

The structural evolution of the Higher Himalayan and Tethyan units of Upper Kaghan has been suggested to show a remarkable similarity to the "Pennine style of nappe formation" and deformation in the Alps: i.e., complex large-scale folding subsequent to fold nappe emplacement (Spencer, 1991, 1993). However, one of the major problems that exist in the interpretation of the "Penninic folding" model for the Upper Kaghan Nappe, is the Indus Suture. Whilst no evidence for extensional movement on the Indus Suture was found in the brittle structures, extensional movement during ductile deformation could have occurred. The Indus Suture may have had, in its early stage of deformational history, a significant effect on the eclogite facies metamorphism because the pressure-temperature-time data show that a significant amount of early exhumation had taken place during the first 15 m.y. since peak

metamorphism. Erosion alone is probably not fast enough to achieve the exhumation and the suggestion of an early phase of extensional tectonics along the suture is likely.

Froitzheim (1992), describing the D2 folds of the Swiss Austroalpine nappes, suggested that the footwall folding during extensional tectonics is not only possible, but exists to depths of several kilometers even with only moderate shear deformation. He shows the D2 folds in the Ela and Err-Carungas nappes are related to ductile crustal stretching and thinning contemporaneous with normal faulting in the Silvretta nappe. High competence contrasts and the fact that the folds are not restricted to mylonite zones, are used to suggest that a sheath fold model does not apply. A pure or simple shear extension model is suggested where both would result in footwall folding. In simple shear extension, it is suggested that the most intense folding is likely to occur in layers that dip in the same direction as the shear plane, but at a slightly steeper angle. The model is termed “Collapse Folding”.

The “Collapse Folding” model provides a solution for the formation of recumbent folds in a simple shear environment (thrusting at the base and extensional tectonics at the top). It also allows for the vertical thinning (and, therefore, exhumation) of footwall lithologies. A combination of the deformation with a thrust fault at the structurally lowest level (Main Central Thrust), recumbent nappe folding between the structurally lowest and highest levels and extensional movement at the structurally highest level (Indus Suture) is described and can explain how footwall folding (eclogite uplift in the core of the Upper Kaghan Nappe) can occur from extensional movements. The effect of uplifting the footwall with folding and lowering the hanging wall (essential for eclogite exhumation) is relatively unknown. Moreover, the timing of these features is important. If the extensional sense of movement had occurred along the Indus Suture, this would have had to develop at the same time as the footwall deformation, which produced the recumbent folds.

The following listed evidence suggests that the Upper Kaghan Nappe may be associated with the first (and subsequent second) major phase of deformation (50-35 Ma):

Rapid cooling rates within the Upper Kaghan Nappe from 50-35 Ma

Change in cooling paths within the Upper Kaghan Nappe at 32 Ma

Rapid exhumation rates within the Upper Kaghan Nappe from 50-35 Ma

Change in exhumation paths within the Upper Kaghan Nappe at 35 Ma

Convergence of cooling paths from the footwall and hanging wall of the Indus Suture after 20 Ma, suggesting that the movement that had caused their separation was now complete and underwent a common thermal history. The localized nature of the eclogite facies metamorphism which is interpreted as being controlled by the first phase of folding in that it only occurs in the core of the Upper Kaghan Nappe

Thrusting on the Main Central Thrust, which forms the lower boundary plane of the nappe, is shown by the large mylonite zone that marks its delineation with all sense of shears showing a “top-to-the-southwest” sense of movement

Early thrusting on the Main Central Thrust is shown by the fact that leucogranites, which are suggested to be formed by movements along the shear zone, give ages of $\approx$ Ma (Zeitler and Chamberlain, 1991).

The “Collapse Folding” model relies on the fact that ductile deformation can occur in an extending crust below a certain depth, which is in turn dependent on the magnitude of the least principals stress, geothermal gradient, fluid pressure and deformation mechanisms, amongst other factors. For the model to be applied in mountain-forming orogens, a steep initial orientation of the layering and then a phase of lateral extension is then required for footwall ductile folding to occur. Extension can be caused by any mechanism (gravitational spreading, pull-apart extension, lateral, etc.) and the results are suggested to be the same.

An interpretation of the above evidence explains the rapid exhumation of the Upper Kaghan Nappe whilst the early D1 folding was occurring (Spencer, 1993). The “Collapse Folding” is interpreted to occur coeval with the thrusting along the Main Central Thrust and extension along the Indus Suture. The fact that the “Collapse Folding” occurred so early in the deformational history allows for the conditions of ductile folding to occur in the footwall whilst the extension is still occurring. Most importantly however, unroofing and uplift that would not be present if the Indus Suture maintained its thrust sense of shear. Discussion on the reasons for the change from thrusting to extensional movement at or around 50 Ma and a model to show the formation of recumbent folds in a simple shear, “Collapse Folding” regime will be shown.

Key words: Structural evolution, collision, Kaghan valley, Himalaya.

S/486. Spencer, D.A., 1996b. The Upper Kaghan Nappe (NW Himalaya, Pakistan): Regional Synopsis. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona, 145-146.

The tectonic evolution of the Upper region involves two simple considerations: the mechanism of subducting the Indian Plate to depths within a specific time that is constrained by the large-scale plate tectonic forces and, secondly, its subsequent exhumation to the surface where it is found today. The relation between the timing of peak metamorphism and the timing of collision of the Indian Plate shows that Himalayan metamorphism in the Upper Kaghan region was well under way by 50 Ma and that peak metamorphic conditions were reached very soon after collision. It is important to ascertain whether the Upper Kaghan eclogites can be subducted to the appropriate depths in the given time available and whether the lithologies will heat up to produce the suggested 650°C suggested for the peak metamorphic temperatures. Theoretical thermal observations suggest that Himalayan metamorphism is the result of thermal relaxation after crustal thickening and has been used by previous researchers as a type example in the continental collisional models. Predictions necessitate that at least 20-25 m.y. is needed for thermal equilibrium to heat the Indian Plate to 650°C, unless an alternative heat source is found. If the Himalayan metamorphism is not related to crustal thickening, then its relationship to the actual processes of subduction of the Indian Plate beneath the Kohistan Island Arc is the most viable alternative. Plate models rely on a rather simplistic set of parameters: plate velocity, depth of subduction, distance of subduction, angle of subduction and finally the time needed for subduction.

The results for the rates of subduction, with variations in the angles of subduction range from 5° to 45° which subsequently alters the distance to subduct (to eclogite forming depths of 60 km) from 42 km to 688 km. This is coupled with the velocity of the plate movement, which is varied from between 15cm/year to 1cm year. If the most generally accepted velocity of Indian Plate movement (15cm/year) and angle of subduction (30°) are considered, then only a minimum time interval of less than 1 m.y. is needed to produce the depth sufficient to attain eclogite facies metamorphism in the Upper Kaghan region. With virtually any angle of subduction from 5°-45°, the subducting slab will reach depths of eclogite formation in less than 5 m.y. This suggests that collision can have occurred at any time from 0.8-4.6 m.y. before the peak metamorphism, and any estimate that can therefore range from 50-56 Ma for the timing of collision is acceptable for the depths achieved for eclogite formation. The time needed to reach the temperature of formation of the eclogite is calculated by solving the one-dimensional conduction equation. Here, temperature of eclogite formation can be obtained by heating as a result of subduction as the depth of penetration of a given isotherm increases with plate velocity. Therefore, the depth of the slab temperature inversion within the slab decreases with increasing plate velocity, easily resulting in the necessary temperature recorded by the Upper Kaghan eclogites. The fundamental key to achieving this result is the temperature recorded by the Upper Kaghan eclogites. The fundamental key to achieving this result is the velocity of the Indian Plate at the initiation of collision. If it is fast, subduction will be rapid and eclogite depths of formation easily achieved with corresponding medium (600°C) temperatures.

Exhumation consists of the amount of material that has been removed by erosion or tectonic thinning (i.e., relative uplift combined with erosion). The exhumation rate is the rate at which a rock rises from depth of burial towards the earth's surface. Time-averaged rates of exhumation can be obtained from depth-time averages. Maximum pressure estimates of the eclogite path give 16-18 Kbar, which equates to depths of formation at 60-65 km with peak metamorphism at 49 Ma. The average exhumation rate is, therefore, 1.2-1.3 mm/year. By contrast, maximum pressure estimates for the amphibolite path give 8-9 Kbar which equate to depths of formation at 30-35km with peak metamorphism around 40 (?) Ma. The exhumation rate is, therefore, 0.7-0.9 mm/year. These exhumation rates are more or less consistent with previous authors, interpretations of exhumation rates for the areas to the west of Upper Kaghan e.g., for Nanga Parbat at 1 mm/year and for the Suru region at 1.4-2.1 mm/year. Nevertheless, whilst these exhumation rates are comparable for the Northwest Himalaya, they bring rocks in the core of the upper Kaghan nappe to the present surface from depths of almost double those exposed in Nanga Parbat. This is simply due to the timing of peak metamorphism and the depths from which they originated. Exhumation rates can also be derived from pressure-temperature paths (i.e., the appropriate depth at which the cooling age occurred). The amphibolite facies area plots with an early stage of rapid exhumation and then a slowing down at 35 Ma. For the eclogite nappe core, the results again show an early stage of rapid exhumation and then a slowing down at 35 Ma. This shows that the exhumation was much greater in the early part of the Himalayan orogeny than in the later. Perhaps as much as two thirds of the exhumation took place in the first 15 m.y. with a noticeable change in the exhumation rates at around 37 Ma. This exhumation is suggested to be related to two main tectonic processes: early extension along the Indus Suture with associated "Collapse Folding" and late fold superposition combined with erosion. The evidence shows a fast exhumation history in the first 15 m.y., that is, in the early stages of the nappe emplacement combined with extension. This is suggestive of exhumation during convergence. Other evidence, however, does come from the pressure-temperature path which changes from the perturbed/stable to the relaxed state (i.e., heating begins signifying that the subduction is over). The underplating of the Indian Plate below the nappe is considered to be of

crucial importance in driving the exhumation as it is this that creates the normal faulting along the Indus Suture that appears to thin the crust and exhume the nappe.

In summary, the exhumation history and exhumation rates all point to the fact that Upper Kaghan appears to be the most far traveled nappe known so far in the Northwest Himalayas and possibly in the Himalayas. This may assert that, during the collision of the Indian Plate, the Upper Kaghan nappe was the first impinging part of the Indian Plate to collide due to the Indian Plate promontory and again suggests that the Indian Plate collision was not simply one of head-on collision, but one that varied from west to east across the Himalayan belt. For an overview of some of the features associated with the Upper Kaghan Nappe, a time chart for the structural, metamorphic and cooling history, related to the Indian Plate motion, is given. Its aim is to show how many aspects of the tectonic history of Upper Kaghan show some remarkable interactions with each other. A summery model of the collision and subsequent exhumation of the Upper Kaghan Nappe is also presented.

S/487. Spencer, D.A., 1996c. Structural geology of the upper Kaghan nappe, NW Himalayas, Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona, 151-152.

The structural geology of the Upper Kaghan area shows a complex history of Himalayan-aged deformation which resulted in the formation of many small-scale and large-scale features. Many observations of small-scale structure were made at the micro-, macro- and megascale.

Planar Structures

Planar structures, such as the preservation of original sedimentary bedding surfaces, which are surfaces of primary accumulation, are only preserved in the Higher Himalayan First and Second Covers. No evidence was found for bedding in the Higher Himalayan Basement. A schistosity is often parallel to a gneissic foliation or banding consisting of impersistent laminae and segregations of mineral grains. All evidence suggests that the schistosity that is observed in the Upper Kaghan region is of Himalayan age. This is based on the fact that the mineral grains show a preferred orientation (such as mica, flattened quartz and amphibole) that form as a result of the imposed tectonic strain field have been dated as Himalayan. No evidence has been found that suggests that the schistosity cuts a pre-existing penetrative fabric. The orientation of the schistosity in the Upper Kaghan area is extremely varied, explained by subsequent refolding of the S1 schistosity by a later F2 folding event. An axial planar crenulation cleavage occurs that is approximately parallel to the axial planes of the folds of the deformation, which produced the schistosity. The axial planar crenulation cleavage generally has a northeast-southwest or north-south orientation and are parallel (or subparallel) to the F2 folds. The position of the limbs and hinges of the fold cause a striping known as the crenulation cleavage fold axes to occur. This banding forms due to the relative enrichment or depletion of insoluble and soluble minerals such as quartz and mica. The calculated crenulation cleavage fold axes lies close to the great circle of the F2 fold axes and the F2 fold axis congregate around this position. The mean vector of all the data shows a consistent northeast-southwest orientation. A plot of the crenulation cleavage traces joins the axial surfaces of the small-scale crenulation cleavage folds. These directions can generally not be extended over very large areas as the folds are often impersistent. Nevertheless, they provide further indication of the strain ellipse XY plane orientation of the second phase of deformation. All crenulation cleavage traces indicate a ubiquitous northeast-southwest orientation, apparently parallel to the crenulation cleavage fold axes and the L1 mineral-stretching lineation.

Planar-linear and linear structures

Four lineations were measured. An intersection lineation is either aligned parallel to the axes of the F1 folds showing a low to moderately dipping, northeast-southwest orientation or sub-parallel to the mineral-stretching lineation. A mineral-stretching lineation is defined by mica, amphiboles and phyllosilicates and is low to moderately plunging, with a southwest-northeast orientation. The lineation is far less common around the Basal area due to the fact that the Basal area comprises of the structural core of the Upper Kaghan nappe where the metamorphism appears to predate the main deformational period. A few observations of a crenulation cleavage intersection lineation are found in regions where the F2 folds form a fold hinge. Variations in orientations ranged from plunges of north to northeast, although always at moderately dipping angles.

Folds

Folds form an important structural component of the Upper Kaghan area. The large, nappe scale F1 fold axes were never directly measured in the field (as no hinges to these major folds were directly observed). The existence of the F1 folds through smaller scale folds however possibly relate to the major fold axes. In general, the fold axes strike

form northwest-southeast, plunging at low to high angles. The F1 fold axes are sub-perpendicular to the mineral-stretching lineation. The folds are generally recumbent (tight to isoclinal). F1 fold axial planes were generally oriented at low dips, although the values were often quite variable due to subsequent refolding by F2. F1 fold axial traces varied throughout the Upper Kaghan nappe due to the refolding of F2. In the Besal area, this probably had an initial strike east-west, but this direction was subsequently changed orientation to north-south. The F2 fold axes are found to be associated with the crenulation cleavage folds and crenulation cleavage and were probably formed synchronously. The F2 fold axes show a northeast-southwest trend and plunge at moderate to very steep angles. The dimensions of the F2 fold are regional in scale. They are open to tight folds. The axial planes have a northeast-southwest orientation with dips to the southeast and, occasionally, to the northwest. The F2 fold axial planes are almost vertical-moderately dipping tectonic features that could be fairly continuously traced through the Upper Kaghan Nappe in a northeast-southwest orientation. The F2 fold axial trace structures continue across the whole region and roughly trend with the present outcrop of the Indus Suture suggests that there is a common link between them. A structural domain calculated F2 fold axial plane is virtually vertical-dipping 87° to the southeast. The folds are tight due to the wide spread of the poles to bedding over the great circle. Other minor structures that were found in the Upper Kaghan are syn-sedimentary extension faults, veins and joints.

Strain Analysis

Strain analysis was attempted on strain markers such as xenoliths, schlieren, marble lenses, amygdaloids, folded veins, stretched feldspar in augen gneiss and a stretched amphibole dyke. Two main types of strain ellipse were found in the Upper Kaghan Nappe: one of uniaxial flattened ellipsoids and the other of uniaxial constricted ellipsoids. Amounts of extension in stretched grains varies to a maximum of 32%. All strain analysis indicates that the strain values are very high, typical for the internal zones of mountain belts where ductile deformation is the main style for deformation. Sense of shear of the movement along the suture zone, such as imbrications, ramping, rotated boudins, overfolds, slickensides, kink bands, crenulation cleavage fold axes, crenulation cleavage and mineral-stretching lineation relations, fold intersection lineation, orientations of the fibres and overstepping fibres all give a “top-to-the-south” sense of shear. No evidence for brittle extensional movement was found along the Indus Suture at Babusar Pass.

Regional Tectonics

The geometric relationships of the mesoscopic structures can be used in the Upper Kaghan region to infer what is happening on a more regional scale. The delineations of the geometric relationships suggest that two/three? major phases of deformation will account for what is observed. The superposition observed does not seem to fall under a simple classification. It appears to be a series of domes or basins of the type 1 classification, which, due to the high ductility environment in which they were found, resulted in the rotation of the first formed fold axis sub-parallel to the second tectonic transport direction, especially noted in the Naran area. In the Besal area, the interference pattern that occurs is possibly a type 1 to 3, where 1 is the dome itself and 3 is the convergence and divergence pattern of the first formed fold axis. The two main phases of deformation are: a First phase of deformation (D1) and Second phase of deformation (D2) although locally there are indications of a Third phase of deformation (D3) and a Pre-Himalayan deformation. D1 consists of the development of the Indus Suture followed by the Main Central Thrust with deformation continuing throughout early stages of fold formation; extension along the Indus Suture and southwest-northeast transport movement producing major folds, schistosity and mineral-stretching lineation. D2 is fold formation with southeast-northwest regional fold superposition, crenulation cleavage formation, although it may be a progression (i.e., anticlockwise rotation transport direction) of D1. This is followed by a late regional fold compression leading to the basin and dome formation, possibly east-west.

Comparison of the suggested structural evolution of the Upper Kaghan nappe to the other regions of the Higher Himalaya which lie to the east (Nanga Parbat Syntaxis and Zaskar area) and the west (Besham area and Swat region) show that similarities exist with the Zaskar and Swat regions for the overall regional deformation. However, the thrust imbrication of nappe pile by late stage tectonic movements is not seen and correlations with the tectonic history of Besham are difficult. Except for the timing of the tectonic events, broad correlation can be made with the Nanga Parbat area, in terms of the structural style of deformation, although the latter formed in a time period by which the deformation in the Upper Kaghan area was virtually complete.

S/488. Spencer, D.A., 1997. Reactivation of early collisional structures-the long and varied geological history of the Indus suture (NW Himalaya Pakistan). Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 223.

Suture zones are boundaries between crustal blocks carried on two different tectonic plates that were subsequently juxtaposed by plate motions. As such, they are sites of former oceans that play an important role in our interpretation of the geodynamic evolution of orogenic belts. Almost by definition, a suture zone marks one of the earliest events in any collisional cycle. Paradoxically, these early zones of deformation are often reactivated at later stages in their tectonic history, to such an extent that even neotectonic activity can be seen along these older structures. These late stage deformational events can, in many cases, completely wipe out any evidence of the typical suture zone lithologies (such as ophiolites).

Although suture zones are often characterized by the presence of ophiolites, their subsequent obduction and preservation is inevitably a question of their structural evolution throughout the subsequent collisional processes. As continental collisions themselves are generally not simple head-on processes, it is inevitable that the along-strike development and preservation of suture zones vary. For example, there is a marked difference along the strike of the Indus Suture, which separates the Indian Plate and the Asian Plate. This is especially so in the western part of the Himalayan chain (i.e., Northwestern India and Northern Pakistan) where the suture between the Indian Plate and the Asian Plate is located at the base of the Kohistan-Ladakh complex.

Why are suture zones targets for fault reactivation? What do they inherit that allows them to be subsequently deformed by later tectonic movements? It is known that documented ophiolite remnants in the Himalayas of Pakistan are restricted to a few regions (e.g., Shang-La, Dargai). Intervening areas have been strongly affected by post collisional deformation that has now removed most of the evidence that this tectonic boundary was once a former site where oceanic subduction had taken place. Intriguing questions therefore remain about what controls these post-collisional movements? In particular, why is it that across the border from Pakistan into India, the Suture Zone is preserved almost relatively free from any of the severe deformation associated with the Himalayan Orogeny? In this context, it is necessary to examine the reasons why (in Pakistan) one of the earliest structures associated with the oceanic subduction/continental collision cycle seems to play such an important role in the late stage deformational (and therefore exhumation) history of the footwall plate.

S/490. Spencer, D.A. & Gebauer, D., 1996. Shrimp evidence for a Permian Protolith age and a 44 Ma metamorphic age for the Himalayan eclogites (Upper Kaghan, Pakistan): Implications for the subduction of Tethys and the subdivision terminology of the NW Himalaya. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona, 147-150.

Since the discovery of the High Pressure Metamorphism in the Upper Kaghan region (Pakistan), a number of questions were raised that needed to be answered for a better understanding of the geodynamic evolution of the eclogites and their country-rocks. Some of these questions have now been answered and the results published (summary give below). New results are presented here to solve another question, which is related to the eclogite protolith age and a more age of HP-metamorphism.

Proof of eclogite existence

Microprobe analysis showed the presence of omphacite + garnet (no plagioclase was found), confirming the discovery of high-pressure eclogite facies metamorphism in the Himalayan belt. A typical high-pressure assemblage found in the Upper Kaghan consists of omphacite-garnet-quartz-rutile (Spencer et al., 1990, 1991; Pognante and Spencer, 1991; Spencer, 1993).

Pressure-temperature conditions of formation

The analysis of the eclogites has given calculated depths of formation, based on mineral geobarometry, of around 60 km (Spencer et al., 1990; Pognante and Spencer, 1991; Spencer 1993) and are the deepest known rocks to have been exhumed from the Indian Plate. Geothermometry calculations of the suggested peak metamorphism by the garnet-clinopyroxene geothermometer gives $T=650^{\circ} \pm 50^{\circ}\text{C}$.

Geochronology of eclogites

Tonarini et al. (1993) showed that the eclogite facies metamorphism of Upper Kaghan was of Himalayan age. Specifically, a peak metamorphic age of 49 ± 6 Ma was obtained by the Sm/Nd method in garnet-clinopyroxene. Cooling ages were obtained with the Rb/Sr radiometric dating in phengite at 43 ± 1 Ma and U/Pb in rutile at 39–40 Ma, both of which are interpreted to constrain the thermal evolution of the eclogite down to $\approx 500^\circ\text{C}$. Tonarini et al. (1993) and Spencer (1993) also showed that Ar/Ar and K/Ar analysis of phengite and hornblende can give meaningless results when compared to the Sm/Nd, Rb/Sr and U/Pb ages obtained in the same sample. This is almost certainly due to excess argon.

Mechanism of exhumation

The fact that the high pressure rocks are located within the NW Himalayan syntaxial region suggests that, in part, their late-stage erosion-dominated exhumation was also controlled by the large-scale late-stage folding associated with the syntaxial formation. However, evidence exists that the majority of the exhumation was achieved by a reactivation of the Indus Suture from initial thrust tectonics (associated with the subduction of the Indian Plate beneath the Kohistan Island Arc) to ductile extensional tectonics, a “collapse folding” scenario which is driven by the movements on the Main Central Thrust (Spencer, 1993).

Geochemical characteristics

Bulk rock geochemistry and Sr-Nd isotopic composition were made and results were compared to lower grade metamorphic equivalents of rocks of the same as well as to unmetamorphosed basalt. Major and trace element diagrams indicate tholeiitic to alkalic magma compositions, which evolved by fractional crystallization. $^{87}\text{Sr}/^{86}\text{Sr}$ initial values 270 Ma for the eclogite are 0.7053–0.7073 with values increasing for metabasites of lower metamorphic grade. $^{147}\text{Sm}/^{144}\text{Nd}$ values range from 0.1397–0.2096. Nd(270) from +4.9–10. The lowest initial values occur in the least metamorphosed rocks. Based on their bulk geochemistry and isotopic data, the eclogites could be the equivalents of the Permian Panjal Traps (Spencer et al., 1995).

Protolith age

In the Higher Himalaya of Kaghan Valley (and in the areas further to the west), a basement-cover sequence was recognized that is clearly different from the last known occurrence of the basement-only lithologies to the east in Zaskar (Greco et al., 1989). The basement consists of the Higher Himalayan Crystalline (*sensu stricto*) with granitoids and metagranites. This is overlain by a cover unit of metagrawackes of suggested Lower Paleozoic age with a clear sedimentary origin. This is then diachronously and unconformably overlain by a distinctively mappable unit consisting of some 30–40 extensive amphibolite layers at the base of the cover. It is associated with syn-volcanic marine deposits (marble). This sequence then develops into an extensive dolomite-rich shelf sequence with minor mica-schist horizons.

Two main ideas exist on the age of the cover units and the associated eclogites:

The metasedimentary units were thought to be part of the Precambrian Salkhala Formation proposed by Wadia 1931. This interpretation has been incorporated into numerous works since.

Greco et al. (1989) and Papritz and Rey (1989) first made the suggestion that the cover sequence was not Precambrian, but suggested a correlation and comparison between adjacent regions. To the east, for example, the Permian Panjal Traps and overlying Triassic series have a distinct similarity to the Cover units found in Upper Kaghan. Subsequently, numerous lines of evidence link the metamorphosed (eclogite/amphibolite facies) cover to the unmetamorphosed (with up to greenschist facies transition) equivalent (Greco et al., 1989; Papritz and Rey, 1989; Spencer et al., 1991; Spencer, 1993). This is based on field, petrographic, geochemical, stratigraphic, structural, fossil, stable isotope and regional correlations.

Accurate determination of protolith and metamorphic peak ages of mafic rocks is a difficult geochronological task (for a summary, see Gebauer, 1990). This fact is also illustrated with the Upper Kaghan eclogites as Sm-Nd whole-rock data (Spencer, 1993; Spencer et al., 1995) yielded an unpublished errorchron ‘age’ of 337 ± 434 Ma. SHRIMP-dating, especially when combined with cathodoluminescence information of the zircon to be dated, is the most promising technique available today to obtain this required information (e.g., Gebauer et al., 1988; Gebauer, 1990, in press; Schafer et al., 1993; Vavra et al., in press). Thus, zircons from the eclogites of Upper Kaghan (Sample 90/80 used in Tonarini et al., 1993) were analyzed to help solve the problem of the disputed and geochronologically poorly constrained protolith ages of the Higher Himalayan Cover and hopefully get a precise as possible age of high pressure metamorphism. Within the oscillatory-zoned zircon domains that were formed during precipitation of zircon in the mafic protolith, a Permian protolith age of about 269 Ma was found. It is important to note that, based on the size of the magmatic zircons, the protolith was not effusive (basaltic) but intrusive (e.g. gabbroic). This is in accordance with the outcrop locality—a basement feeder (Tonarini et al., 1993; Spencer, 1993); this data confirms a Tethyan affinity and, therefore, the stratigraphic correlations that were first suggested by Greco et al. (1989). Apart from a number of clearly discordant ages, a metamorphic rim age of 44 ± 3 Ma was found, in accordance with the Sm-Nd mineral data of Tonarini et al. (1993) which gave 49 ± 3 Ma. However, due to the smaller error of the

SHRIMP-data, the pressure peak, coinciding closely with the temperature peak, is now better constrained. One spot age giving ca. 470 Ma in a magmatic domain proves the presence of inherited zircon components of very probably early Paleozoic age. This may therefore indicate that the Higher Himalayan Basement can be correlated with the ≈ 500 Ma Lesser Himalayan “Mansehra” Granites of the “Pan-African” event. This contamination is probably one reason for the scattered Sm-Nd WR-data and subsequent errorchron ‘age’.

Implications for the Subduction of Tethys

Not only do these new results provide for a modified extension of the Tethyan Himalaya into Pakistan, they more importantly give geologists a unique metamorphic record of a continental collision. The Panjal Traps, which consist of basalts with interlayered carbonates, can be stratigraphically mapped in Upper Kaghan (Pakistan), where they are found in eclogite, amphibolite-eclogite facies and amphibolite facies, along-strike to their lower grade equivalent (greenschist facies and unmetamorphosed) in the Tethyan Himalaya of Zaskar (India). This complete record of vertical (dominantly depth-controlled) progressive metamorphism for a colliding and subducting continent has been differentially exhumed to its now relatively horizontal position. One stratigraphic unit can therefore be traced in five metamorphic grades to provide a unique record of a colliding continent. Each metamorphic grade will show the effects of the prevalent pressure-temperature conditions and provides a progressive record of the subducting continent on the same stratigraphic protolith.

Implications for the Subdivision Terminology of the NW Himalaya

The arcuate curvature of the Himalayan mountain belt becomes more complex in the northwest (Pakistan and India) and northeast (Tibet and India) syntaxial regions. The northwest Himalayan syntaxial region is dominated by the structural anomalies of the Nanga Parbat, Kaghan, Hazara-Kashmir and Besham syntaxes (Spencer, 1994). Here, the linearity of the Himalayan topography changes in direction from a general northwest-southeast orientation to a more southwest-northeast orientation. The structural reorientations of lithologies that resulted from syntaxial formation give evidence for some of the fastest exhuming metamorphic regions in the world. Subsequently, the interpretations of the tectonic setup to the Himalayas changed from one of relatively simplicity to a complicated terminology with numerous indications suggesting that the Lesser-, Higher- and Tethyan Himalaya terminology should be totally abandoned in these areas. Only recently have both the separation, terminology and definitions of the Lesser- and Higher Himalaya become apparent (Chaudhry et al., 1994; Greco and Spencer, 1993). The new SHRIMP evidence now shows that the Higher Himalaya and Tethyan Himalaya can also be clearly distinguished in the NW Himalayan region. However, the Tethyan Himalaya is clearly modified in this region and, for the sake of consistency and conformity, we suggest that the term “Higher Himalaya” be kept in the Pakistan Region, even though it is now shown that this Higher Himalayan unit act as a basement to its cover of the “Tethyan Himalaya”.

S/491. Spencer, D.A., Ghazanfar, M. & Chaudhry, M.N., 1988. Deformation on the Main Mantle Thrust zone at Babusar Pass Karakoram Highway Pakistan. Geological Bulletin, Punjab University 24, 44-60.

The Main Mantle Thrust Zone passes through the Babusar Pass area as a complex zone of, not just one, but three thrust faults that enclose a complex assemblage of two tectonic mélanges. This Indus Suture Mélange Group includes an earlier subduction-related ultramafic mélange and a later metavolcanic mélange. Deformation on the suture zone results in the formation of various structures that give a six phase deformation history, dividing the area into four structural domains. This leads to a four stage tectonic evolution, comprising of a subduction stage, obduction stage, lateral movement stage and a neotectonic stage.

Key words: Deformation, MMT, Babusar, KKH.

S/492. Spencer, D.A., Ghazanfar, M. & Chaudhry, M.N., 1990a. Structural of the Higher Himalaya, upper Kaghan valley, NW Himalaya, Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 1-2.

The Higher Himalaya of the NW Himalaya is a complex sequence of granites, gneisses, metapelites, marbles, amphibolites, quartzites and in situ ultramafics. It is bound by two major thrusts: the Main Central Thrust (MCT) to the south and the Main Mantle Thrust (MMT) to the north, which have subsequently led to the exposure of some of the deepest level rocks of the Indian plate during collision with the Asian plate. A complex deformational history of pre-, syn-, and post-“Himalayan” age is associated with a pre- to syn- deformational upper amphibolite (kyanite to

sillimanite) facies metamorphism which reached in places over 6500C, as evidenced by in situ migmatization and granitization.

The Higher Himalaya of Kaghan Valley is structurally positioned between three major syntaxes: the Hazara-Kashmir syntaxis (HKS), the Kaghan Syntaxis (KS) and the Nanga Parbat Syntaxis (NPS) which are interpreted as forming due to a change in transport direction. Between the Kaghan Syntaxis and the Nanga Parbat Syntaxis, the Higher Himalaya consists of a polyphase, superposed folded domain which produces the Burawai synform, the Besal antiform and other large-scale features located to the south in Neelum Valley. The fold interference patterns are affected by the extreme ductility of the rocks and caused the rotation of, not only the first fold axis, but also the whole interference structure itself, as seen by the asymmetrical shape of the Besal antiform.

A provisional tectonic analysis of the features observed suggest that the first southwestwards-directed phase of nappe transport led to a thickening of the tectonic pile, and that thickening was followed by a northeast-southwest directed deformation. This is in accordance with movements suggested for the formation of the Hazara-Kashmir and the Kaghan syntaxis and leads to the suggestion of a similar model, with a further increment of anticlockwise transport direction change, for the formation of the Nanga Parbat Syntaxis.

S/493. Spencer, D.A., Ghazanfar, M. & Chaudhry, M.N., 1990b. Fold interference patterns in the higher Himalayan crystalline unit, upper Kaghan valley, NW Himalaya, Pakistan. Abstract volume, 5th Himalaya-Karakoram-Tibet Workshop, Milano, p.58.

The Higher Himalayan Crystalline Unit (HHCU) of the NW Himalaya is complex sequence of granites, gneisses, metapelites, marbles, amphibolites, quartzites and insitu ultramafics. It is bound by two major thrust: the Main Central Thrust (MCT) to the south and the Main Mantle Thrust (MMT) to the north, which have subsequently led to the exposure of some of the deepest level rocks of the Indian plate during its collision with the Asian plate. A complex deformational history of pre-, syn-, and post "Himalayan" age is associated with a pre- to syn-deformational upper amphibolite (kyanite to sillimanite) facies metamorphism which reached in places over 6500C, as evidenced by insitu migmatization and granitization.

The HHCU of Kaghan Valley is structurally positioned between three major syntaxis: the Hazara-Kashmir Syntaxis (HKS), the Kaghan Syntaxis (KS) and the Nanga Parbat Syntaxis (NPS) which are interpreted as forming due to change in transport direction. Between the Kaghan Syntaxis and the Nanga Parbat Syntaxis, the HHCU consists of a polyphase, superposed folded domain which produces the Burawai synform, the Besal antiform and other large-scale features located to the south in Neelum Valley. The fold interference patterns are affected by the extreme ductility of the rocks and caused the rotation of, not only first fold axis, but also the whole interference structure itself, as seen by the asymmetric shape of the Besal antiform.

A provisional tectonic analysis of the features observed suggest that the first southwestward-directed phase of nappe transport led to a thickening of the tectonic pile, and that thickening was followed by a northeast-southwest directed deformation. This is in accordance with movements suggested for the formation of the Hazara-Kashmir and the Kaghan syntaxis and leads to the suggestion of a similar model, with a further increment of anticlockwise transport direction change, for the formation of the Nanga Parbat Syntaxis.

Kaghan valley, in north Pakistan, provides an unparalleled cross-section of the Indian Plate in the Himalaya, with all of the tectonic units, structural features and metamorphic grades of the Indian Plate exposed in one valley. The Higher Himalaya Crystalline of the NW Himalaya, which exposed in one valley. The Higher Himalaya Crystalline of the NW Himalaya, which crops out in the upper reaches of the valley, is a complex sequence of granites, gneisses, Calc-pelites, metapelites, marbles, amphibolites, quartzites and eclogites. It is bound by two major thrust: The Main Central Thrust (MCT) to the south and the Main Mantle Thrust (MMT) to the north, which have subsequently led to the exposure of some of the deepest level rocks of the Indian plate during its collision with the Asian plate. A complex deformational history of pre-, syn-, and post- "Himalayan" age is associated with a pre- to syn- deformational upper amphibolite (kyanite to sillimanite) to eclogite facies metamorphism, which reached in places over 6500C, as evidenced by minor insitu granitization.

S/498. Spencer, D.A. & Herren, E., 1992. Geochemistry of higher Himalayan leucogranites: Comparison between upper Kaghan, Zaskar, Manaslu and Bhutan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 128.

Late stage leucogranite Intrusions In the Higher Himalaya and Tethyan covers are well known all along the length of the Himalayas, although they are far more prolific in the central parts of the Himalayas than the NW Himalaya. A few exposures of these Intrusions have been recorded in Kaghan In the NW Himalaya. They are of special Interest for Himalayan evolution as they are one of the rare magmatic products of the Himalayan collision zone. Geochemical analysis of leucogranites has been previously carried out by workers at the Swiss Federal Institute of Technology with leucogranites from two other areas (Zaskar and Bhutan) from the Himalayan belt. Similar methods of preparation and measurement have been made on the Kaghan rocks and allows direct comparisons between the major and trace element analysis with a higher degree of certainty. The analysis of the Zaskar leucogranite were carried out by Herren (1987) and of the Bhutan leucogranite by Dietrich and Gansser (1981). Reference is also made the Manaslu Leucogranites (Le Fort et al., 1987).

Analyses are presented in three chemical mineralogical diagrams (Debon and Le Fort, 1983). In a Q-P Diagram, the Manaslu leucogranites center on the adamellite sector; Zaskar leucogranites range from granites to granodiorites, whilst the Kaghan leucogranites range from adamellite to granodiorite. Characteristic mineral (A/B) plots show all samples In the leucocratic field ($B < 38.8$), with the exception of one sample. In the O-B-F diagram, all samples plot In the leucogranites field, with most plotting below the critical quartz-poor field line. Kaghan. Manaslu and Zaskar leucogranites show a negative correlation between Na₂O and K₂O with (Na₂O+K₂O) varying from 8-8.5 for Manaslu, 7.9-8.6 for Zaskar and 7.2-8.9 1 for Kaghan.

Major and trace element spider diagrams for Kaghan and Zaskar were normalised to a Bhutan mean standard deviation. Discrimination Is made for the tourmaline-, garnet-biotite and garnet-varieties in the Zaskar region, but only tourmaline leucogranites are found in the Kaghan region. The Kaghan leucogranites, compared to Bhutan normalizations, are enriched In Ba, Sr, Y, Zr, Ti, Sc and Zn but are depleted In Rb, K, P, Na, K, Pb and Co. The actual values more or less mirror the Zaskar tourmaline leucogranite, except that the Kaghan samples are far more enriched or depleted In the respective minerals with the notable exceptions of Sr, Zr, Ti and Zn. A-F-M plots of the Kaghan leucogranite compared to a typical calc-alkaline differentiation trend, for example in granitoid rocks from the Trans-Himalayan Batholith, are unusual In that they seem to be the only leucogranites that show any differentiation. Selected trace element variation diagrams (Zr, Y, Ba and Rb) with increasing SiO₂ also show a magmatic differentiation trend.

These results show that there is a variation along the Himalaya of the leucogranites in terms of selective major and trace element geochemistry. Previous workers (e.g. Villa, 1988 and Pognante, 1991) have also noted changes in leucogranites in terms of cooling ages (20-19 Ma in the NW Himalayas to 16-14 Ma in the eastern Himalayas) and PT evolution (kyanite $\pm$ sillimanite bearing in the NW Himalayas and cordierite - andalusite bearing in the eastern Himalayas). The main reason for this variation is due to the timing of collision and the state of development of the MCT for the liberation of large quantities of fluid and anatexis melting of the crust. The MCT was mature enough for this process in the central Himalayas, but not in the Kaghan region. Furthermore, PT paths and cooling histories of the Upper Kaghan nappe suggest that the relaxation of the geotherm was very rapid, with a decrease of temperature below the level where anatexis melting is possible. As such, inverse prograde metamorphism below the MCT in Kaghan was probably too fast to liberate large quantities of fluid necessary to produce the melting temperature of this crustal source and therefore only produce a limited number, and rather differentiated suite, of leucogranite. Zeitler and Chamberlain (1991) also notes SHRIMP ion microprobe analysis to obtain U-Pb dates on zircon in leucogranites in Upper Kaghan of about 50 Ma, which would again support the notion of rapid metamorphism and exhumation after collision.

S/499. Spencer, D.A., Hubbard, M.S. & West, D., 1995. The role of the Indus suture in the exhumation of the Nanga Parbat massif (Indian Plate, NW Himalayas). Abstracts, International Symposium on Himalayan Suture Zone of Pakistan. Pakistan Museum of Natural History, Islamabad, 8-9.

Whilst there is no doubt that the initial sense of movement along the Indus Suture has to be a bulk 'top-to-the-south' thrust sense of shear associated with the subduction and underthrusting of the Indian Plate underneath the Kohistan Island Arc it is obvious that, if this sense of movement, continued from the time of collision until the present day a very active type of exhumation process would be needed to explain how the Higher Himalayan Crystalline in the footwall of the suture is exhumed. In the Central Himalaya, the effective means of exhuming the Higher Himalayan Crystallines has been achieved by extensional tectonics (accompanied by erosion), occurring along the boundary that separates the Higher Himalayan Crystalline and the Tethyan Sedimentary Series. In Pakistan, these Tethyan sediments were subducted with the Indian Plate and arc now overlying the Higher Himalaya Crystalline.

Recent fieldwork results from locations along the Suture Zone show that extensional deformation has been, in part, responsible for the exhumation of the Indian plate. However, this clearly varies in timing duration and the amount of exhumation that has occurred and was, in most locations, subsequently overprinted by brittle, top-to-the-south thrust sense of shear. This is interpreted as the end of the extensional tectonics and the welding together of the plates.

Hubbard and Spencer (1990; Geol. Bull. Univ. Peshawar, Vol. 23, pp.101-110) and Hubbard, Spencer and West (1995, Earth and Planetary Science Letters), also investigate the Indus Suture around parts of the Nanga Parbat Syntaxis. Numerous studies have documented the recent uplift of this massif as one of the fastest rising metamorphic terrains in the world. New structural and kinematic analysis of the Nanga Parbat region shows that extensional deformation has been, in part, responsible for the exhumation of the gneissic rocks of the Indian Plate basement complex that dominates the Nanga Parbat Massif. Fieldwork along the Suture Zone and within the Indian plate rocks in the area between Babusar Pass and Toshe Gali, southwest of the peak of Nanga Parbat, provides evidence from shear fabrics and a shallowly-plunging stretching lineation for a dominant phase of extensional deformation that moved rocks of the Kohistan sequence and the Indian Plate Cover sequence to the west-southwest relative to the rocks of the Indian plate basement, including the Nanga Parbat gneissic rocks. This ductile fabric is pervasive at the Suture Zone contact and within the Indian plate cover sequence below the suture, but decreases in the Indian Plate basement rocks and the Nanga Parbat gneisses. The fabric is post metamorphic and, with $^{39}\text{Ar}/^{40}\text{Ar}$ geochronology of hornblendes, the age of pre-deformational, amphibolite facies metamorphism has been constrained to 40-56 Ma. Published cooling ages from the Babusar Pass region further document that the extensional deformation was completed by 20 Ma. This ductile, extensional shear is interpreted as being the mechanism responsible for significant tectonic exhumation of the gneissic and granitic rocks of the Nanga Parbat Massif which may have then been followed by flexural, surface uplift and accompanying erosion which continues to the present.

S/500. Spencer, D.A. & Mullis, J., 1994. Fluid inclusion analysis in eclogites and associated high pressure rocks, Upper Kaghan, NW Himalaya, Pakistan. *Journal of Nepal Geological Society* 10 (Abstract Volume, 9th Himalaya-Karakoram-Tibet Workshop, Kathmandu), 135-136.

Fluid inclusions are small quantities of liquid (or glass) and/or vapour trapped in cavities, a “sample” of the fluid phase present in the rock at some time during its evolution. They provide information on one or more intervals in the history of a metamorphic rock between peak temperatures of the metamorphism and arrival of the rock at the surface. The vast majority of fluid inclusions in metamorphic rocks are secondary, the fluids being trapped along fractures of various sizes. Most fluid inclusions in metamorphic rocks originate by devolatilization reactions in the immediately surrounding rock and are in equilibrium with the host mineral assemblage at the time of the formation of the inclusion. Inclusions are most commonly found in quartz due to the fact that it is stable at all metamorphic conditions within the crust. Studies in high-pressure lithologies (such as blueschist and eclogite facies metamorphism) are relatively rare and to date, the maximum-recorded depth of fluid inclusion formation is around 45 km. In general, most densities observed were much lower than inferred peak metamorphic pressure-temperature conditions and the synmetamorphic fluids were not present.

Fluid inclusions were analyzed in Upper Kaghan by the non-destructive microthermometry technique using an optical microscope combined with a heating and freezing stage. In all the samples studied, some primary (?) but mainly secondary fluid inclusions were found. The host minerals of the fluid inclusions were obviously dependent on the rock lithology. Results were obtained for five samples. Sample 89/55.A is a quartz host in quartzite, which shows one population of fluid inclusions and one cluster of inclusions. The single phase system suggests that the inclusion consists essentially of CO₂ and that other gases than may be present (e.g. N₂ or CH₄) are very minor. Sample 89/55.B is a quartz host in quartzite, which shows a population of secondary inclusions consisting of aqueous H₂O rich solutions of intermediate density. Sample 89/56.B.2 also shows another population of inclusions, which are not found in trails, but clusters. The inclusion cluster is a higher density aqueous H₂O rich solution inclusion showing no bubble before heating. After heating the bubble was one of a different size, indicating that stretching and decrepitation had taken place. Sample 89/86 is a quartzite showing secondary inclusions consisting of gaseous CO₂-rich solution of low density. Sample 89/178.A is a garnet host in eclogite, which shows one population of fluid inclusions consisting of gaseous CO₂-rich solution of high density.

Based on the melting and homogenization temperatures, as well as the estimated gas water volumes, the composition of the fluid and the density of the fluid inclusions were determined. Isochores were then calculated using a Redlich-Kwong form for the equation of state, which are modified for the relevant system of H₂O-CO₂-NaCl (89/55.B and 89/156.B), H₂O-CO₂-CH₄ (89/55.B and 89/56.B) and CO₂ (89/55.A and 89/56.B, 89/86 and 90/178.A). From the isochore calculations, the secondary conclusions show that they were all produced in the late stages of metamorphic retrogression, and subsequently can be interpreted as forming as a result of retrogressive reactions that lead to the liberation of H₂O and CO₂.

There are two main phases of fluid inclusions: early and late. The early fluid inclusions are characterized by low fluid pressures whereas the late inclusions are characterised by higher fluid pressures suggesting a younger retrograde fluid evolution event. The relationship between these early and late inclusions is somewhat contradictory to what is normally expected in metamorphic rocks. The maximum densities are commonly assumed to characterize the fluid closest to the peak metamorphism. However, other recordings of the exceptions where there is a density increase for later inclusions (generally related to conditions where the isochores pass above or below the peak metamorphic temperatures and pressures and do not represent a syn-metamorphic fluid phase) are published. Timing relationships also help confirm the observations of the two phases of fluids: the earlier lower density fluid inclusions are cut by the later higher density fluid inclusions. Subsequently, as a result of this renewed activity, the earlier inclusions are evacuated and filled with the later more dense fluid along the same trail. The main evidence that supports this hypothesis is the occurrence of trails of several inclusions in the same direction. An alternative explanation is that the two separate fluid densities reflect a true metastability or that one is a late filling of the other, although no observational evidence for this was found. One of the most obvious questions that result from the observations made on the fluid inclusions is the source of the CO₂ and H₂O. The most likely and accepted source of H₂O in inclusions in deep-seated metamorphic belts is by dehydration and devolatilization. The most reasonable source for the CO₂ is decarbonation, a well-known result of regional metamorphism.

A zone of high pressure (eclogite facies) metamorphism, characterized by eclogites with an assemblage of omphacite - garnet - quartz - rutile -+ yhengite, has been recognized in the higher Himalaya in the Indian Plate of NE Pakistan. This suggests that the Upper Kaghan nappe is the deepest derived part of the Indian Plate to have been subducted and subsequently uplifted along the whole length of the Himalaya. Mineral chemistry by microprobe analysis suggests that the eclogites formed at temperatures of 650~50 OC and pressures of 13-18 kbar, suggesting depth of eclogite formation at 60 km. The eclogites show an incipient decompressional re-equilibration which probably occurred at decreasing temperatures.

S/503. Spencer, D.A., Ramsay, J.G., Ghazanfar, M. & Chaudhry, M.N., 1991a. A revised stratigraphy for the higher and Tethyan Himalaya in North Pakistan. *Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Grenoble, France*, 81.

Recent investigations into the stratigraphy of the Higher Himalaya in Upper Kaghan valley, north Pakistan has led to a complete revision for the tectono-stratigraphy for this region of the Himalayas. The whole of the region south of the suture was always correlated with Salkhala unit until workers located the Main Central Thrust and divided the area into the Lesser and Higher Himalaya. The later unit was again all classified under one group, the Sharda Group (Ghazanfar et al., 1989), until recently when another reclassification (Greco et al., 1998) was made. Modifications to this are now proposed:

Basement: The oldest pre-Cambrian unit consists of granitoids that have intruded into an even older meta-pelite.

First cover: Unconformably overlying the basement is a lower Paleozoic metagraywacke unit. The unconformity is only recognized on a regional scale with a transgression gently cutting out the underlying granite. Excellent metamorphically-reversed graded bedding is found in the unit showing the original way-up structure. Its composition suggest a turbidite environment.

Second cover: Unconformably above these two units is a Tethyan sedimentary sequence. Recognition of this unit is difficult and controversial, as it was metamorphosed and deformed during the nappe formation to eclogite and amphibole grade, which is not seen in the rest of the Himalaya where they are unmetamorphosed. It unconformably lies over the first cover and then eventually the basement, again showing the transgressive nature of the unit. They begin with the Permian Panjal Traps, which are subaerial basaltic lavas with intercalated limestone, now marble, horizons, before a Triassic sequence of marbles, dolomites and garnet-mica schists.

Himalayan leucogranites: All the units are cut by Himalayan age tourmaline-bearing leucogranites with some minor in situ anatexis found.

The Higher- and Tethyan Himalayan units are bound to the south by the Main Central Thrust mylonites which separate it from the Lesser Himalayan Salkalah Unit and to the north by the Indus Suture Mélange Group which separates it from the Kohistan Island Arc Group. This revised stratigraphy has already been used in the recognition of the controversial Main Central Thrust in the Swat area of the western Himalaya.

The Upper Kaghan nappe of the NW Himalaya is of crucial importance in the understanding of deep seated orogenic processes associated with the Himalayan collision. Bounded by the Main Central Thrust to the south and the Indus Suture to the north, this Higher Himalayan and Tethyan tectonic unit thus represent the deepest exposed part of the Indian plate. Evidence of the deep subduction and subsequent erosion of the tectonic unit is shown by the presence of eclogites- the only eclogites so far recorded in the whole of the Himalayan belt –from which recent analysis suggest formation at temperatures of $650^{\circ}\text{C} \pm 50^{\circ}\text{C}$ and pressures of 14 kbar (Pognante and Spencer, in prep.). The exhumation rate for this unit is very rapid.

Stratigraphically, the basement consists of granites that have intrude into a garnet-mica schist: its first cover (a metagraywacke unit showing excellent metamorphically reversed graded bedding) and a second cover of Permian Panjal Trap volcanics with associated syn-sedimentary marine deposits, which give carbon and oxygen stable isotope ratios of a high temperature, deep marine water environment (Spencer and Spencer-Cervato, in prep.). All units have a very unusual metamorphic history of progressive eclogite facies metamorphism and retrogressive amphibolite facies metamorphism.

The structural evolution of the High Himalayan and Tethyan units in Pakistan show a remarkable similarity to the Pennine style of nappe formation and deformation in the Alps: i.e. complex large scale folding subsequent to nappe emplacement. Previous research suggests that, in general, the large-scale crustal nappes in the NW Himalaya are each internally imbricated and separated from each other by late thrusts.

However, in the Higher Himalaya of Kaghan, where ductile deformation was the main process of deformation, this is certainly not the case, as no internal thrusts or shear zones were recognized. Evidence suggests that polyphase ductile- penetrative overprinting occurred after the original nappe forming movement. This led to the development of a system of major post nappe folds, which deformed a pre-Himalayan history of deformation.

As with the Pennine nappes of the European Alps, the post-nappe folds can be subdivided into two groups: main Himalayan folds and late Himalayan folds. The main Himalayan folds are large, isoclinal and recumbent fold structures, which produce a series of sheets that are associated with a penetrative foliation, which is either a newly formed axial planar schistosity or a rotated and modified earlier foliation on the limbs of folds. The late Himalayan folds, which affect an already developed penetrative foliation and, when present, lineations show a minor crenulation cleavage. They are superimposed on the main Himalayan folds with type 1 or 3 interference patterns giving very large scale domes, which are found in the Hazara-Kashmir, Kaghan and Nanga Parbat syntaxes, as well as basins and domes in the areas between the syntaxes, such as that in Upper Kaghan.

S/510. Spencer, D.A., Ramsay, J.G., Pognante, U., Ghazanfar, M. & Chaudhry, M.N., 1991b. The significance of eclogites in the Indian plate, NW Himalaya. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Grenoble, France, 85.

High-pressure assemblages are widespread in the Alpine belt with blueschist and eclogite facies rocks occurring both in ophiolitic and in continental rocks. However, in the Himalayan belt, only blueschist rocks have been recognized in the ophiolites associated with the suture and, to date, true high-pressure assemblages were never recognized in the continental rocks. A new discovery of eclogite facies metamorphism in the Higher- and Tethyan Himalaya of the Indian plate in north Pakistan leads to the suggestion that the Upper Kaghan nappe represents the deepest derived rocks of the Indian shield known.

The medium grained, granoblastic and metamorphically foliated eclogites consist of: sodian augite and omphacites with $X_{\text{Jd}} < 0.42$, almandine garnets ($X_{\text{Alm}} = 0.46-0.60$) with low grossular and pyrope contents. Only slight zoning with almandine and spessartine rims occur and minor simplectic reaction rims are seen, consisting of diopside and albite. Preliminary temperatures estimates, based on the CPX-GRT geothermometer, give $T = 650 \pm 50^\circ\text{C}$, while pressure estimates, based on the stability of the omphacite ($X_{\text{Jd}} < 0.42$) and quartz, give $P > 13-14$ Kbar. These pressure estimates are significantly greater than any other estimates concerning the Higher Himalaya of Indian plate. The eclogite facies assemblage shows an incipient recrystallization producing amphibole, epidote, diopside and albite. This recrystallization registers a decompressional path at decreasing temperatures, which probably reflects high uplift rates. This was achieved initially by thrusting along the Main Central Thrust and then by post-nappe folding, resulting in the doming of the structure to its present elevation.

The significance of this only true high pressure assemblage to be discovered so far in the Indian plate Himalaya raises many questions as to why it only occurs in one particular area (total area approx. 700-km²) of the orogenic belt. A relationship to the Indian plate promontory and the syntaxes of the western Himalaya is suggested which account for some of the most unusual tectonic features of the Himalaya. A comparison is also made to the Central parts of the Himalaya where none of these features are seen.

S/513. Spencer, D.A. & Spencer-Cervato, C., 1992b. Exhumation and cooling history of eclogite and amphibolite facies rocks in the Upper Kaghan Nappe. NW Himalaya. Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 85.

The Upper Kaghan Nappe in the NW Himalayas appears to have gone through a tectonic history that involved differential subduction and differential exhumation. The nappe does not show constant metamorphic, deformational, cooling or exhumation histories, but rather a gradual gradient between the structurally deeper Inner core and the more outer shallower sheet structures. This has been described as a 'Penninic style of nappe deformation'. A traverse, from southwest (Type area: Safu Maluk) to northeast (Type area: Besal) across the nappe, most strikingly shows these differences in the metamorphic grade: from amphibolite facies in the southwest to lithologies that contain a high pressure eclogite facies mineral assemblage of omphacite - almandine garnet - quartz - rutile at Besal (formation at $650 \pm 500^\circ\text{C}$ at 15 kbar). Detailed structural mapping has shown that there are no tectonic imbrications of any type, as documented in the nappes to the west of Upper Kaghan (e.g. Besham, Hazara). Furthermore, the deformation is pre- to syn-metamorphic in the Besal area and syn-metamorphic in the Safu Maluk area. Pressure-temperature paths show a characteristic anticlockwise rotation, as expected for continental collision belts.

Further insights into the cooling history of the Upper Kaghan Nappe can be made with multisystem radiometric dating. Ten different systems have been used on lithologies from the Upper Kaghan Nappe (Sm/Nd - garnet and clinopyroxene; U/Pb - rutile; Rb/Sr - phengite, garnet and clinopyroxene; Rb/Sr - biotite; K/Ar - hornblende; K/Ar - muscovite; K/Ar - biotite; Ar/Ar - muscovite; Fission Track - zircon and Fission Track - apatite). These ages have been obtained by Tonarini et al. (Submitted), Zeitler (1985) and Treloar et al. (1989). The ages suggest that the cooling history varies with locality with cooling rates differing between the two type areas, although the trends are similar. The eclogite nappe core initially cools rapidly at $19.30^\circ\text{C Ma}^{-1}$ for 15 Ma until 35 Ma; it then slows to $7.20^\circ\text{C Ma}^{-1}$ for 33 Ma until 2 Ma and then rapidly cools again at $600^\circ\text{C Ma}^{-1}$ in the last 2 Ma. A similar trend (i.e. rapid - slow - rapid), but with different rates, is found for the amphibolite path (outer sheet at Safu Maluk). This sheet initially cools rapidly at $400^\circ\text{C Ma}^{-1}$ for 7 Ma until 33 Ma; it then slows to $7.50^\circ\text{C Ma}^{-1}$ for 36 Ma until 4 Ma; and then rapidly cools at $250^\circ\text{C Ma}^{-1}$ in the last 4 Ma. It is difficult to envisage such a cooling history, where the eclogite and amphibolite cooling paths cross each other during their exhumation in any other environment other than a nappe. In comparison, cooling paths of the adjacent regions of Besham and Nanga Parbat, are very different. Nanga Parbat shows progressively increasing cooling rates from 20 Ma onwards to present, whilst the Besham area shows the complete reverse of the Upper Kaghan area (slow - rapid - slow) in a much shorter time span. The cooling history is also significantly different from the East Central Kohistan Island Arc, with the notable exception of the last 15-17 Ma, where a time averaged cooling was simultaneously $110^\circ\text{C Ma}^{-1}$.

Exhumation rates can be obtained from depth-time averages. Maximum pressure estimates of the eclogite path give 15-16 kbar, which equates to depths of formation at 60 km with peak metamorphism at 49.7 Ma. The average exhumation rate is therefore 1.2-1.3 mm/yr. Maximum pressure estimates for the amphibolite path give 8-9 kbar which equate to depths of formation at 30-35 km with peak metamorphism around 40 Ma. The exhumation rate is therefore 0.7-0.9 mm/yr. These rates provide supportive evidence for the exhumation model of fold superposition, which predicts that exhumation rates cannot be constant (higher relative uplift by folding in the core of the nappe produces greater relative erosion rates). Searle (1991) calculated the exhumation rates for Nanga Parbat (1 mm/yr.) and for the Sum region (1.4-2.1 mm/yr.). These exhumation rates are comparable for the NW Himalaya, but bring rocks in the core of the Upper Kaghan nappe to the present surface from depths of almost double those exposed in Nanga Parbat. This is simply due to the timing of peak metamorphism and the depths from which they originated. The Upper Kaghan Nappe was the first part of the Indian Plate to collide in Eocene times: it was the deepest part of the Indian plate to subduct and began its exhumation long before the 'Main' Central Himalayan Collision. This could only have been due to a promontory on the Indian plate that had a major influence on the deformational history of the NW Himalaya.

S/516. Stanin, S.A., 1966. Laterite and other aluminous deposits of West Pakistan. US Geological Survey/Geological Survey of Pakistan, Information Release, PK-11, 25p.

Laterite and other aluminous deposits in West Pakistan are briefly described, and their locations are shown on accompanying base sheets of West Pakistan, scale 1:2,000,000. Localities in Muzaffarabad, kotli tehsil, and Sangar Marg, Azad Kashmir, and in the margalla Hills, Rawalpindi District, may contain bauxite that could be mines profitably. These deposits may extend into the Garhi Habibullah area of Hazara district. The laterite rocks near surg and Campbellpore, Attock District, might be valuable for alumina production. The laterite in the Ziarat area, Sibi and Loralai districts, are rich in Fe₂O₃; these deposits may contain iron resources. Small production of laterite for several year at one locality in Loralai District furnished material for the manufacture of cement.

Detailed stratigraphic, structural, lithologic, mineralogic and economic studies are required to evaluate the resources and potential of these and other deposits in West Pakistan and to appreciate their value as raw materials for aluminum, abrasive, refractory, chemical and other industrial uses.

Key words: Minerals, laterite, West Pakistan.

S/517. Stanin, S.A. & Hasan, M.S., 1966. Reconnaissance for phosphate in West Pakistan. Geological Survey of Pakistan, Information Release 32, 7-11.

Low-grade phosphatic nodules have been found in (1) the lower argillaceous sections of the Jakkher group in the Pab Range; (2) strata of the Mughal Kot formation, Drazinda Shale Member, Domanda Shale Member, and the lowermost beds of the Ghazij Shale in the Sulaiman Range; (3) the Patala Formation and the basal shale member of the Chhidru Formation in the Salt Range; and (4) the basal glauconitic beds of the Chichali Formation in the Kohat Range. The phosphatic nodules seem to be original constituents of the containing rocks. X-Ray diffraction data show that the phosphate in nodules from the Chichali Formation derives from apatite. The Habib Rahi limestone member along the eastern flank of the Sulaiman Range contains beds of slightly phosphatized, dark-coloured, cherty limestone that suggests these rocks may have been deposited under upwelling marine conditions. None of the formations in the areas investigated seem to contain sufficient reserves to be of economic importance. Encouraging indications, however, of phosphate in the Habib Rahi limestone member, Ghazij Shale, and Chichali Formation warrant detailed investigations of these formations in adjacent areas.

S/522. Stauffer, K.W., 1968a. Silurian-Devonian reef complex near Nowshera, West Pakistan. Bulletin of the Geological Survey of America 79, 1331-1350.

The first Paleozoic reef belt on the Indo-Pakistan subcontinent has recently been recognized near the town of Nowshera (lat 34°00' N., long 72°00' E.) in northern West Pakistan. It consists of nine separate hills aligned in a 15-mile-long, east-west band rising out of the Peshawar alluvial plain. Each hill is composed of one or more reef cores whose thicknesses range from less than 100 feet to more than 700 feet. The reef cores are separated by relatively unfossiliferous carbonate rocks thinner than the reefs.

The reef belt contains a fauna entirely new to Pakistan that has been dated as Early Devonian to Late Silurian (Ludlovian to Gedinnian). The reef carbonates are the first sediments of possible Silurian age found anywhere in the country and the southernmost Devonian deposits in West Pakistan. Individual reef cores consist of faunal zones or layers that indicate a gradual growth of the reef mass from relatively quiet water upward into rough water.

The presence of these reefs and correlative fossiliferous carbonate sediments in the Peshawar area suggests that in Silurian and Devonian times much of northern West Pakistan was covered by warm, shallow seas bordered by reefs or containing reef platforms. The association of these Paleozoic reefs with extensive deposits of fetid black limestones and porous dolomites may indicate economic potential for the accumulation of oil.

S/523. Stauffer, K.W., 1968b. Geology of Khyber Pass, Khyber Agency, West Pakistan. US Geological Survey/Geological Survey of Pakistan, Information Release, PK-22, 42p.

The defile of the Khyber Pass is cut in massive gray recrystallized Limestone whose thickness exceeds 3000 feet. Although no fossils have been found in the immediate vicinity of the pass, assemblages collected at the end of the last century from 5 miles south of the pass, and recently collected fossils from Afghanistan suggest strongly that the limestone is Carboniferous to Permian and perhaps Jurassic in age. The basal contact of Khyber Limestone in places appears to be conformable upon the quartzites and tuffs of Ali Masjid Formation; elsewhere it is probably an unconformity or a fault, especially where the limestone lies directly on the Ordovician to Carboniferous Landi Kotal Slates. The Ali Masjid Formation overlies the shagai Limestone, which, in turn, rests in fault contact on the Landi Kotal slates. A sodic granite intrusion 10 miles northeast of the Khyber Pass on the Kabul River has altered nearby parts of the Khyber Limestone to a fine-quality marble that is today the only mineral resource of commercial importance in the Khyber area.

Structurally the area is characterized by at least four major, roughly east-west trending thrust or reverse fault, along which relatively older rocks have moved southward over younger rocks. A north-northeast-trending system of alternating anticlines and synclines has been superimposed on the earlier structures. Elevated terraces and alluvial valleys suggest a very recent uplift of about 600 to 1000 feet.

S/524. Stauffer, K.W., 1968c. Heavy minerals in the stream sands of the southern Hazara, West Pakistan. Geological Survey of Pakistan, and U.S. Geological Survey, Information Release, PK – 18, 42p.

The real distribution of heavy minerals in 99 samples from stream sands in the southern Hazara District, West Pakistan, indicate that the metamorphic grade of the rocks in the area increase towards the northwest. Minerals of potential economic value in the heavy-mineral samples include scheelite from the Oghi-Batgram-Battal area and hematite from the Galdanian area. The total weight of magnetite sand grains transported down the Indus Rive past

Darband is calculated to be about 200,000 tons per year, a quantity which may be of economic value. Radioactive minerals are not present in any of the samples in sufficient quantity to be of economic importance.

S/525. Stauffer, K.W., 1968d. Geology of the Gilgit-Hispar area, Gilgit Agency, West Pakistan. United States Geological Survey, Information Release PK-10, 42p.

This is an account of the geology of the lower Hunza river valley. The transect from Gilgit to Matum Das is occupied by granitic rocks (now called the Kohistan Batholith). Further north is a wide terrain of pillowed volcanic rocks stretching up to Chalt. Then on is a mixture of low grade pelitic to calcareous metasedimentary rocks and some talcosic rocks. Onward of Hini is a sequence of higher grade metasedimentary rocks followed by granitic rocks of the Karakoram Batholith. In the present day terminology the rocks between Chalt and Hini are considered to be Suture zone mélangé, whereas those to the north are put in the Karakoram plate.

S/526. Stauffer, K.W., 1969. Devonian laterite in Chitral State, West Pakistan. Economic Geology 64, 252-254.

A Devonian laterite has recently been discovered near Reshun in the Mastuj valley of Chitral State, West Pakistan. It is believed to be the fourth recorded Paleozoic laterite in the world. The laterite is entirely within a thick carbonate of the Shogram Formation of Upper Devonian (Frasnian) age. A chemical analysis of the laterite shows the principal constituents to be: Al_2O_3 35.5%, SiO_2 21.7% Fe_2O_3 16.0%, FeO 10.3%, TiO_2 3.5% CaO 0.97%, and MgO 0.70%. Minerals determined by X-ray analysis include hematite, boehmite, diaspore, anatase, rutile, kaolinite, pyrophyllite and what is probably chamosite.

S/528. Stauffer, K.W., 1975. Reconnaissance geology of the central Mastuj valley, Chitral State, West Pakistan. US Geological Survey/Geological Survey of Pakistan, (IR) PK-24, 51p.

The Mastuj Valley in Chitral state is a part of the Hindu Kush Range, and is one of the structurally most complicated areas in northern Pakistan. Sedimentary rocks ranging from at least Middle Devonian to Cretaceous, and perhaps Early Tertiary age lie between ridge-forming granodiorite intrusion and are cut by thrust faults. The thrust planes dip 10 to 40 degrees to the northwest. Movement of upper thrust plates has been towards the southeast relative to lower blocks.

If this area is structurally typical of the Hindu-Kush and Karakoram ranges, then these mountains are much more tectonically disturbed than previously recorded, and suggest compression on a scale compatible with the hypothesis that the Himalaya, Karakoram, and HinduKush Ranges form part of a continental collision zone.

The thrust faults outline two plates consisting of distinctive sedimentary rocks. The lower thrust plate is about 3000 feet thick and consist of the isoclinally folded Upper Cretaceous to perhaps Lower Tertiary Reshun Formation. It has overridden the Paleozoic metasedimentary rocks of the Chitral Slate unit. This thrust plate is, in turn, overridden by an 8000 foot thick sequence containing largely of Devonian to Carboniferous limestones and quartzite.

S/529. Stauffer, K.W. & Calkins, J.A., 1966. Heavy mineral prospecting. US Geological Survey/Geological Survey of Pakistan, (IR) Pk-16, 35p.

Heavy mineral prospecting is a method of tracing potential ore minerals to their source by systematically examining the heavy minerals of stream sand. The heavy minerals are partially concentrated in the field by panning. In the laboratory the heavy minerals are further concentrated by floating off the quartz and feldspar in a heavy liquid, such as boroform, having a specific gravity of 2.89. Magnetite is separated magnetically and scheelite is identified under short-wave ultraviolet light. To obtain quantitative results on the minerals present, the sample is reduced by coning and quartering, mounting on a slide in oil, and a count of a minimum of 250 grains made. The chi-square test applied to the splitting and counting techniques shows them to be statistically valid. The properties of some heavy minerals most useful for their rapid identification is listed. Methods here described are those utilizing a minimum of field and laboratory equipment and may be appropriate for application in many areas of the world.

A > 10-my.-long sequence of ratite (e.g., ostrich) eggshells from Siwalik Group sedimentary deposits of northern Pakistan and India shows a dramatic (~8‰) increase in the $\delta^{13}\text{C}$ in biomineralogic calcite by ~4 Ma. Values of $\delta^{13}\text{C}$ from ratite eggshell carbonate older than 7 Ma are about the same as those from carbonate from contemporaneous fossil mammal tooth enamel and paleosols. However, after 4 Ma, the ratite eggshell carbonate $\delta^{13}\text{C}$ values are ~5‰ less than these coexisting materials. These findings are evidence of the development of a C3-C4 vegetative mosaic probably mirroring the sedimentologic-edaphic mosaic of the aggrading alluvial plain of the Siwalik depositional system.

S/538. Stewart, A.G., 1990. For debate: Drifting continents and endemic goiter in northern Pakistan. *British Medical Journal* 300, 1507-1512.

Although Baltistan, north East Pakistan, is in a region of iodine deficiency disorders, the distribution of goiter within the district, according to age and sex, has not been clearly defined. To establish the prevalence of the condition and to measure the reported difference in prevalence in the north and south of the district thyroid size was assessed in new patients attending the Aman clinic, Khapalu, and outlying areas between April and September from 1981-1986. Samples of potable water collected from villages were analysed for iodine (as iodide) concentrations in Britain. Population weighted prevalences were: in the north in males 28.1% and in the south in males 13.9%, in females 21.2%. There was an overall deficiency of iodine in the water (mean iodine (as iodide) concentrations (north) 11.0 nmol/l (1.4 µg/l), (south) 11.8 nmol/l (1.5 µg/l) (95% confidence interval -0.7 to 0.9). The differences followed the Main Karakoram Thrust, suggesting a geological goitrogen in the north, which might be minerals containing ions such as BF_4 and SO_3F , and molybdenite and calcium which are present in rock in Baltistan.

A new hypothesis for the genesis of endemic goiter is proposed—that is, that continents on crustal plates drift across the earth and collide, one plate sliding under the other and melting, giving rise to characteristic mineral assemblages in the overlying rocks. As the minerals weather out they enter the diet of the local population, where in the presence of iodine deficiency they produce or enhance iodine deficiency disorders. Despite the current iodised oil campaign by the Pakistani government with UNICEF a long term working iodisation programme is still urgently needed.

S/544. Stump, E. & Sorkhabi, R.B., 1993. Syntaxial tectonics at Nanga Parbat and Denali. Abstracts with Program, Annual Meeting of the Geological Society of America, p.A-123.

NangaParbat (NP) and Denali (Mt McKinley), two of the loftiest and most rapidly exhuming massifs on earth occur at syntaxies of major fault systems from FT analysis. The average rate of exhumation for Denali is more than 1 mm/yr for the last 6 my; for NP exhumation has increased for the past 7 ma from 0.5 mm/yr to over 7 mm/yr. the differences in tectonic settings of the two areas include: 1. NP sits at the corner of two obliquely opposed thrust systems; denali occurs at the apex of and orcuate right-lateral strike – slip fault, 2. In map view, NP is a tightly appressed structure; Denali is open, 3. NP results from continent-continent collision; Denali occurs in a continental margin orogenic belt, 4. The current pulse of exhumation of NP follows a long history of uplift of the Himalaya (at least 20 ma), whereas that of Denali had no precursors prior to 6 ma.

The tectonic feature of that both denali and NP share is that they have formed in large-scale plan view, convergent stress systems.

S/546. Sulaiman, M. & Iqbal, S., 1972. Geology of the northern part of Jandul, District Dir, N.W.F.P., M.Sc. Thesis, University of Peshawar, 51p.

The northern part of the Jandul valley is underlain by the Palaeozoic rocks of the amphibolite facies. These metamorphic rocks were intruded by the igneous rocks in the Mesozoic times. The early phase of intrusive activity is represented fey diorites, granodiorites, granite and apparently later phase by morite. During the Tertiary period these intrusives were followed by the volcanic rocks of andesitic and dacitic composition. The volcanic rocks also include porphyritic volcanic dykes which are abundant in both palaeozoic and Mesosoic rocks. The porphyritic rocks have suffered a low grade metamorphism. This phase was followed by a granite intrusion. Quartz and pegmatitic veins represent the last phase of igneous activity.

Structurally the area is very complex. Shearing and local folding is very prominent. Repeated tectonic activities seem to have occurred in the area as is evident from deformation. Copper mineralization and vein quartz, which occur in the area, are not of any economic value at present.

Key words: Structure, metamorphic rocks, igneous rocks, Jandul, Dir

S/547. Sullivan, M., 1990. The roof zone of the Kohistan batholith, Pakistan. In Abstract volume, 5th Himalaya-Karakoram-Tibet Workshop, Milano, 59.

The final stages in the evolution of the Kohistan terrane are represented by the eruption of volcanic material onto a continental margin, formed after the Cretaceous collision of Kohistan with the Asian plate.

Recent fieldwork during 1988-1989 has shown that the sub-volcanic basement lithologies of this area include meta-pelitic schists and metaquartzites of the Kamila amphibolite belt, which were intruded into by Cretaceous hornblende-biotite-pyroxene diorite and granodiorites.

Uplift and erosion of this basement preceded volcanism, with the development of a basal unconformity in the tuffaceous material, stretching from Swat westwards into Dir. Volcanism was predominantly explosive with the development of between 700m-1000m of reworked ash and agglomerate/breccia. Lavas are more restricted (200m-500m) and these range in composition from andesite to rhyolite, often ignimbritic. These volcanics are dated as Paleocene/Lower Eocene by foraminifera assemblages (*Discocyclina*, *Elphidium* and *Ranikothalia bermudezi*).

The volcanic pile was then intruded by later Paleocene/Middle Eocene calc-alkaline diorites, granodiorites and granites, with associated pegmatites. Finally, southeastward directed thrusts imbricated the roof zone and provided pathways for copper-rich fluids to develop strata-bound mineralization in the Dir area.

Key words: Tectonic evolution, volcanic, erosion, Kohistan batholith, Himalaya.

S/548. Sullivan, M.A., 1991. Continental margin volcanism along the leading edge of Eurasia: the Dir Volcanics. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Grenoble, France, 91.

In northwestern Pakistan (Kohistan) volcanic rocks associated with the northward subduction of Indian oceanic crust beneath Eurasia record two discrete episodes of activity:

1/Early tholeiitic and calc-alkaline basalts, andesites and rhyodacites, which make up part of the Kohistan, island-arc (early Cretaceous Chalt Volcanics).

2/ Later silicic lavas and tuffs (Dir Volcanics dated 55 Ma 40Ar-39Ar) which erupted subsequent to the accretion of the Kohistan arc onto Eurasia, but prior to the collision of India.

Mineralogical and geochemical characteristics indicate that as a whole the Dir volcanics belong to an calc-alkaline continental margin series. They are L.I.L.E. enriched, depleted in H.F.S.E. (i.e. Nb) and show L.R.E.E. enrichment. The majority of material is rhyolitic in composition with few basalts. Such substantial amounts of silicic volcanism imply the existence of extensional tectonics. Limestone clasts in conglomerate at the base of the Dir Volcanics are dated at 58 Ma, and record a period of marine incursion onto the margin of Eurasia. Attenuation of the continental lithosphere may have resulted in the development of small marginal seas, in contact with the ocean, which later were subject to uplift and erosion at the onset of volcanism at 55 Ma.

Along the northern margin of Kohistan the Shamran Volcanics have yielded a radiometric age of 54 Ma (40Ar-39Ar). This implies that rather than being associated with the Chalt Volcanics they are more likely contemporaneous with the later Dir Volcanics. They have similar geochemical characteristics and indicate that the extent of continental margin volcanics in Kohistan is greater than was first thought, recording perhaps the migration of the magmatic-arc with time.

Key words: Volcanism, tectonics, Eurasia margin, Dir-

S/549. Sullivan, M.A., 1992. A palaeogeographic reconstruction of the Dir group: Evidence for magmatic arc migration in the N.W. Himalayas. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 89.

The Dir Group records the resumption of volcanic activity along the southern margin of Eurasia after a prolonged period of uplift and erosion. Two contrasting depositional environments are identified; a distal deep-water marine fore-arc (Baraul Banda Slate Formation) and a proximal subaerial volcanic core facies (Utror Volcanic Fm. and Shamran Volcanics). Eruptive style was predominantly explosive, with poorly sorted polymict volcanic breccias and sandstones testifying to the importance of epiclastic processes. Sedimentary thicknesses and the abundance of rhyolite lavas and pyroclastic flows indicates extensional tectonic control (hinge roll-back) even though the arc developed at a convergent margin. Fore-arc sediments show provenance from a dissected arc source implying either blockage of volcanogenic detritus due to coastal topography or by-passing by submarine canyons. Juxtaposition of the two different facies along the Dir Thrust excludes any record of shoreline or coastal processes from the volcanic stratigraphy. The inferred original geographical separation of the two environments (50-100 km), coupled with their individual relationships to dated plutons reveals that between Upper Cretaceous (ca. 78 Ma) and early Eocene (ca. 48 Ma) times the locus of magmatic activity within the Kohistan-arc migrated northward. Furthermore this

palaeogeographic reconstruction also implies that considerable shortening has taken place within the Kohistan Terrane subsequent to the closure of Tethys.

Key words: Palaeogeography, magmatic arc, sedimentology, volcanics, Dir group, Kohistan.

S/550. Sullivan, M.A., 1993. The geology of the roof zone of the Kohistan batholith, northwestern Pakistan. Ph.D dissertation, University of Leicester.

S/551. Sullivan, M.A., Saunders, A.D. & Windley, B.F., 1996. The petrology and geochemistry of the Utror and Shamran volcanic Formations, Kohistan, NW Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona, 155.

The Utror and Shamran Volcanic Formations represent the extrusive parts of the Dir Group, and are remnants of an elongate, dominantly subaerial volcanic arc that was active along the southern edge of Eurasia during the subduction of the Indian plate. They were erupted between ca. 55 Ma and 48 Ma, above an erosion surface cut deep into the Kohistan Batholith, during a brief period of caldera activity prior to continent-continent collision. They are broadly contemporaneous with the Dras II and Khardung Volcanic sequences of Ladakh and the Lingzizong Volcanics of Tibet.

Fragmental material dominates the volcanic record, and pyroclastic flows and ignimbrites testify to a highly explosive eruptive style. Coherent lava flows consist of a variably-altered suite of tholeiitic and calc-alkaline lavas, that range in composition from basalt to high-silica rhyolite. All lavas are holocrystalline, although there is textural evidence for the existence of originally glassy rhyolite. All lavas are holocrystalline, although there is textural evidence for the existence of originally glassy rhyolite flows. Lavas are strongly porphyritic throughout the compositional spectrum, containing between 5% and 45% (volume) of phenocrysts.

Secondary alteration effects, such as devitrification, polyphase hydrothermal alteration, and metamorphism influence the petrology of both lava suites. Augite, hornblende, titanomagnetite, and Ca-rich plagioclase dominate in the more basic compositions. Ferromagnesian minerals have Mg-rich compositions, with no tendency to show Fe enrichment, indicating that conditions were sufficiently oxidizing to prevent a tholeiitic evolutionary trend. Hornblende and pyroxene phenocrysts rarely coexist and probably reflect varying water contents of the magmas. Dacites and rhyolites are dominated by quartz and plagioclase feldspar. No primary ferromagnesian phases are observed and there is a notable absence of orthoclase feldspar. Textural evidence suggest that many of the rhyolites were originally obsidian with phenocryst contents indicating high viscosities.

Plagioclase, hornblende, clinopyroxene and titanomagnetite controlled early mineral fractionation with fO₂ fluctuations resulting in two identifiable trends. LILE are enriched relative to HFSE (Ba/Nb=4.7-101) and LREE relative to HREE (Ce/Ybn=2.3-9.9). Unlike typical orogenic arcs, which are dominated by andesite/dacite volcanic rocks, much of what remains of the Utror and Shamran Volcanic fields consist of a bimodal suite of andesite and rhyolite lavas and ash-flow tuffs. Crustal anatexis although favored by volume considerations does not agree with observed fractionation trends and thin-section evidence. Unfortunately considerable petrological variability exists even within a restricted geographical location, and this, coupled with an intense and varied alteration state, make detailed petrogenetic modeling inappropriate. Much of the variability that does exist appears related to initial source characteristics, magma ascent paths, fluctuating oxidation conditions and fractionation crystallization processes. Geochemical characteristics confirm existing isotopic data indicating that the Shamran Volcanics are contemporaneous with the continental margin suite of rocks (Dir Group) rather than with the earlier Chalt Volcanic island-arc suite.

Key words: Petrology, geochemistry, Utror, Shamran, Kohistan, Himalaya.

S/552. Sullivan, M.A., Windley, N.F., Saunders, A.D., Haynes, J.R. & Rex, D.C., 1993. A paleogeographic reconstruction of the Dir group: Pakistan. In: Treloar, P.J. and Searle, M.P. (Eds), Himalayan Tectonics. Geological Society of London, Special Publication 74, 139-160.

The Late Palaeocene Dir Group records the resumption of volcanic activity along the southern margin of Eurasia after a prolonged period of uplift and erosion. The group forms an integral part of the Kohistan Batholith and is readily divisible into two distinctly contrasting volcanic successions.

The Baraul Banda Slate Formation comprises 2700 m of fore-arc sandstones and siltstones. The basin formed during the collapse of the Kohistan continental margin and was filled initially by subaerial debris and mass-flow deposits. Subsidence was rapid such that >90% of the sedimentary record consists of thin-bedded sheet turbidites. These maintain a remarkable lateral continuity and indicate deposition in a restricted deep-water environment. Rare interbedded limestones have yielded a Thanetian (60.2–54.9 Ma) marine fauna of *Miscellanea miscella* and *Actinosiphon tibeticus*.

In direct contrast the Utror Volcanic Formation comprises 3000 m of volcanoclastic sedimentary material, lava flows and ignimbrites. Eruptive style was predominantly explosive with fragmental material dominating the volcanic record. Lavas range in composition from 53% to 79% SiO₂ with rhyolite the predominant rock type. A basaltic andesite has an ⁴⁰Ar-³⁹Ar age of 55 ± 2 Ma. Although the volcanic stratigraphy is complex preliminary investigations suggest accumulation in a predominantly subaerial ring-plain or flanking facies distal to the main focus of volcanic activity. Sedimentary thickness and the abundance of silicic lavas and pyroclastic flows imply extensional tectonic control even though the arc developed at a convergent margin.

Juxtaposition of the two facies along the Dir Thrust excludes any record of shore-line or coastal processes from the volcanic stratigraphy. The inferred original geographical separation of the two environments coupled with their relationships to isotopically dated plutonic suites reveals that between Late Cretaceous and Early Eocene times the locus of magmatic activity within the Kohistan arc migrated progressively northward.

The Shamran volcanic rocks although originally correlated with the island-arc Chalt Volcanic Group are now identified on the basis of a 58 ± 1 Ma (⁴⁰Ar-³⁹Ar) age as a northern continuation of the Late Palaeocene volcanic arc.

S/553. Sultan, M., 1970. Volcanic rocks from Kalam, Upper Swat. Geological Bulletin, University of Peshawar 5, 138-141.

Green and pink mottled volcanic rocks occur about three miles northwest of Kalam. A detailed investigation of these rocks has not been carried out so far, and the purpose of this paper is to give a preliminary report on the petrography of some of them. This report is based on the study of three thin-sections cut from rocks apparently different in hand specimen; one of these is a banded dacite, and two are pyroclastic dacite. The writer considers that the Kalam volcanics are a part of the Panjal Volcanics of Upper Carboniferous age.

Key words: Petrography, volcanics, Kalama, Swat.

S/554. Sultan, M., 1996. Heavy and trace metal abundance related to pollution in Peshawar Cantt, and along Jamrud Road, N.W.F.P., Pakistan. M.Phil. Thesis, University of Peshawar, 89p.

Polluted air, water and soil are considered to be the sources of several fatal diseases in human beings and animals. Among other pollutants, heavy metals are one which if incorporate with air, water and soil, could cause many diseases in human beings. The heavy metals incorporate with air, 'water and soil from different sources like mineral and ore processing industries, chemical industries, glass and paper industries, textiles, fertilisers, petroleum refining and vehicular emanations. Pakistan is one of the developing countries where the rapid growth of infrastructure including mad systems and vehicular traffic is in progress. One of the major sources of heavy metals along the roadsides, in the big cities of the Pakistan, is automobiles. Besides cocktail of toxic gases, exhaust from automobiles contain various heavy metals, which directly contaminate air, and when fall on ground, could enter into the surface and subsurface water systems. Such waters, if reach the aquifer and are utilised by the municipality, could be distributed in the city for both drinking and agricultural/ gardening purposes.

The present study has been conducted to analyse and determine the levels of heavy metals including Cr, Co, Cu, Ni, Zn, Fe and Pb in air, sewerage drains and subsoil samples from various parts of Peshawar cantonment and along Jamrud road. Air dust samples (48) were taken from different busy chouks/intersections from the Peshawar cantonment and along Jamrud road. In addition 30 sewage water and mud samples were taken from the sewerage system of Peshawar cantonment to determine the contamination levels in drains which ultimately join the Kabul river. Ten soil samples were taken along the Jamrud road and from the busy chouks in Peshawar cantonment at a

depth of two feet, and one foot away from the metalled roads to find the extent and effect of surface air pollution in the subsurface soils along the roads.

Results revealed that higher concentration of heavy metals especially Pb, Fe and Zn were present in air and sewage samples. In general the deposition and dispersion systematics of these metals are related to their atomic masses as well as to their availability in the surroundings. It was found that Pb is the most prevalent element in the air along the roads of Peshawar. Emission from automobiles is one of the major sources of lead in the atmosphere.

Analysis of all the sewage samples showed the presence of high levels of heavy metals. The heavy metals, being heavier than water, tend to settle at the base of the drains. The mud sewage samples contained more heavy metals than water sewage samples. Different shops, working in metals, printing presses and roads contiguous to the uncovered drains are the major sources of heavy metals in the drains of the Peshawar cantonment. These drains, containing heavy metals, ultimately fall into the Kabul river through Shahi kata and Budni canal. Soil samples show the levels of heavy metals within the normal ranges and are, therefore, not bothersome from environmental point of view.

S/555. Sultan, M. & Ali, A.N., 1970. Sedimentology and petrography of Ghundai Sar reef complex, Jamrud, Khyber Agency. M.Sc. Thesis, University of Peshawar, 64p.

A belt of Silurian-Devonian. Coralline Limestone of pink, yellowish-pink, and greyish-white colour, is exposed in the hills of Ghundai Sar, near Jamrud; Khyber Agency. This belt, which unconformably overlies the Phyllitic rocks, (Kandar phyllite) intruded by dolerite and gabbroid intrusion, is divisible in two definite units, that is,

(1) the Reef Core and (2) Reef Breccia. The two collectively are known as the Nowshera formation. The entire formation represents deposition on a stable shelf, the environments were conducive for the development of coral reefs. The orthoquartzite associated with dolomite and limestone support this observation,

In this paper, petrography and sedimentology of the reef limestones is discussed in detail 101 Samples were collected and 30 sections were cut to describe the petrography. The Limestone and dolomite show variations in their mineralogical composition. All variations from arenaceous limestone to calcareous orthoquartzite occur.

It is observed that dolomite is both primary (originally secreted by organisms) and secondary, introduced by low grade regional metamorphism afterward. Early Tertiary and Late Cretaceous intrusions have caused silicification and introduction of crystalline Quartz and feldspar in limestone. Limonitization is most probably a recent phenomenon, and might have introduced by the leaching of iron from overlying arenaceous formation.

S/556. Sultan, S.A. & Arbab, K.U., 1985. The Geology and the structure of a part of southern flank of Attock-Cherat Range, West of Indus River, N.W.F.P. (Pakistan). M.Sc. Thesis, Department of Geology, University of Peshawar, 84p.

The area of investigation covers 25 square kilometres on the eastern side of Attock-Cherat Range which stands as a structural high between southern portion of Peshawar Plains and Nizampur valley.

Structural style of the area is controlled by two major thrust faults, i.e. Khairabad fault in the north, which separates Dakhner Formation of late Pre-Cambrian age from Utch Khattak Formation and Cherat fault towards southern end of Attock-Cherat Range, which separates Dakhner Formation from Palaeozoic rock sequence. The Tertiary sequence is represented by Lockhart limestone, lying in the form of isolated patches and bands in Dakhner Formation. Their contact is considered to be of tectonic origin. Some strike-slip faults are identified in the area which may have formed in response to southward movement of the sequence along Cherat thrust.

Economically, the area holds a promise for setting up Cement Industry in future.

Key words: Structure, geology, Attock-Cherat Range, Indus River.

S/557. Suzuki, M. & Khan, S.R., 1992a. Geochemical exploration in Jijal area. Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad 2, 79-109.

This report describes the results of a geochemical exploration targeting mainly precious metals (Gold and Platinum Group) in the Jijal Complex, north of Besham, which was carried out by Japan International Cooperation Agency

(JICA) and Geological Survey of Pakistan (GSP). The study area occupies the southern limit of the Kohistan island arc terrain and samples were collected mostly from the area between Indus River and Duber Khwar. From Jijal to the eastern foothill of Mt. Gabar, a jeepable metalled road is available. However the general topography of the area is quite steep, and accessibility is poor on the whole. The geological mapping and the sampling of stream sediments were carried out for 30 days during October, 1990 to February, 1991, and the check survey to the results of geochemical analyses was conducted for 5 days in May, 1991.

Key words: Geochemistry, exploration, ultramafics, Jijal, Kohistan, Himalaya.

S/558. Suzuki, M. & Khan, S.R., 1992b. Regional geochemical exploration in Gilgit area, Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad, 2, 110-159.

The present report is to summarize the results of a geochemical exploration targeting gold in the Gilgit Agency.

The study area is divided into the northern and southern parts by the EW-trending Main Karakorum Thrust (MKT) in the central part. The Aslan Plate terrain on the northern side of the thrust is largely underlain by Paleozoic to Mesozoic sedimentary formations that have been intruded by Jurassic to Tertiary batholiths, whilst the Island Arc terrain on the southern side consists mainly of sedimentary and volcanic formations, which have been intruded by granitoids ranging from 102 to 25 Ma. Sampling for the geochemical exploration, which used stream sediments and panned concentrates as media, was conducted along the main streams of the Hunza and Gilgit Rivers and their major tributaries. Sampling density was slightly enhanced in the neighborhood of Gilgit, where a number of alteration zones have been found. One hundred and twenty samples of stream sediments were analyzed for gold, while 92 samples of panned concentrates underwent chemical assays of Au, Ag, As, Bi, Cu, Mo, Pb, Sb, and Zn in Chemex Laboratory.

Gold contents in the study area are generally higher than the average of the earth crust, implying a high probability of some gold mineralization in this area. A univariate analysis demonstrates that all elements except Cu and Mo show high concentrations along the MKT and on the northern side as a whole. Gold shows particularly high concentrations along the MKT. Factor analyses have led to the extraction of the following two factors related to gold mineralization: 1) a factor represented by a combination of Au-Ag-As-Sb (Factor 4) and 2) a factor represented by a combination of Bi-As-Ag-Au (Factor 2). High factor scores for the Factor 4 are found along the MKT. High-scored points for the Factor 2 are distributed mainly around the glacial areas.

A survey on the alteration zones was conducted in the northern area of Gilgit simultaneously with the geochemical exploration. Results of gold assays for prominent quartz-veins and highly silicified zones were disappointing. The results of the geochemical exploration and geologic survey on the alteration zones indicate a low potentiality of economically promising gold mineralization. The present survey leads to a conclusion that it is along the MKT, above all, the Chatorkhand area showing high contents of 11.0 ppm and 50.5 ppm Au as well as high scores for factor 4 that deserves a high priority to a follow-up survey.

Key words: Geochemistry, exploration, ultramafics, Gilgit, Himalaya.

S/559. Suzuki, M., Khan, S.R. & Khan, I.H., 1992. Lithogeochemical exploration in Mansehra area. Proceedings of Geoscience Colloquium, Geoscience Lab, Geological Survey of Pakistan, Islamabad, 3, 35-83.

The present report is to summarize the results of lithogeochemical exploration targeting tungsten and surveys of the mineralized zone. The study area is underlain by the Tanawal Formation consisting of schists and quartzites, the Mansehra Granite composed of granitic gneisses and schistose granites, and the Younger intrusions comprising porphyritic granites, aplites and diabbases. Sampling for the exploration was implemented on the basis of a grid net with an interval of 200 m in a 4 km by 4 km area selected by the previous geochemical exploration by stream sediments. The following 25 elements were analyzed: Ag, Al, Ba, Be, Bi, Ca, Cu, Cr, Co, F, Fe, K, Mg, Mn, Mo, Na, Ni, P, Pb, Sr, Sn, Ti, V, W, and Zn. Analysed samples amount to 305.

Univariate analysis led to detection of a large anomaly of W, F, Al, and P and a small anomaly of Ba, Ca, K, Ti, and V. Above all, F has been found to be an effective index element, which forms strong geochemical anomalies around the porphyritic granites, an ore bringer. As a result of factor analysis, W, F, Al, Ca, P, Ti, and V were extracted as elements related with W-mineralization (Factor 5). The distribution map of this factor shows a widespread distribution of high-scored areas from the Khabbal primary school to the southeastern slope of the Mt. Manna

Danna, indicating that they are most promising in the study area. In addition, comparison with univariate analysis demonstrate the effectiveness of factor analysis for erasing anomalies derived from background fluctuations.

W-mineralization found in the vicinity of the Knabbal primary school is of greisen type, which occurred near the top of a sheet-shaped intrusion of porphyritic granites. Impermeable caprocks covering the porphyritic granites presumably prompted concentration of scheelite. Showings of the mineralization in this area are so small for the strong geochemical anomalies, that any more discovery of larger mineralizations seems impossible.

Orbicular dioritic-noritic rocks from an area of mixed metamorphic and igneous rocks in Swat Kohistan, northern Pakistan, have been examined petrographically and chemically in order to determine the nature and origin of the orbicular texture. Using textural and compositional sequences it has been possible to relate the apparently different orbs to one another, and obtain a sequence of orb formation. The majority of the orbs comprise a series of distinct layers (shells) surrounding a central zone (core). Plagioclase, clinopyroxene, orthopyroxene and hornblende form the bulk of the shells. The cores have been extensively recrystallized. The development of a 'comb-layered' texture in some orbs and in associated layered rocks is comparable to that commonly described from other occurrences. A dual igneous/metasomatic crystallization history is invoked to explain the features of the orbs in this locality, the oscillatory zoning of the orbicular structure being caused by the alteration of primary minerals, such as pyroxene to amphibole, due to fluctuations in the p_{H_2O} of the magma.

Kyanite pockets occur in quartz veins and pegmatites associated with granitic rocks of Swat area. The granites intrude pelitic and calcareous rocks metamorphosed under Barrovian-type conditions. This report describes kyanite showings near Landakai at the border of Malakand Agency.

Key words: Kyanite, Swat.

T/6. Tahirkheli, R.A.K., 1960. Investigations of gold and other placer minerals in the Indus alluvium. GSP, Information Release 14, 9p.

This report furnishes the interim results of field and laboratory studies on samples collected from a selected 25 acre area at Amb, and results of analyses of four samples of concentrates from Bunji, Amb, Mian Dheri, and Attock.

The radioactivity of the Indus alluvium at Amb ranges from 0.013 to 0.18 mR/hr with the mantle sand giving slightly higher reading than gravel. Content of uranium in the Indus alluvium at Amb ranges from less than 0.001 to 0.007 percent.

Gold won by the local goldwashers from a ton of sand scrapped from between boulders and cobbles in the gravel bar averages about 0.25 grams. Study of gold washing shows that each working day, a goldwasher collects 3 to 4 pounds of a highly concentrated product containing these heavy minerals, listed in decreasing order of relative abundance; magnetite, ilmenite, garnet, zircon, scheelite, monazite, uranorthorite, uraninite, and gold.

Key words: Gold, placers, alluvium, Indus.

T/7. Tahirkheli, R.A.K., 1965a. Economics of Indus River sands. Geological Bulletin, University of Peshawar 2(a), 11-15.

The Indus River has for centuries attracted the attention of the prospectors and geologists because of gold in its alluvials. The goldwashers are still working along the Indus River banks, using primitive methods to extract gold by washing sand and gravel. Recent studies conducted by the author show that an experienced goldwasher extracts about 1.05 grains of gold per cubic yard. The high value minerals left behind in gold tailings are scheelite, uraninite, and cassiterite. An attempt has been made in this paper to evaluate their proportions in the heavy fraction and bulk sands to see whether they can be won economically as co-products of gold.

Key words: Economic geology, gold, Indus River.

T/8. Tahirkheli, R.A.K., 1965b. Recent observations on the undifferentiated Attock Group. Geological Bulletin, University of Peshawar 2(b), 10-23.

Under the light of recent investigations the Attock Slates are found to contain five distinct lithological units which are easily differentiated in the field and belong to different ages. Three of these units are dated to be Upper Mesozoic, one is assigned a pre-Cambrian age and the fifth unit is still under observation and is tentatively placed in the Paleozoic. The argillaceous part of the Attock Group which was previously, considered to be one homogeneous unit is split into two divisions and named "Manki Slates" and "Dag Slates." The later contain fossilized bands of limestone and on the basis of diagnostic fossil (Cerithiopsidea), have been dated to be Upper Cretaceous age. These two slates have got tectonic contact and the older Manki slates are found to have thrust over the younger Dag slates.

Key words: Lithology, slates, Mesozoic, Pre-Cambrian, Attock, Manki.

T/9. Tahirkheli, R.A.K., 1967. Reconnaissance for radioactive minerals in Dardistan, Baltistan and Haramosh in Gilgit agency, West Pakistan. GSP Information Release, 33, 17p, one map.

The eastern and north eastern parts of the Gilgit Agency which constitute Baltistan, Dardistan and Haramosh were reconnoitered for radioactive minerals during the period of July – October 1960. A geological map of the traverse – route was prepared and radioactivity of the rocks exposed was plotted thereon. Samples of sand were collected from the tributaries of Indus river for radiometric and mineralogical study. The radioactivity in the gneissic band in metasediments measured between 0.035 and 0.7 mR/hr. some of the granite intrusions and acid dykes of later phases read 0.03 to 0.07 mR/hr. few sand samples from the tributaries of the Indus yielded relatively high radioactivity, pointing the possibility of uranium mineralization in their catchment areas. These favourable indications of possible mineralization warrant an expeditious programme for having a thorough radiometric check in this area.

T/14. Tahirkheli, R.A.K., 1969b. Another Paleozoic reef discovery in Tangi Ghar, Peshawar District. Geological Bulletin, University of Peshawar 4, 90-91.

The Tangi Ghar spread over some three square miles, and is divided into seven isolated rounded to subrounded hillocks, the highs attaining a height of 1582 feet. The general trend of the ridge is east - west, which conforms to the strike of the rocks, which dip to the north. The major hillock (1982 feet) forms a steep escarpment along the northern edge. The mountain ranges exposed around Tangi Ghar lie at distances varying between 8 and 20 miles; the nearest ones are those of Takhtbai and Mohmand Tribal Territory, lying towards the east and west respectively. Three distinct lithological units are 1) Light to dark gray slate, phyllite and phyllitic schist, 2) Thin-bedded to massive crystalline siliceous limestone, 3) Slate, phyllite and phyllitic schist.

Consult Tahirkheli (1970c) for further information.

Key words: Geology, stratigraphy, Attock-Cherat.

T/17. Tahirkheli, R.A.K., 1970c. The geology of the Attock-Cherat Range, West Pakistan. Geological Bulletin, University of Peshawar 5, 1-26.

The Attock-Cherat Range is exposed in an area of about 50 square miles in Attock district and 360 square miles in the Peshawar district, on both the sides of the Indus River. Around Attock the relief is low; the elevations range from 1300 to 2079 feet which on the other side of the Indus culminate to 4546 and 5033 feet at Cherat and Jalala Sar respectively, which are the commanding heights in the Peshawar Plain. Between Attock and Mir Kalan village, the general trend of the range is east-west which coincides with the strike of the rocks. Beyond this point, the range swings to the south-west and ultimately merges into the Nizampur-Kohat mountains in Darra Adam Khel tribal territory. In the Attock plain the slates are lost beneath the alluvium beyond Kamra hillock till they crop out again in southern Hazara. In the west, the last slate outcrop mapped is exposed near Dag village, beyond which the slates are covered by thick alluvium till they crop out in the Khyber Mountains.

Two types of lithological elements, with a tectonic contact, are exposed in the Attock-Cherat Range. One comprises the Paleozoic metasediments (phyllite, phyllitic slate, slate and crystalline limestone) forming the northern face of the range. They are correlated with the rocks of Khyber in the west, Hazara in the east and Swabi-Lower Swat in the

north. The dominantly sedimentary rocks belonging to the Mesozoic-Tertiary eras, developed along the southern face of the Attock-Cherat Range, may be correlated with the rocks of Samana Range, Kala Chitta hill, Salt Range and Hazara.

The pelites of the Attock-Cherat Range are divided into two parts on the basis of fossil evidences. The older, Manki Slate is of Lower Silurian age and the younger, Attock Shale has been placed in the Middle Jurassic-Cretaceous. Altogether, thirteen mappable lithological units have been distinguished in the Attock-Cherat Range. Of these, four have been placed in the Paleozoic, four in the Mesozoic and five in the Tertiary. The Shahkotbala Formation is the oldest lithological unit exposed in this area and is (?) Upper Ordovician to Lower Silurian in age. No Precambrian rocks have been recorded in the Attock-Cherat Range.

The two major thrust faults running along the northern and the southern fronts of the range traverse the area in the east-west direction. The northern thrust is the result of overturning of the southern flank of an anticlinal fold. Another anticlinal fold skirts the Attock-Cherat Range on the south in the Nizampur valley. The northern limb of this fold is intact. The southern limb is eroded away and is buried under the alluvium. The Attock Shales are folded into asymmetrical parallel isoclinal folds with their axes dipping towards the north. The faulting pattern in the Attock-Cherat Range yielded imbricate type structure, which are conspicuously observed all over the area.

Key words: Geology, stratigraphy, Attock-Cherat.

T/18. Tahirkheli, R.A.K., 1971a. The geology of the Gandghar Range, District Hazara, NWFP, Pakistan. Geological Bulletin, University of Peshawar 6, 33-42.

The Gandghar Range is located on the western tip of the Hazara district, due to its isolated position it could attract a few geologists during the past. In the Geological Map of Pakistan (1964), the Range is partly mapped as Pre-Cambrian and partly Silurian-Devonian.

The Gandghar Range exposes a suite of metasedimentary rocks, comprising of slate, phyllite, phyllitic-slate, schists, quartzite and crystalline limestone. Five lithological units are differentiated which have been correlated with the Palaeozoic sequences of the southern Hazara and the Attock – Cherat Range. The oldest unit is the Mohat Nawan Limestone and the youngest is the Pirthan Limestone, which are respectively homotaxial to the Shahkotbala formation of the Attock-Cherat Range and the Sirban Formation of the Abbottabad Group in the southern Hazara. The former is placed in the Upper Ordovician – Lower Silurian and the latter in the Permo – Carboniferous.

Key words: Stratigraphy, metasedimentary rocks, Hazara.

T/19. Tahirkheli, R.A.K., 1971b. Phosphatic mineralization as a basis for stratigraphic correlations. Geological Bulletin, University of Peshawar 6, 117-119.

The author during geological mapping of Gandghar Range in the western Hazara, Cherat Range east of Peshawar, and the Rajgal area of Tirah in Khyber Agency has located a thick sequence of siliceous dolomitic limestone which was considered identical to Sirbon Formation on lithological grounds. To further authenticate this correlation, the author had collected scattered samples from each section, for chemical examination, to confirm whether phosphorite mineralization of same type as in the Kakul and Sirbon Formation in their type sections, is also present.

T/25. Tahirkheli, R.A.K., 1972. A proposed mineral strategy for the N.W.F.P. and the adjoining Tribal belt. Directorate of Mineral Development, Government of N.W.F.P., Peshawar, Information Release 6, 27p.

A number of metallic and non-metallic minerals occur in the accessible areas in the N.W.F.P. and the tribal territories, which do not need much investment to raise an infrastructure for their development and exploitation. Therefore it is advised to first plan mining ventures and mineral industries based on these minerals. A number of mineral based industries have been suggested in various parts of this province where suitable raw material is available.

During future planning for the road and railway extensions in this region, care should be taken to give priority to open up those areas which are potentially favourable for the natural resources, such as minerals, forest, etc.

Bank loans, railway freight concessions, even for the domestic markets along with other technical and economic incentives discussed in this paper, can provide a sound basis for the progressive development of the mining industry in this province. A substantial part of this province remains geologically unexplored and thus needs proper planning to gear up exploration based on modern scientific lines to trace the history of subsurface mineralization of the surficial metallic mineral showings.

The private investment on mineral ventures has become shy because of lack of the above mentioned incentives. Therefore it is in the interest of the government to create favourable conditions to make the mining sector more attractive. This would solve three fold purpose, (a) participation of the private sector in raising the infrastructures, thus sharing a considerable part of the capital cost which otherwise would have to be invested by the government,

(b) to make the minerals located in the far flung interior more competitive in the market, because of relatively low cost of mining venture by the private sector as compared to the public sector, and (c) infusion of technical know-how and inflow of private finances which are directly needed to create a sound footing for the mining industry in this region.

T/26. Tahirkheli, R.A.K., 1974. Alluvial gold prospects in the northwest Pakistan. University of Peshawar, Information Release 7, 48p.

The auriferous alluvials of Chitral, Gilgit, Hunza and the Indus rivers have been discussed in the paper. A goldwashing Industry, based on primitive technique, have flourished for centuries in this region, and even now one can see goldwashers working on wooden sluice, locally called nava. The river alluvials are composed of mantle sand, bouldergravel, cobble-gravel, and pebble-gravel, ranging in size from over 6 feet in diameter to less than 1/256 mm. The assemblage of heavy minerals including gold is relatively higher in the gravel deposit. The mantle sand shows higher concentrations of heavy minerals where the natural accumulates in the form of streaks and thin films occur.

The closely-packed pebble-gravels usually form the favourite sites to wash sands for gold, though in the upper reaches of the mountainous terrain, boulder-gravel and cobble-gravel have indicated reasonably high concentrations of gold.

Among the valuable minerals which would be won as co-product of gold are opaque ore minerals, zircon, garnet, monazite, scheelite, cassiterite, apatite, rutile. In size, over 85 percent of these minerals pass through minus 80 mesh screen. The distribution of gold in the alluvials is erratic. A rough estimate based on nava, washing revealed the following results:

Twenty-eight percent of the alluvials are barren with No gold showings, 58 percent of the alluvials yielded gold worth less than 35 paisas per cubic yard and only 14 percent of the alluvials showed consistent gold occurrences and yielded from 35 to 650 paisas of gold per cubic yard.

The treatment of goldwasher's stage III concentrate

(magnetite-free) in Isodynamic Magnetic Separator revealed the following mineral assemblages in various fractions, 1st fraction - dominantly opaque ore minerals.

2nd fraction - 75-85 percent opaque ore minerals.

3rd fraction - garnet-rich.

4th fraction - gold, zircon, monazite, scheelite, cassiterite, apatite, rutile; recovery of gold is 100 percent.

T/27. Tahirkheli, R.A.K., 1979a. Geology of Kohistan and adjoining Eurasian and Indo-Pakistan continents, Pakistan. Geological Bulletin, University Peshawar 11, 1-30.

Kohistan constitutes about 36000 square kilometers of territory located between the Indo-Pakistan and Eurasian Plates, on the northwestern tip of the Himalaya. Earlier, Desio (1964) has differentiated this part as a tectonic zone of Karakoram.

Bulk of Kohistan sequence consists of amphibolite, diorites, meta-norites (pyroxene-granulites) and associated volcanic rocks which are considered to be the crust of an ancient calc-alkaline island arc. This sequence has been obducted on to the Paleozoic rocks of the Indo-Pakistan continent on the south and subducted under the Eurasian Platform along the northern megashears.

The northern megashear along Hini-Chalt-Yasin-Drosh was formerly used to be considered the only extension of the Indus suture west of Nanga Parbat. Recent studies by Tahirkheli et al (1977, 77) have brought to light a southern megashear marked by the occurrence of ultramafics and high pressure metamorphic rocks, called Main Mantle Thrust (MMT), which delineates the southern contact of the Kohistan Island arc and the Indo-Pakistan continent. This confirms the bifurcation of the Indus suture into two suture zones, west of Nanga Parbat.

In this paper, an attempt has been made to introduce the geology of Kohistan island arc and the adjoining Eurasian and Indo-Pakistan continents.

Key words: Stratigraphy, structure, Kohistan, Eurasia, Indo-Pak plate.

T/28. Tahirkheli, R.A.K., 1979b. Geotectonic evolution of Kohistan. Geological Bulletin, University of Peshawar 11, 113-130.

Kohistan Zone is located on the north-western tip of the Himalaya and constitutes a tectonic unit in the Indo-Pakistan-Eurasia suture zone between Himalaya and Karakoram. Its characteristics nature distinguishes it from the surrounding well known geological provinces of Hazara and Kashmir on one side and Gilgit, Baltistan and Chitral on the other side. Most of Swat and Dir belong to Kohistan along with the southern part of Gilgit, Chitral and northern Hazara.

The Kohistan Zone is bounded by two megashears: the Hini-Chalt-Yasin-Drosh fault lying to the north, which extends into Baltistan through Tissar-Hashupa in Shigar Valley and Machelu in Shyok Valley. Another is recently deciphered Main Mantle Thrust traversing the southern periphery of Kohistan.

In addition, there exists a series of late thrust tectonic features, the two prominent among them being the Hazara syntaxial bend located on the south and a dominant Naze of Nanga Parbat – Haramosh massif on the northeast, which was considered by Wadia to be a horst of the Indian Peninsula, but the author interprets it as a transverse antiform fold.

These major tectonic features, located in the vicinity of the Kohistan Zone, have played a major part in the evolution of its structural history. A chronological account of various tectonic episodes is presented in this paper.

Key words: Tectonics, Kohistan, MMT, Himalaya.

T/29. Tahirkheli, R.A.K., 1979c. An indepth analysis of Pakistan's mineral policy with special reference to northern region. Geological Bulletin, University of Peshawar 12, 41-54.

Since the creation of Pakistan all the Governments have shown keen interest in the development of mineral resources for which various steps were taken to accelerate and generate momentum in the development of minerals. In spite of these efforts no concrete results were achieved.

The author being a member of the advisory committee on planning for mineral resources has observed some pitfalls which directly or indirectly created sluggish environment which caused the retardation in the development and exploitation of mineral resources. In this paper the author has attempted to shed light on the impediments in order to generate a healthy climate for strengthening the base to raise structure in which the mineral could get a square deal for their economical and commercial exploitation. This paper was presented in a seminar held at Lahore and had a limited circulation. The publication of this paper in this bulletin is intended for its wider publicity both in private and public sector in order to create awareness for skittling the loopholes faced by the mineral-based industry.

Key words: Mineral resources, Mineral policy, Pakistan.

T/30. Tahirkheli, R.A.K., 1980a. Major tectonic scars of Peshawar vale and adjoining areas, and associated magmatism. Geological Bulletin, University Peshawar 13, 39-46.

The Vale of Peshawar, spread in about 1800 sq. km area, constitutes an important tectonic zone in the northwestern margin of the Indo-Pakistan plate. It is surrounded by well carved mega-tectonic features, which originated during post collisional alpine orogenic episodes, starting from Late Cretaceous and lasting till Early Pleistocene. The main tectonic evolutionary history of the Vale is syngenetic to these episodes, though some pre-alpine tectonic scars have also been distinguished.

Ten major fault tectonics have been described in this paper, out of which six located within the Vale and the remaining four occur in the adjoining areas. An attempt has been made to decipher these tectonic scars and to delineate associated magmatism in the Vale of Peshawar.

Key words: Tectonics, magmatism, Peshawar Valley.

T/31. Tahirkheli, R.A.K., 1980b. The Main Mantle Thrust: Its score in metallogeny of northern Pakistan. Geological Bulletin, University of Peshawar 13, 193-198.

Major shear zones in the collisional orogens like the ones exposed in Pakistan, can create important pathways for the movement of the mineralized solutions along with magmatic emanations. The Main Mantle Thrust (MMT), which has come to limelight recently, constitutes one of the important major tectonic scars on the northwestern terminus of

the Himalaya. It extends for over 500 km across the northern part of Pakistan, welding the Indo-Pakistan plate with the Kohistan island arc. Several magmatic bodies, some of them of batholithic dimensions are associated with this megashear.

In this paper an attempt has been made to focus upon the magmatic environments associated with MMT to discern various episodes of metallic mineralizations and their localizations in the subducted Indo-Pakistan marginal mass, obducted Kohistan mass and in the main Mantle Thrust zone.

Key words: Metallogeny, Shear zones, MMT, Himalaya.

T/35. Tahirkheli, R.A.K., 1981c. An analysis of litho-tectonic zones associated with the Himalayan orogeny, in northern Pakistan. Geological Bulletin, University of Punjab 16, 98-110.

The Karakorum Himalayas is characterized by some unique tectonic features, which distinguish it from the rest of the Himalayas. Some of these are; occurrence of an Island arc on its north-western margin, existence of two suture zones west of Nanga Parbat-Haramosh antiform, and the absence of the Main Central Thrust, which, in the Central Himalaya demarcates so prominently the boundary between the Lesser Himalaya and the Himalayan Crystallines.

In this paper, under the light of new tectonic data, an analysis is attempted to differentiate various litho-tectonic zones in northern Pakistan, which were involved in the Himalayan orogeny.

Key words: Tectonics, MMT, MKT, MCT, Himalaya.

T/36. Tahirkheli, R.A.K., 1982. Geology of the Himalaya, Karakoram and Hindukush in Pakistan. Geological Bulletin, University of Peshawar 15, 1-51.

The northern segment of Pakistan hosts three of the best known mountain chains of the world, namely, the Himalaya, Karakoram and Hindu Kush. Among them the Lesser Himalaya received more attention by the earlier workers because of an easy access, but the other two were landlocked and remained isolated till 1960's, when the Karakoram Highway patched them with the modern amenities.

In spite of manifold problems, the geologists remained attracted to this segment of the Central Asia and continued their relentless efforts from the mid 1970's to bring this unsympathetic but enchanting terrain within the fold of geological investigation. Some of them intruded this terrain along with the climbing and scientific expeditions and a few made solo efforts, which paved a good base to provide a best possible geological account on this area. In this regard, the author gratefully acknowledges the pioneering efforts of these stalwarts who for the sake of science faced all kinds of hardships while taming this terrain and have emerged with wealth of information which enabled their

successors to continue smoothly. The author's first acquaintance with the geology of the Karakoram-Hindu Kush was cherished in 1957 while accompanying the Kyoto University (Japan) scientific expedition. Subsequently, this visit was fostered into a permanent feature during which a mapping program was initiated. Since, 1964, after being transferred from the GSP to Peshawar University, this work was accelerated and more attention was given to mapping of the virgin terrain lying blank on the first geological map of Pakistan, published in 1964. This work has helped to discover a new crustal section intervening the Indo-Pakistan and the Eurasian plates, which now is well known as the "Kohistan Island Arc". Although some geological base was attained by the Karakoram-Hindu Kush, yet there existed a vacuum to provide a comprehensive coherent regional geological interpretation to this terrain under the context of plate tectonics. The presence of the Kohistan Island arc juxtaposed between the two mighty continents produced a mosaic other than existing in the rest of the Himalaya, which further aggravated this problem.

These shortcomings greatly handicapped a regional geological correlation with Ladakh and northeastern Afghanistan with which the Karakoram and Hindu Kush respectively, are geographically linked.

To answer and arrest these problems, the best course to be adopted for their solution was to conduct a geological mapping program. Firstly, to knit together the observations made by the earlier workers lying dispersed in the isolated valleys and secondly to supplement this with fresh data to augment and up to date the already known informations on the geology of this region.

To achieve these objectives, a new geological map of the Karakoram and Hindu Kush has been introduced, a stratigraphic scheme of each geological domain has been devised which partly overlaps those produced by the earlier workers and diagrammatic sketches of all the important sections in the Himalaya, Karakoram and Hindu Kush giving a regional bias to their geological setup have been added. Besides, a regional correlation based on the new observations is attempted through with meager published literature available to the author from across the border. This is first attempt to present a regional geological mosaic of approximately 165000sq. Km area in the northern Pakistan, which was cradled by the tectonic emerging from the Indo-Pakistan-Eurasian collision and culminated during the attainment of structural configurations by the Pamir Knot, Nanga Parbat-Haramosh loop and the Hazara-Kashmir syntaxis.

The author is well aware of the shortcomings because of limitations in observations made by the author, lack of published literature and inaccessibility to nearly one-third of the area. However, it is hoped that this humble contribution will be helpful to bridge the geological gap existing between the Himalaya, Karakoram, Hindu Kush and the adjoining areas across the border.

Key words: Tectonics, geology, Himalaya, Karakoram, Hindukush.

T/37. Tahirkheli, R.A.K., 1983. Geological evolution of Kohistan island arc on the southern flank of the Karakoram-Hindu Kush in Pakistan. *Bollettino di Geofisica Teorica Applicata (Pamir-Himalaya)* 25, 351-364.

The Kohistan island arc covers approximately 36000 sq. km in the Northern part of Pakistan. It is bounded by two sutures, namely, the Main Karakoram Thrust (MKT) and the Main Mantle Thrust (MM1) which tectonically differentiate it from the Eurasian and the Indo-Pakistani plates respectively.

In the Himalaya, ophiolitic rocks mark the suture between the Eurasian and Indian continents. But in Pakistan along the southern flank of the Karakoram and the Hindu Kush an approximately 40 km thick complex of calc-alkaline plutonic/volcanic and metasedimentary rocks is emplaced between the two sutures and is considered to represent a complete cross-section of an island arc. On the north, this arc is subducted under the Eurasian marginal mass (Baltic Group and Chitral Slates) along the MKT and on the south is obducted onto the Indo-Pakistan plate (unfossiliferous lesser Himalayan sequence) along the MMT.

This arc had evolved due to intraoceanic subduction subsequent to the northward movement of the Indo-Pakistani plate which began during Late Jurassic. Its first contact with Eurasia, based on sedimentation and faunal evidences, is postulated during Late Cretaceous-Early Tertiary time and subsequently the second contact with the Indo-Pakistani plate occurred during post Paleocene.

However, Klootwijk et al. (1979), based on paleomagnetic data from Ladakh, considers the Ladakh arc to have collided first with the Indian plate during Late Paleocene-Early Eocene and with Eurasia during Eocene-Oligocene time.

T/38. Tahirkheli, R.A.K., 1985. Recent additions of the geotectonic net of northern Pakistan. Proceedings, First Pakistan Geological Congress, Lahore, 82-91.

The northern region of Pakistan comprises a variety of litho-tectonic domains, namely northwest Himalaya, Kohistan island arc, Karakoram plate and Hindukush Range. This contribution presents the new contributions to the already complex geology, structure and tectonics of the region.

Key words: Tectonics, Himalaya, Karakoram.

T/39. Tahirkheli, R.A.K., 1986. An overview of the major tectonic and geologic elements of the Himalaya and Karakoram in northern Pakistan. Geological Society of America Annual Meeting, 18.

In north Pakistan, there are three distinct geological domains, comprising NW Himalaya (Indian plate), Kohistan island arc, Karakoram-Hindukush Eurasian block. These are separated by major sutures, the Main Mantle Thrust (or Indus suture) in the south and the Main Karakoram Thrust (or Shyok suture) in the north. There are other major faults, including the Main Boundary Thrust.

Key words: Tectonics, Kohistan, Himalaya, Karakoram.

T/40. Tahirkheli, R. A. K., 1987. Shontargali thrust: an analogue of the main central thrust (MCT) in the NW Himalaya in Pakistan. Geological Bulletin, University of Peshawar 20, 209-214.

The Main Central Thrust (MCT) is one of the three principal megashears of the Himalayan orogenic belt which is formed as a result of collision between the Indian and Eurasian plates. Present studies in the substreams of the Kel Nala, one of the tributaries of the Nilam river in Kashmir and in another section located in Baloshbar area about 12 Km south of Astor in close vicinity of the Nanga Parbat massif, have revealed a new megashear which in stratigraphic, tectonic and metamorphic settings appears to be an analogue of the MCT in the NW Himalaya. This megashear is named Shontargali Thrust and like MCT, separates the Salkhala series of the Lesser Himalaya from the Nanga Parbat Gneisses of the Great Himalaya in Kashmir and Hazara in Pakistan.

Key words: Tectonics, MCT, Shontargali Thrust, Himalaya.

T/41. Tahirkheli, R.A.K., 1988. Presence of the Main Central Thrust in the tectonic domain of northwestern Himalaya in Pakistan. Geological Bulletin, University of Peshawar 21, 131-140.

The tectonic model of the northwestern Himalaya remained obscure for years for lack of demarcation of the Indus Suture Zone (ISZ) and Main Central Thrust (MCT) which are the two important tectonic features of the rest of the Himalaya. The problem of the ISZ was solved about a decade ago by locating two suture zones, the main Mantle Thrust (MMT) and the Main Karakoram Thrust (MKT) with an intervening Kohistan island arc (Tahirkheli et al., 1976, 1979). The location of MCT remained a debatable issue because of its discontinuity beyond west (Simla) Himalaya towards northwest in Kashmir and northern Pakistan. As a result, the Main Boundary Thrust and the Panjal Thrust in Kashmir and NW Himalaya, respectively, were considered as analogues of MCT.

This paper discusses a newly discovered deep level thrust named "Shontargali Thrust" which on the basis of geographic location and tectono-stratigraphic setup, compares favourably with the Main Central Thrust.

Key words: Tectonics, Shontargali Thrust, MCT, Himalaya.

T/42. Tahirkheli, R.A.K., 1989. Whether newly discovered Shontargali Thrust is an analogue of MCT in the Northwestern Himalaya in Pakistan. Kashmir Journal of Geology 6 & 7, 23-28.

Shontargali Thrust is a newly discovered megashear in the northwestern domain of Himalaya. A brief introduction to its broad geological aspects is intended in this paper. Its geographic location is at the base of Nanga Parbat massif, Higher Himalaya. It has been investigated for a stretch of about 50 km in Barai stream, a tributary of

Neelam=Kishenganga river in Kashmir and in Mir Malik stream, a tributary of Astor river, in Gilgit Agency. Both of these streams follow the strike of the thrust.

In the Shontargali Thrust, the Salkhala series Jatog Fm. is thrust over by the Nanga Parbat gneisses Central crystalline Vaikritta Group. The thrust has a northeast-southwest strike and dips between 250-350 towards east. In more tectonized sections, the angle of dip could be more. The Shontargali Thrust zone, between 3-5 km wide, is highly deformed giving rise to squeezed recumbent or reclined folds. Imbrication in the footwall zone of the thrust is manifest in highly deformed sections which usually give rise to duplex structures. The presence of mylonite and migmatite point to ductile deformation which is frequently noticed in the footwall zone of the thrust. On the basis of its geographic location and grade of metamorphism of the associated rocks, couple with its stratigraphic and tectonic settings, the author considers the Shontargali Thrust as an analogue of the Mian Central Thrust (MCT) in the northwest Himalaya in Pakistan.

Key words: Tectonics, MCT, Shontargali Thrust, Himalaya.

T/43. Tahirkheli, R.A.K., 1990. Tectonic zonation of the northwestern Himalaya in Pakistan. Abstracts, 2nd Pakistan Geological Congress, University of Peshawar, 6-7.

The tectonic zonation of the NW Himalaya in Pakistan, for years, could not be spelt out adequately because of the absence of the major tectonic scars which are so prominently manifest in the rest of the Himalaya. Recent studies on this problem have added a new dimension to the interpretation of the tectonic frame of this region by locating the extension of the Indus Suture Zone (ISZ) and the Main Central Thrust (MCT) in the NW Himalaya in Pakistan.

The ISZ, west of Ladakh, bifurcates into two sutures with a sandwiched Island arc. The northern suture which welds the Kohistan arc with the Eurasian plate is called the Main Karakorum Thrust. The southern suture juxtaposes the Kohistan arc with the Indo-Pakistan plate and is named the Main Mantle Thrust. Nowhere in Pakistan, the Eurasian Plate comes in direct contact with the Indo-Pakistan plate.

The two sutures and the Kohistan Island arc have been given due attention in several papers published within the country and abroad. But the extension of the MCT is a new addition which completes the regional tectonic net for correlation of the tectonic Zonation of NW Himalaya with the rest.

The analogue of the MCT in NW Himalaya is called the Shontargali Thrust and is mapped in the Kel stream, a tributary of the Kishanganga-Neelum river in Kashmir and the Mir Malik stream, a tributary of Astor river in Gilgit Agency. On the basis of geographic location, stratigraphic setting, tectonic frame and mode of deformation of the rocks involved, the Shontargali Thrust appears as an analogue of the MCT in the NW Himalaya in Pakistan.

Key words: Tectonics, stratigraphy, MCT, Himalaya.

T/47. Tahirkheli, R.A.K., 1992-93. Tectono-metamorphic domains of the Karakoram in Pakistan. Regional Postgraduate Training Course in Plate Tectonics, Punjab University, 24-25.

The Karakoram constitutes the southern marginal mass of Eurasia which is tectonically delineated from the Himalaya-Kohistan/Ladakh arc by the Main Karakoram Thrust, the northern suture. Its northern, eastern and western boundaries are shared respectively, by Kun Lun-Wakhan (SE Pamir), southern Tibet, east of Shyok and the eastern Chitral along Yarkun River. On the basis of tectono-metamorphic settings, the Karakoram terrain is divisible into three east-west trending linear belts:

(1) The southern Preheroyanian marginal crystalline mass, (2) The central magmatic domain, and (3) the northern Permian-Jurassic Karakoram microplate.

The southern marginal mass is comprised of metasediments ranging from slate, phyllite, various types of schists, para-gneisses, flaggy quartzite, conglomerate, medium crystalline limestone and very coarse grained marble. The grade of metamorphism is low, but in more tectonized sections, this level could rise to kyanite and sillimanite grade. The rocks are named Chitral Slate in Chitral, Darkut Group in the Yasin valley, Damurdu Formation and Baltit Group in the Hunza valley. The ages assigned to these rocks by various authors are, Cretaceous by Calkin et al., (1981), PermoCarboniferous by Ivanac et al., (1956), Permo-Triassic by Desio (1975), Triassic by Pudsey et al., (1985) and Precambrian by Tahirkheli (1982).

The central magmatic domain in the Karakoram is named Axial Karakoram Batholith and constitutes a composite assemblage of hornblende granodiorite, granites, pegmatites, aplites and vein quartz belonging to pre- and post-tectonic phases. The radiometric dates (Debon et al., 1987) place various magmatic phases in three broad categories: Middle Cretaceous (ca 110-95 Ma), Palaeogene (ca 43 Ma) and Neogene (ca 15-9 Ma).

The upper Hunza valley (UHV) sequences of the northern Karakoram microplate investigated along the Karakoram Highway reveal the following sequential order (Tahirkheli et al., 1990): Gircha Formation, Passu Slate, Dih Quartzite, Gugal Dolomite and Shanoz Conglomerate. This is a modified stratigraphic scheme, earlier presented by Desio et al. (1972). Their age ranges from Permian (on faunal basis) to Cretaceous (Shanoz Conglomerate) on lithostratigraphic correlation with the Reshun Conglomerate in Chitral. This microplate is Gondwanic (Gaetani et al., 1990) and is accreted on to Eurasian margin during pre-Main Karakoram Thrust (MKT) accident.

On the basis of lithostratigraphic, tectonometamorphic and biostratigraphic evidences, it appears that there existed two paleogeologic domains in the Karakoram. The northern one on faunal support is assigned a Permo-Jurassic age (Gaetani et al., 1990) and the southern one has a pre-Devonian/Ordovician basement. In a tectonic scenario of the Karakoram with the northern Karakoram microplate, it will be problematic to find an adjustable place for the southern mass. The northern Karakoram microplate has two neighbours Kun Lun and Qiantong microplates which have their ancestors located in Eurasia. The lithostratigraphic and tectonometamorphic frames of the southern mass of the Karakoram relate it sympathetically with the Kabul and Lhasa microplates, lying on its east and west respectively.

T/49. Tahirkheli, R.A.K., 1997. Tectono-stratigraphic framework of the Hindukush Range in Chitral, Pakistan. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, 68-69.

The rock formations encountered in the Chitral domain of Hindukush are:

i. The Chitral Slates are dominantly pelitic ranging from slates to various types of schists along with para-gneisses, interbedded flaggy quartzites, medium crystalline limestone and conglomerate. Two principal mappable lithologies incorporated in the Chitral Slates are Kaghozai Greenschists and Gahirat Marble. Diorite, dolerite and amphibolite intrusions in the basic realm and pegmatite, aplite and vein quartz in the acid are common. Based on

lithostratigraphic correlation with their counterparts in the west, (in Nuristan) in Afghanistan and in the east in the Karakoram and Ladakh, the Chitral Slates are placed in the Precambrian-Lower Palaeozoic.

ii. The Broghil Formation is composed of medium crystalline limestone, siliceous dolomitic limestone, flaggy quartzites and interbedded siliceous slates. About 5 meters thick bed of siliceous dolomitic limestone bed has yielded conodont fossils on the basis of which this sequence has been assigned and Ordovician age.

iii. The Shogran Formation at its stratotype is about 900 m thick and is divisible into three faunal units; a lower crinoidal massive dolomite, a middle coral-bearing thick bedded dolomite along with interbedded black shales and upper flaggy quartzite and thin bedded limestone with brachiopods. A lower to upper Devonian age is assigned to Shogran Formation.

iv. The undifferentiated Turikho Group constitutes a thick sequence of dominantly argillaceous rocks with subordinate crystalline limestone, quartzos sandstone and conglomerate along with host of acid and basic sills and dykes. These rocks have been mapped in different sections as Lun shales, Sirikol Shales, Khandhot Shales, Wakhan Slates and Fusilina Limestone. Some limestone beds in the Mastuj valley have yielded fossils, on the basis of which Permo-Carb, Triassic and Jurassic ages have been assigned to the rocks of this group.

v. The Reshun Formation is divisible into three litho-stratigraphic units. The lower one is medium crystalline, thick bedded to massive Krinj Limestone, followed by Awi Conglomerate with larger part of its clasts derived from the underlying limestone and from the Chitral Slates. The top bed consists of maroon marly shales. Some Orbitolina-bearing pebbles conglomerate along with Hippurites in Krinj Limestone in Lutkho valley places Reshun Formation into the Cretaceous.

vi. The Tirich Mir Granites occur in isolated plutons intruding Turikho Group of rocks and constitute an assemblage of quartz diorite, granodiorite, monzogranite and granite. Rb/Sr radiometric age on granodiorite has yielded an age of 115 my.

vii. The westward termination of the Axial Karakoram batholith in the Hindukush of Chitral is marked by three east-west trending plutons located within the Chitral Slates. The Buni Zorn pluton west of Sor Laspuir among them, is the largest. Granodiorite and granites are its main constituents with basic and acid sills and dykes occurring as minor intrusions. Radiometric dates on granodiorite and granites of Karakoram batholith range from 96 to 15 my. The four major tectonic scars in the Chitral area are, (a) Reshun Fault, (b) Ayun Fault, (c) Tirich Fault and (d) Shishi Koh Fault. The last one is regarded to demarcate the northern Himalayan suture, namely the Main Karakoram Thrust. Tirich Fault in the northern domain has indicated some basic igneous and metavolcanic signatures and could mark a boundary between Hindukush and Southern Pamir Block.

T/50. Tahirkheli, R.A., Asif, M.K. & Tahirkheli, T., 1992. Regional geological framework of the Karakorum in Pakisatn. In: Zheng, D., Zhang, Q. & Pan, Y. (Eds.), Proceedings of international symposium on the Karakorum and Kunlun mmountains. China Meteorological Press, Beijing, 54-71.

The 600x150 km Karalorum Range covers about 90,000 km² area of Pakistan, China and India. It comprises three linear belts, from S to N, 1: Southern Pre-Hercynian (Precambrian-Early Paleozoic) crystalline marginal mass which is delineated from the Kohistan arc and Himalaya by the Main Karakorum Thrust; 2: The central magmatic domain of batholithic dimension. It comprises pre-tectonic phases of Late Cretaceous age and post-tectonic phases emplaced in Miocene, and 3: The northern Hercynian (Pero-Cretaceous) sedimentary belt, referred to in the paper as the Upper Hunza Valley sequence.

Key words: Tectonics, Northern Karakoram plate, Main Karakorum Thrust, Hunza

T/51. Tahirkheli, R.A.K., Baqri, S.R.H. & Dawood, H., 1992. A new status of the pelitic sequences in the upper Hunza valley in Karakoram, Pakistan. Abstracts, First South Asia Geological Congress, Islamabad, p.43.

Briefly describes the pelitic rocks (e.g., Misgar slates) that cover large areas in northern Hunza valley, in the central Karakoram Range. For further detail, See Tahirkheli, SUN, Pan et al., 1990.

Key words: Pelitic sequence, slates, Hunza, Karakoram.

T/53. Tahirkheli, R.A.K. & Jan, M.Q., 1979b. A preliminary geological map of Kohistan and the adjoining areas, N. Pakistan. Geological Bulletin, University of Peshawar 11.

This is the first compilation of the geological map of northern Pakistan, where much of the blank area shown on the Geological map of Pakistan (Bakr & Jackson, 1964) was also covered. The terrain is divided into Eurasian, Kohistan island arc, and Indian plate domains. Major thrust faults, i.e., Main Karakoram Thrust, Main Mantle thrust and Main Boundary Thrust, are also shown on the coloured map.

Key words: Geological map, Indian plate, Kohistan, Karakoram.

T/54. Tahirkheli, R.A.K. & Jan, M.Q., 1984. The geographical and geological domains of the Karakoram. In Miller K.J. (eds), The International Karakoram Project, Volume 2, 57-70. Cambridge University Press.

This paper deals with some of the existing geographical and geological problems of the Karakoram and the authoress presents their views for their solution and better understanding.

The western and eastern boundaries of the Karakoram with the Hindukush and the Himalaya, respectively, still remain an unsettled issue. The authors on the basis of their observations have extended the western boundary to the high ranges forming the main divide between the Gilgit and the Yarkun rivers, lying southwest of Mastuj between 72° and 73° E. In the north this boundary passes slightly east of Broghil between Long. 73° and 74° E.

In the east, the limit of the Karakoram has been stretched deep into Ladakh; and the eastern extent of the Deosai-Ladakh range with its eastern boundary with the Himalaya.

Under the context of plate tectonics, the rock sequence established by authors in the western section of the Karakoram (Hunza valley), from south to the north as follows:

Kohistan Island Arc Mass	Ladakh Granodiorite
Chalt Ophiolite	
Yasin Group	
Main Karakoram Thrust	
Asian	Darkut Group
Karakoram Granodiorite	
FAULT	
The rock sequence of the Tethyan folded belt lying towards north of the Main Karakoram Range

T/57. Tahirkheli, R.A.K., Jan, M.Q. & Mian, I., 1971b. Hydrothermal graphite in Tirah, Khyber Agency. Geological Bulletin, University of Peshawar 6, 114-117.

During recent years, some samples of graphite from Tirah, Khyber Agency, which were analysed in various laboratories in Pakistan, have yielded over 50 % fixed carbon. This created special interest for the authors to conduct investigations concerning the origin and economic potentials of the mineralization. The graphite is located near Spinkai (Lat. 33° 55' ½, Long. 70° 41') in Tirah tribal territory and is accessible through Chora, Bazar, Bara and Rajgal Valleys. The area can also be approached from Kohat via Sra Mela and Maidan. The mineralized area is along the northern slope of Bijor Sar (ca. 9,000 feet) at an elevation of about 6,500 feet.

Key words: Metamorphic rocks, graphite, Khyber Agency.

T/58. Tahirkheli, R.A.K., Jan, M.Q. & Mian, I., 1975. A geological traverse through Tirah, Khyber Agency, NWFP, Pakistan. Geological Bulletin, University of Peshawar 7 & 8, 79-88.

This short paper presents the results of a geological traverse conducted through the northern part of Tirah in Khyber Agency during the last week of July, 1971. The rocks encountered between Lala China and the Rajgal area are, Lala China Slaty-shale, Chura Kandao Limestone, Walai Limestone, China Limestone, Spinkai Limestone, Mughalbagh Shales, Paleocene Limestone and Murree sandstones and shales; the latter two units are well developed in the Bara and Rajgal valleys, west of Bazar.

The Palaeozoic sequence, besides Lala China and Chura Kandao (Khyber Pass), were encountered at two places; in a Khwar about 3 miles upstream of Mughalbagh and in Baraghat nala in the Rajgal area. Four differentiable mapable units from bottom to top are; Lwarai Mela Limestone, Baraghat Slate, Barai Quartzite and Spinkai Limestone, which have been placed as members of the Rajgal Formation. Acid igneous intrusions consisting of granite and granite-gneiss with pegmatite and aplite veins lie in contact with the upper part of Spinkai Limestone. Graphite mineralization occurs in the granite and granite-gneiss near the contact of the Spinkai Limestone.

T/59. Tahirkheli, R.A.K. & Kamal, M., 1981. Whether tectono-magmatic regimes offer any prospects for primary uranium mineralization in northern Pakistan. Geological Bulletin, University of Peshawar 14, 95-100.

The northern segment of Pakistan inhabits some of the loftiest mountain systems of the world. Nearly forty per cent of the rocks covering the surface area in this terrain are igneous, out of which over seventy per cent belong to the acid igneous domain. The Late Mesozoic – Cenozoic orogenic events had brought into being some of the major lineaments, which have regional dimensions. Magmatic emanations associated with these shears belong to several generations; some of them belonging to the late phases have indicated metallic mineral associations. A few known primary uranium mineralizations in this region are associated with some of these magmatic episodes. This paper discusses the tectono-magmatic environment of the northern Pakistan and delineates the metallogenic zones under the context of plate tectonics – where favorable conditions may exist for finding primary uranium mineralization.

T/60. Tahirkheli, R.A.K. & Majid, M., 1977. Geology of the Tanawals in the southwest Tanawal and Gandghar Range, Hazara, Pakistan. Geological Bulletin, University of Peshawar 9 & 10, 1-21.

In the Hazara Paleozoic sequence, the Tanawal Formation overlies the Hazara Slates and underlies the Abbottabad Formation. A pebbly bed marks the contact between the Hazara Slates and the Tanawals, which is not persistent, but elsewhere in Kashmir and the Central Himalayan sections gradational contact has been reported by the earlier worker.

The Tanawal comprise dominantly of arenaceous rocks which constitute quartzite, quartzitic schist and quartzitic sandstone with interbedded arenaceous slaty shales, slates, phyllitic slates and conglomerate which are intruded by the igneous rocks. Among the quartzose rocks, arkosic wacke, suabarkose, arenites and quartz arenites are differentiated. Amphibolites, epi-diorites, porphyritic micro-tonalite, dacite, rhyo-dacite, pegmatite and quartz veins are the igneous rocks which occur in the Tanawals as sills, dykes and veins.

The Tanawals are unfossiliferous. Their sympathetic stratigraphic relationship with the fossiliferous Paleozoic rocks in Kashmir, Central Himalaya and Swabi – Lower Swat areas, suggest for them a Devonian – Lower Carboniferous age. The discovery of Hyolithids of Cambrian age near the contact of overlying Abbottabad Formation and Hazira shales will depress the age of the Tanawals to Precambrian. However, this fossil find is very localized and appears to have been derived from the older horizon and incorporated in these rocks.

T/62. Tahirkheli, R.A.K., Mattauer, M., Frost, F. & Tapponnier, P., 1979. The India-Eurasia suture zone in northern Pakistan: synthesis and interpretation of recent data at plate scale. In: Farah, A. & Dejong, K.A. (eds) Geodynamics of Pakistan. GSP, 125-130.

In north Pakistan, there are three distinct geological domains, comprising NW Himalaya (Indian plate), Kohistan Mountains, and Eurasian block. These terrains are separated by major faults. The authors were amongst the earliest ones to propose that the Kohistan terrain is a sandwich of an island arc between Eurasia in the north and Indian plate in the south. Its northern boundary is delineated by a regional fault that they named as the Main Karakoram Thrust, and its southern boundary with the Indian plate delineated by what they called the Main Mantle Thrust.

Key words: Sutures, tectonics, Kohistan, Indian plate, Eurasian plate.

T/63. Tahirkheli, R.A.K. & Riaz, M., 1991. Tectono-stratigraphic implication in extending the Panjal thrust, west of the Hazara-Kashmir syntaxis. Geological Bulletin, University of Pakistan 24, 25-32.

The Panjal Thrust (PT) is one of the principal tectonic scars of the Lesser Himalayan domain in Kashmir. Its type section is located in the Panjal Range from where it extends northeast wards along the eastern flank of the Hazara-Kashmir syntaxis and terminates at its apex. In the Panjal Thrust the Precambrian Salkhalas thrust over the Permo-Triassic Panjal Group. This tectonostratigraphic setup is retained by this thrust throughout its course in Kashmir. During recent years, some geologists have extended this thrust west of the syntaxis through Galiat, Abbottabad, Gandghar Range, and terminated it across the Indus in the Attock-Cherat Range. The tectono-stratigraphic and lithostratigraphic frames of these sections are not akin to the ones displayed in the Panjal Thrust sections in Kashmir. This controversial aspect of the Panjal Thrust has been studied to ascertain whether the western counterparts of the Panjal Thrust west of the Hazara-Kashmir syntaxis has any justification to be correlated with its tectono-stratigraphic net displayed in Kashmir.

Key words: Tectonics, stratigraphy, structure, Panjal thrust, Hazara-Kashmir-syntaxis.

T/64. Tahirkheli, R.A.K., Sun, D., Pan, Y., Deng, W., Zhang, Y., Baqri, S.R.H. & Dawood, H., 1990. Review of stratigraphy of the upper Hunza valley (UHV), NW Karakoram, Pakistan. Geological Bulletin, University of Peshawar 23, 203-214.

Recent collaborative work of Pakistani and Chinese scientists has established five mapable stratigraphic units which, from old to young, are: i. Gircha Fm., ii. Pak-China Friendship Fm (Dih Fm.), iii. Passu Slate, iv. Gujal Dolomite, and v. Shanoz Conglomerate. A NNW-SSE trending Sost Anticline is the major structure in this area which bifurcates the stratigraphic net of this valley. The oldest formation exposed in the core of Sost Anticline is Gircha Fm. The base of the Gircha Fm is not exposed in UHV. The age of stratigraphic sequence in the UHV, based on fauna, ranges from Late Permian to Late Cretaceous-Early Tertiary.

Key words: Stratigraphy, structure, Hunza valley.

T/65. Tahirkheli, T., 1998. Geochemistry, mineralogy and petrology of the sulfide mineralization and associated rocks in the area around Drosh, north Pakistan. Ph.D. thesis, NCE geology, University of Peshawar.

Copper mineralization in the Drosh-Shishi area is localized in the upper crust of the Kohistan arc terrane in Chitral, northern Pakistan. It is confined to the Gawuch Formation in the area, comprising variably metamorphosed volcanics and sediments intruded by the plutons of diorite and granodiorite composition. The metavolcanics of the Gawuch Formation and the diorite-granodiorite minor plutons have calc-alkaline compositional characteristics. In comparison, the metavolcanics of the Darosh Formation, occupying the top of the succession, are island-arc tholeiites. Copper mineralization in the area is related to hydrothermal activity and is mainly associated with altered diorites and quartz veins. It occurs in different forms; in the quartz veins, along the foliation planes, in dissemination and as supergene enrichment. Tetrahedrite, chalcopyrite, pyrite and galena are the dominant ore minerals along with subordinate amounts of sphalerite, magnetite, malachite and azurite. Fluid-inclusion studies indicate that the salinity of the hydrothermal solution is <26 equivalent wt% NaCl and the homogenization temperature is in the range of 160 to 350°C. Oxygen isotope data suggest that the quartz in the mineralized quartz veins has $\delta^{18}\text{O}$ values ranging from 14.49 to 18.32 per mil with mean value of 16.63 ‰. This, when combined with the homogenization temperature obtained from the fluid-inclusion studies, indicates involvement of magmatic fluids ($\delta^{18}\text{O} = 5.79\text{--}9.62\text{‰}$) in the formation of quartz veins and associated copper mineralization.

The lead isotopic compositions of three galena samples suggest that $^{206}\text{Pb}/^{204}\text{Pb}$ ranges from 18.728 to 18.793, $^{207}\text{Pb}/^{204}\text{Pb}$ from 15.658 to 15.728 and $^{208}\text{Pb}/^{204}\text{Pb}$ from 39.040 to 39.285. These Pb-isotope ratios yield model ages of 42 – 140 Ma with the μ values of 9.86 to 10.01. The minimum age (i.e., 42 Ma) is in close agreement with 40Ar-39Ar age of the Lowari pluton, which is considered to be the source of hydrothermal solutions. The lead isotopic composition of studied galena samples indicate involvement of lead derived from older sources. These sources could be the arc volcanics or pelagic sediments of oceanic crust of Neotethys or the continental crust of the subducting Indian plate. It is concluded from these studies that the copper mineralization in Drosh-Shishi area was produced by the hydrothermal activity related with syntectonic dioritic magmatism.

T/66. Tahirkheli, T., Khan, M.A. & Mian, I., 1990. A- type granites of Warsak, Khyber Agency, N Pakistan: Rift-related acid magmatism in the Indian plate. Geological Bulletin, University Peshawar 23, 187-202.

Three varieties of granite from Warsak have been analysed for their geochemical composition, particularly trace elements. Two of the three varieties contain aegirine and riebeckite and are thus peralkaline. The third variety comprises biotite and muscovite with rare garnet, and varies between meta- and peraluminous compositions. Irrespective of these differences in mineralogical and major-element characteristics, there is a close match in incompatible trace elements between all the three varieties of granite from the studies area. A close scrutiny of the trace-element composition reveals A-type nature of the Warsak granites. Palaeozoic fragmentation of Gondwana,

involving breakaway of India, may be responsible for the generation of the Warsak A-type granites and other similar granites in the Peshawar plain at Ambela, Shewa-Shahabazgarhi, Malakand and Terbela.

Key words: Geochemistry, petrology, granites, magmatism, Indian plate.

T/67. Tahirkheli, T., Khan, M.A. & Mian, I., 1993. The Warsak basic rocks: Initial- rift stage continental tholeiites of Permo-Triassic “Panjal” affinity. Geological Bulletin, University of Peshawar 26, 17-33.

A suite of basic rocks, comprising microgabbros, dolorites, metabasalts and volcanoclastic sediments, occurs associated, both in space and time, with the alkaline granites at Warsak near Peshawar. Detailed geochemistry, mainly based on trace elements, suggests that the magmatism responsible for the Warsak basic rocks was tholeiitic in composition and was erupted/intruded in a within-plate continental setting. Furthermore, the Warsak basic rocks have geochemical composition closer to rift volcanics rather than the plateau basalts.

The Warsak basic rocks, in this study, have been identified to be related with the suite of tholeiitic basalts commonly encountered as dykes and sills in the Lower Palaeozoic or older rocks of northern part of the Indian plate. The volcanic and volcanoclastic component in the Warsak area is directly correlatable with the Karapa greenschist in Ambela area, and the amphibolite marker horizon in the upper part of the Marghazar Formation of Lower Swat, which are in turn correlatable with the Permo-Triassic Panjal volcanics of Kaghan and Kashmir.

Key words: Geochemistry, petrology, granites, magmatism, Indian plate.

T/68. Tahirkheli, T., Khan, M.A. & Shah, M.T., 2001. Geochemistry and petrogenesis of igneous rocks in Drosh-Shishi area, Chitral, Northern Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.11.

Drosh-Shishi area is localized in the upper crust of the Kohistan arc terrane in Chitral, northern Pakistan. It comprises two groups of igneous rocks, metavolcanics and diorites. Metavolcanics occur as two stratigraphic entities i.e. Gawuch and Drosh formations. Gawuch Formation comprises of variably metamorphosed volcanics and sediments intruded by the plutons of diorites and granodiorite composition.

The metavolcanics of Gawuch Formation are divided into two types: porphyritic and fine-grained to glassy. The former vary from fresh to highly altered and commonly dissected by quartz and calcite veins. Volcanic rocks belonging to the Drosh Formation are massive to weakly foliated, fine-grained and commonly altered. In composition, they are mostly andesitic. Three varieties of diorites are distinguished in Gawuch Formation on the basis of texture and degree of alteration, 1) diorites, 2) altered diorites, and 3) gneissose diorites. Geochemistry involving major and trace elements have been used to characterize the petrology and tectonic setting of igneous rocks of the area. Detailed geochemistry suggests that the magmatism responsible for diorites and volcanics of the Gawuch Formation was calc-alkaline, while that of Drosh Formation was tholeiitic in composition. Detailed treatment in terms of mantle-normalized trace element patterns and discrimination diagrams suggest that diorites and the two groups of volcanics, despite differences in their petrological character, originated with a strong subduction component.

Key words: Geochemistry, petrogenesis, Chitral, Kohistan arc.

T/70. Tahirkheli, T., Shah, M.T. & Khan, M.A., 1997a. Lead isotopic signature of the hydrothermal copper mineralization in Drosh-Shishi area, Chitral, Northern Pakistan. Abstracts, 3rd Pakistan Geological Congress, University of Peshawar, p.69.

For details consult the following account.

Key words: Geochemistry, mineralogy, isotopes, lead, Chitral.

T/71. Tahirkheli, T., Shah, M.T. & Khan, M.A., 1997b. Lead isotopic signature of the hydrothermal copper mineralization in Drosh-Shishi area, Chitral, Kohistan arc terrane, Northern Pakistan. *Geological Bulletin, University Peshawar* 30, 209-217.

Copper mineralization in Drosh-Shishi area is a part of the upper crust of Kohistan arc terrane in Chitral, northern Pakistan. It is generally confined to the Gawuch formation in the area. This formation comprises of variably metamorphosed volcanics and sediments intruded by plutons of diorite and granodiorite. Copper mineralization is related to the hydrothermal activity and is mainly associated with altered diorites and quartz veins.

The lead isotopic ratios of three samples of galena from quartz veins in Drosh-Shishi area were determined. $^{206}\text{Pb}/^{204}\text{Pb}$ from 18.728 to 18.793, $^{207}\text{Pb}/^{204}\text{Pb}$ from 15.658 to 15.728 and $^{208}\text{Pb}/^{204}\text{Pb}$ from 39.040 to 39.285. These lead-isotopic ratios yield wide range of model ages of 42 to 140 Ma. This mineralization is very young in terms of age and have μ values of 9.86 to 10.01. The studied galenas have comparable Pb-isotope ratios to that of Rossie-Type veins of USA and Canada and are more radiogenic to the conformable massive sulfides and less radiogenic to Mississippi Valley-Type sulfide deposits. The Lead isotopic data further suggest that the lead in galena may have been derived from the arc volcanics or pelagic sediments of ocean crust of Neo-Tethys or continental crust of Indian plate and may have relation with orogeny.

Key words: Geochemistry, copper mineralization, isotopes, lead, Chitral.

T/72. Tahirkheli, T., Shah, M.T. & Khan, M.A., 1998. Oxygen Isotopic Signature of the Hydrothermal Copper Mineralization in Drosh-Shishi Area, Chitral, Pakistan. *Acta Mineralogica Pakistanica* 9, 111-116.

Copper mineralization in Drosh-Shishi area is a part of the upper crust of Kohistan arc terrane in Chitral, northern Pakistan. It is generally confined to the Gawuch Formation in the area. This formation comprises of variably metamorphose volcanics and sediments intruded by plutons of diorite and granodiorite. Copper mineralization is related to the hydrothermal activity and is mainly associated with altered diorites and quartz veins.

Nine samples of mineralized quartz veins in Drosh Shishi area were analyzed for oxygen isotopic ratios. The $\delta^{18}\text{O}$ value of quartz veins range from 14.49 to 18.32‰ with a mean value of 16.63‰. The $\delta^{18}\text{O}$ value of the mineralizing fluid of the area has been calculated at the man temperature (255°C) as determined by fluid inclusion studies. The estimated $\delta^{18}\text{O}$ value of the mineralizing fluid ranges from 5.79 to 9.62‰ with a mean value of 7.98‰. This indicates the involvement of magmatic fluids in the formation of quartz veins and associated copper mineralization in the investigated area.

T/75. Tahirkheli, T., Shah, M.T. & Khan, M.A., 2000. Copper mineralization in the western Kohistan island arc terrane, NW Himalaya-Hindukush, N. Pakistan. Abstracts, Third South Asia Geological Congress, Lahore, 175-177.

The Kohistan Terrane in N. Pakistan straddles the suture zone between the collided Indian and Eurasian plates in the NW Himalayas of N. Pakistan. Initiated as an intra-oceanic island-arc crust in Neotethys, the terrane accreted with the southern margin of the Karakoram Plate in the Late Cretaceous (~90 Ma). Continued subduction at its southern margin resulted in Andean type magmatism and tectonics, until collision with the Indian Plate in the Early Eocene. Whereas much of the central and eastern Kohistan expose Cretaceous volcanic and sedimentary rocks of intra-oceanic island arc setting, the western Kohistan in Swat, Dir, Chitral and upper Ghizer valleys preserves remnants of the Late Paleocene-Early Eocene volcanism and sedimentation of Andean type setting. These volcano-sedimentary lithologies in western Kohistan are geographically divisible into two, separated by the Lowari Pluton; 1) Dir-Swat Belt, 2) Drosh-Shamran Belt. Late Paleocene-Early Eocene siliceous volcanics termed Utror Volcanics and Shamran Volcanics are common in the two belts and so are the plutons intrusive into these volcanics (Late Stage-II of the Kohistan Batholith). The difference is in the sedimentary successions present in the two belts. Whereas in the Dir-Swat belt, the sedimentary succession comprises Baraul Banda Slate Formation, deposited in deep-water fore-arc setting and contemporaneous in age with that of the nearby Utror Volcanic Formation (~55-60 Ma), the sediments in the Drosh-Shamran belt are distinctly red beds of fluvial origin (the Purit Formation) those overlie unconformably on top of the Shamran Volcanics and their equivalents. Copper mineralization in western Kohistan is associated with the both volcano-sedimentary belts described above. In the following we outline salient features of copper mineralization in the belts.

Copper Mineralization in Dir-Swat Belt:

In Dir-Swat belt copper mineralization is confined to the Eocene Utror Volcanic Formation. Greenschist facies metavolcanics host the mineralization in quartz veins, shear zones, sphalerite-bearing copper-rich zones and copper and iron-bearing chloritized zone. Chalcopyrite is the main copper-bearing phase along with subordinate amounts of pyrite, bornite, and chalcocite. Malachite and azurite occur as supergene enrichment. High $\delta^{18}\text{O}$ values for mineralized quartz veins (average 10.1 ‰) and the mineralized metavolcanics (8.1-10.3‰) suggest involvement of isotopically heavy fluids ($\delta^{18}\text{O} = 5.9$ ‰) probably related with the late-stage (post-Early Eocene-Stage II) intrusives of the Andean-type Kohistan Batholith. A chemical gain-loss comparison between the mineralized and unmineralized rocks suggests that the mineralizing fluids induced enrichment of elements like Cu, Zn, Pb, Mo, As, Cd, Ag, and Au in the former.

Copper Mineralization in Drosh-Shamran Belt:

The copper mineralization in the Drosh-Shamran belt, unlike the Dir-Swat belt, is localized in the Late Cretaceous volcano-sedimentary sequence (i.e., Gawuch Formation) rather than the Eocene Shamran Volcanic Formation that is equivalent and probably cogenetic with the Utror Volcanic Formation. Within the Gawuch Formation, mineralization is particularly intense in the granodiorites that occur as minor intrusives within the metavolcanics of the Gawuch Formation. A marble band of 2 to 3 meter thickness occurring at the contact of the Gawuch Formation and overlying fluvial sediments of the Purit Formation is most mineralized, suggesting entrapment of migrating mineralizing fluids. Tetrahedrite, galena, chalcopyrite and pyrite are the dominant ore minerals along with subordinate amounts of sphalerite, magnetite, limonite, malachite and azurite. $\delta^{18}\text{O}$ in the mineralized quartz veins is high (14.49 to 18.32‰) that is even higher than those in Dir. The $\delta^{18}\text{O}$ of the mineralizing fluid is calculated to be at average 7.98‰, that falls in the range of values known for magmatic liquids (i.e., 5-9‰). The localization of mineralization in the Late Cretaceous Gawuch Formation suggests that mineralization, unlike in the case of the Dir mineralization, may be of any age between Late Cretaceous and Late Eocene. However, the two plutons close to the mineralized zone indicate ages younger than Early Eocene. The Lowari pluton that separates the Dir-Swat Belt from the Drosh Shamran Belt yields a ^{40}Ar - ^{39}Ar cooling age of 45 Ma while the Mirkhani pluton in the Drosh area intrudes Eocene Shamran Volcanic formation. Therefore there is great probability that copper mineralization in the Drosh Shamran Belt is Post-Early Eocene, related with the late phases of the Kohistan Batholith.

Conclusions:

The two principal copper mineralization zones in western Kohistan, at Drosh and Dir are localized in volcanic lithologies of different ages, Late Cretaceous and Early Eocene, respectively. Both are however characterized by high $\delta^{18}\text{O}$ values suggesting role of magmatic fluids in their origin. Late phases of Kohistan Batholith are considered to be the source of these fluids in both cases.

Copper mineralization, generally confined to the Gowuch Formation, in Drosh-Shishi area is part of the upper crust of Kohistan arc terrain in Chitral, northern Pakistan. It is related to the hydrothermal activity and is mainly associated with altered diorites and quartz veins. It occurs in different forms; within quartz veins, along foliation planes, in dissemination and as supergene enrichment. Fluid inclusion studies indicate that the salinity of the hydrothermal solution is 12.28-13.40 equivalent wt% NaCl and the homogenization temperature ranges from 160 to 350° C. This suggests that the copper mineralization is related to the late stage vein formation as a result of diorite and granodiorite intrusion.

T/78. Takahashi, Y., Kausar, A.B., Takahashi, Y. & Khan, T., 1993. Field relationship between the rock units of the Chilas complex, Chilas, northern Pakistan. *Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad* 4, 41-50.

The Geoscience Laboratory, Geological Survey of Pakistan has started a joint collaborative project with JICA experts who were mainly despatched from the Geological Survey of Japan on the Chilas Igneous Complex in Chilas area as one of the technology transfer programs for the Geoscience Laboratory established under a grant in aid project by JICA, Japan.

The survey in Chilas area is being carried out jointly by experts of both the countries. For the 1991 work, the first phase, the GSJ despatched a survey team consisting of 3 geologists during a period from Nov. 4 to Nov. 19, 1991 (Kubo *et al.*, 1992). For the 1992 work, the second phase, the JICA despatched a team consisting of 2 geologists from Oct. 27, 1992 to Nov. 23, 1992. During 1991, 1 geologist and during 1992, 2 geologists from Geoscience Laboratory participated in this research programme.

The primary purpose of this research is to focus on the following points:

1. Relationship between the gabbro-norite and ultramafic-mafic bodies.
2. Variation of rock facies within the Chilas igneous complex
3. Relationship between ultramafic and mafic rock facies.
4. Layered structure in ultramafic and mafic units.
5. Finding out original flow structure in gabbro, norite-gabbro, and gabbro-norite and then interpreting the younging direction.

T/79. Takahashi, Y., Khan, T., Takahashi, Y., Kausar, A.B. & Kubo, K., 1996a. Mode of plagioclase twinning of two plutonic bodies in Kohistan terrane, northern Pakistan. *Journal of Mineralogy, Petrology and Economic Geology* 91, 242-249.

Mode of plagioclase twinning is examined in the Chilas complex and Kohistan batholith, which are large plutonic bodies in the Kohistan terrane, northern Pakistan. The frequency of C twins, which are defined as all laws other than albite and pericline twins, is mostly 10 to 20% in the tonalite and granodiorite of the Kohistan batholith. These values characterize igneous rocks.

Frequency of C twins in the Chilas complex is low (0 to 5%) in the eastern part and high (20 to 30%) in the central part. The former represents metamorphic features and the latter igneous features. These features result from the

difference of the erosional surface of the complex and explain the petrological discrepancy that the complex is deduced to have been metamorphosed to the granulite facies, but that it locally intruded and gave thermally altered effect to the surrounding amphibolite.

Frequency of pericline twin is almost the same in both bodies. This consistency may be developed by a result of the same tectonic event, i.e., collision between the Indian plate and the Kohistan terrane.

The Chilas Igneous Complex is one of the major geological unit in the Kohistan Island Arc Region, of which southern end is bounded by the Main Mantle Thrust (MMT) and northern end is by the Main Karakoram Thrust (MKT) (Searle, 1991). The Chilas Complex is 60-km wide and elongated 300-km almost parallel to the MMT and MKT. It is intruded into the amphibolite (Kamila Amphibolite), which develops widely on the southern half of the Kohistan Island Arc Region. The Complex is composed mainly of gabbro-norite and contains several masses of ultramafic-mafic complex as large xenolith. Ar/Ar and K/Ar ages of the hornblende from the Complex are at around 80Ma, which may date cooling through 500°C, the hornblende blocking temperature (Treloar et al., 1989). The Complex consists of host gabbro-norite and several masses of ultramafic-mafic complex (UMC). Both of them are deformed together exhibiting foliations, which form several antiforms and synforms striking WNW-ESE, subparallel to the igneous body. Some structures of deformation on the Chilas Complex are discussed.

T/83. Takahashi, Y., Takahashi, Y., Kausar, A.B., & Kubo, K., 1994a. Modes of plagioclase twinning in the Chilas complex and Kohistan batholith, northern Pakistan. *Proceedings of Geoscience Colloquium*, Geoscience Lab, GSP, Islamabad 9, 51-58.

The ratios of pericline twins in the twinned plagioclase of Chilas complex (CC) and Kohistan batholith (KB) are overlapped, suggesting that these are deformed under same physical conditions. The ratio of C twins (all twins other than albite and pericline) in the KB are more than those in the CC. The ratio of C twins in the KB are more than 8%, indicating their igneous origin. The ratio of C twins of the CC is less than 5%, indicating metamorphic origin. It is noted that the CC has been emplaced at depths first and subsequently metamorphosed, which is characterized by low ratio of C twins. On the other hand the KB show high ratio of C twins suggesting comparatively shallow depth of emplacement and lack of metamorphism after emplacement.

Geological relationship between the Chilas complex and the Kamila amphibolite belt, northern Pakistan-Implications for the tectonic development of the Kohistan island arc. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 192-193.

The Kohistan terrain in the western Himalaya, northern Pakistan, is regarded as a tilted island arc type crust sandwiched between the Asian and Indian continental crusts [1]. The Kohistan island arc is bounded along the south by Main Mantle Thrust (MMT), and along the north by Northern Suture (or Main Karakoram Thrust, MKT), which can be divided into some geological units.

The Chilas complex is a huge basic intrusion about 50km wide and elongates 300-km almost parallel to the MMT and the MKT, which is composed mainly of gabbro-norite and several masses of ultramafic-mafic anorthosite association [21]. It has been interpreted as the magma chamber root zone of the Kohistan island arc [3]. On the other hand, the Kamila amphibolite belt is composed of highly deformed amphibolite-facies meta-plutonic and meta-volcanic rocks with calc-alkaline geochemistry [41] situated to the south of the Chilas complex. Geological relationship between the Chilas complex and the Kamila amphibolite belt is not yet confirmed, although they are main constituents of lower crust in the Kohistan island arc. Some people consider that the Chilas complex and the Kamila amphibolite were originally same, but the Chilas complex was metamorphosed to granulite facies and the Kamila amphibolite belt to amphibolite facies [5,6]. On the other hand, it is considered that the Chilas complex and the Jijal complex are lower crusts of different island arcs and they are separated by the Kamila shear zone (Kamila amphibolite belt) [6]. Accordingly, northern part of the Kamila amphibolite belt is hydrated and recrystallized product from the gabbro-norite of the Chilas complex.

The geological relationship between the Chilas complex and the Kamila amphibolite belt is fundamentally important to consider the geologic development of the Kohistan island arc, because they are main constituents of lower crust in the Kohistan island arc. In this paper, we present detailed geological and geochemical data around the boundary between the Chilas complex and the Kamila amphibolite belt and discuss on the relationship between them.

In the Swat valley, the Chilas complex is bounded on the south by the Kamila amphibolite belt. Around the boundary several xenoblocks of the Kamila amphibolite are observed in gabbro-norite of the Chilas complex and gabbro-norite dikes of the Chilas complex occur in the Kamila amphibolite. At the lower reaches of Miandam River which is a small branch of Swat River coming from the east, a xenoblock (about 20*5m) of the Kamila amphibolite occurs in gabbro-norite of the Chilas complex. The amphibolite and gabbro-norite are just contact to each other and a foliation develops in both the amphibolite and gabbro-norite which is oblique to the lithologic boundary. The amphibolite is composed mainly of hornblende and plagioclase, in which original plutonic texture still persists. Under the microscope, hornblende and biotite are aggregates of fine crystals exhibiting a decussate texture, which indicates thermal effect. On the other hand, the gabbro-norite is composed mainly of plagioclase, clinopyroxene and orthopyroxene with minor hornblende and biotite, which is slightly deformed, but there is no evidence of thermal effect. Therefore, it is evident that the Kamila amphibolite was intruded by gabbro-norite of the Chilas complex and suffered contact metamorphism and after that a foliation was formed in both the gabbro-norite and amphibolite by ductile deformation, which may be related to the collision of Kohistan to the Asian continent.

The eastern part of the Chilas complex is bounded on the north by amphibolite. At the upper reaches of Khanbari River, which is a small branch of Indus River coming from the north, gabbro-norite of the Chilas complex and amphibolite are just contact to each other. The amphibolite is composed mainly of hornblende and plagioclase, in which original plutonic texture still persists. Under the microscope, hornblende and biotite are aggregates of fine crystals exhibiting a decussate texture. On the other hand, the gabbro-norite is composed mainly of plagioclase,

clinopyroxene and orthopyroxene with small amount of biotite and hornblende, which is slightly deformed. Therefore, it is evident that the amphibolite was intruded by the gabbro-norite of the Chilas complex and suffered contact metamorphism. The northern amphibolite may correspond to the Kamila amphibolite, because these features are just like those in the Swat River. It is important to note that the Chilas complex is a large intrusive body in the Kamila amphibolite belt.

T/86. Takahashi, Y., Takahashi, Y., Kausar, A.B. & Mikoshiba, M., 1996. Geology and geochemistry of eastern part of the Chilas complex, northern Pakistan- Implications for the tectonic development of the Kohistan island arc. In: Kausar, A.B. & Yajima, J. (Eds.), Geology, Geochemistry, Economic Geology and Rock Magnetism of the Kohistan Arc. Proceedings of Geoscience Colloquium (Geoscience Lab, GSP, Islamabad) 15, 183-205. (Also published in the Proceedings of Geoscience Colloquium (Geoscience Lab, GSP, Islamabad) 14, 39-61)

Geological and geochemical studies of the eastern part of the Chilas complex, Northern Pakistan have been carried out by GeoLab research team. On the basis of the results, a model of tectonic development of the Chilas complex is proposed. The Chilas complex is composed mainly of gabbro-norite and several masses of ultramafic-mafic association (UMA). The UMA is composed mainly of olivine (with or without clinopyroxene) cumulate (dunite, wehrlite) and plagioclase clinopyroxene-orthopyroxene cumulate (two pyroxene gabbro), with minor amount of clinopyroxene-orthopyroxene cumulate pyroxenite). Geochemistry of the gabbro-norite is suitable to island arc non-cumulate, and the UMA is suitable to island arc cumulate. Major element geochemistry of the gabbro-norite and the UMA is explained by cumulate and noncumulate model. Rare earth element and trace element geochemistry of the gabbro-norite indicates island arc type feature, and the UMA indicates its cumulate character.

T/91. Talent, J.A. & Bhargava, O.N., 2003. Silurian of the Indian subcontinent and surrounding regions. New York State Museum Bulletin 493, 221-239.

An overview of the Silurian of the Indian subcontinent and adjacent regions, illustrated by ten stratigraphic columns, underscores uncertainties in precise correlation. Silurian sequences with some biostratigraphic control are documented from the Dasht-e-Nawar region, Afghanistan; the Peshawar Basin, Pakistan; central Nepal; southernmost Tibet; and Shan State, Myanmar (Burma). Near-shore, primarily siliciclastic sequences with reef developments in the western Himalaya, that range from Late Ordovician to Middle and, conceivably, younger Silurian, are not tightly constrained biostratigraphy. Similar sequences in the central Himalaya, often referred to as the Muth Quartzite and regarded as broadly Devonian, are largely Silurian, but need renewed study. The Paleozoic of Bhutan, assumed by some to include Silurian rocks, appears to have a Middle Cambrian-late Devonian hiatus. There is urgent need for a multi-pronged re-investigation of these Silurian and associated late Ordovician and Devonian sequences, particularly if transgression-regression patterns and changes in palaeogeography are to be documented adequately.

Extensive tracts of Devonian and older sedimentary and igneous units occur within the axial region of the western Karakoram Block of northernmost Pakistan over a distance in excess of 200 km between the headwaters of the Karambar valley in northwestern Gilgit Agency to southwestern Chitral. Conodont data indicate that the oldest sedimentary unit so far discriminated within this belt, the Yarkhun Formation, includes horizons of Ordovician (Arenig) age, consistent with an earlier-presented acritarch-based Arenig age for part of the same unit. Conodont data from the "Lun Shale", a stratigraphic potpourri with little known Silurian and Devonian tracts, demonstrate the presence of Early Devonian (early Emsian) horizons. The Shogram Formation, widely distributed through the region, spans an appreciable interval of the Middle and Late Devonian mid-Givetian through until at least early Famennian. A major lacuna in sedimentation may be present, represented by all or most of the earlier half of Frasnian time. A biostratigraphically and possibly biogeographically important new species, *Icriodus homeomorphus*, is described; it is encountered in horizons of early Famennian age (Late triangularis Zone to? Early crepida Zone).

T/97. Talent, J.A. & Mawson, R., 1979. Palaeozoic-Mesozoic biostratigraphy of Pakistan in relation to biogeography and the coalescence of Asia. In: Farah, A. & DeJong, K.A. (Eds.), *Geodynamics of Pakistan*. GSP, Quetta, 81-102.

An overview of Paleozoic-Mesozoic biostratigraphy of Pakistan, especially the northern mountainous region, is given providing, inter alia, preliminary reports of the presence of unequivocal Ordovician (NE Chitral), Silurian (Peshawar district), and carboniferous sequence (S Khyber and NW Gilgit agencies); all systems from Proterozoic to recent are now known to be represented in Pakistan. Comparison of Paleozoic and Mesozoic faunas from Pakistan with approximately coeval faunas from elsewhere in Asia underscore; 1. The provincial heterogeneity of Asia through these time intervals, though only preliminary comments are made on the change within these patterns due to coalescence of the various continental blocks. 2. That the only region of Pakistan with surety not formerly part of Gondwanaland is a narrow strip of the northern mountain region stretching through Chitral, Gilgit (N of the Ghizar valley) and Hunza, i.e. N of the Upper Shayok-Hini (or Chalt)-Drosh-Kunar fault. 3. The zoogeographic integrity of Paleozoic and perhaps Mesozoic faunas south of this lineament, and its E-W extension in Afghanistan beyond the 'Kabul vortex', the Hari Rud or Herat fault zone, is in accord with these areas having been once part of Gondwanaland; conversely, the contrast between faunas from these areas and faunas from regions north of the above lineaments is taken as testimony to the latter not having been parts of Gondwanaland. 4. Nevertheless, there are still insufficient published palaeontologic data to be able to comment on the history of fragmentation, dispersal and reamalgamation of the various bits and pieces of the old portions of Gondwanaland west of the Bela-Quetta-Muslimbagh-Waziristan 'Axial Belt', but the prospects are exciting and the Mesozoic molluscan faunas may yet yield useful biographic as well as chronologic data for this exercise.

T/98. Talent, J.A. & Mawson, R., 2001. Bibliography of Phanerozoic palaeontology and stratigraphy of Pakistan. *Geological Bulletin, University of Peshawar* 34, 1-81.

The stratigraphy and palaeontology of Pakistan covers almost all intervals of geologic time, Precambrian to Recent, some more elegantly than others, especially Permian and younger sequences from the southern two-thirds of Pakistan. Palaeozoic sequences of pre-Permian age are restricted to northern Pakistan where metamorphism has tended to obliterate fossils, and where tectonic complexity-especially frequent thrust faulting-often obscures relationships and, in the absence of fossils, ages may remain controversial and stratigraphic relationships problematic. Palaeontology, taking advantage of occasional "windows of opportunity" with materials which have escaped severe deformation, will continue to have an important role in unravelling the structure of this vast region.

The foundations of the stratigraphy and palaeontology of Pakistan go back to the remarkable pioneering work of. W. T. Blanford, A. B. Wynne, C. L. Griesbach, W. Waagen, F. Noetling and C. S. Middlemiss in the 19th century, to the work of H. H. Hayden and E. W. Vredenberg early in the 20th, to the labours in Hazara of D. N. Wadia and the exemplary mapping by E. R. Gee in the Salt Range 50-70 years ago and, in more recent time, the impact of the sustained energies of R. A. K. Tahirkheli.

Remarkable work was achieved, often under conditions for which the word adverse would be an understatement. E. W. Vredenberg comes to mind, with camel and violin, collecting his way across Baluchistan-a palaeontologist analogue perhaps of artist-violinist J. A. D. Ingres ... G. E. Pilgrim early in this century, and expanded by recent work by a galaxy of vertebrate palaeontologists, especially by P. D. Gingerich, L. L. Jacobs, M. Pickford and D. R. Pilbeam. These faunas are now chronologically constrained by integrated high-precision stratigraphic/sedimentary and magnetostratigraphic investigations undertaken by several people, among them D. W. Burbank, G. D. Johnson, and N. D. Opdyke, working in highly effective collaboration with the Geological Survey of Pakistan and with numerous staff and postgraduate students of the University of Peshawar. The origin of this bibliography derives from the discovery that less than 25 % of the geological literature published in Pakistan is cited in GEOREF, the main source for obtaining a swift coverage of the literature published on a specific topic or specific region. The situation is least satisfactory with regard to literature on vertebrate palaeontology; this has been poorly covered by both GEOREF and Biological Abstracts, though the Zoological Record is useful in helping fill this lacuna. Our compilation is not exhaustive; it expands on a preliminary version issued to participants in the First Pakistan Palaeontological Convention and 6th international meeting of IGCP 421, North Gondwana mid-Palaeozoic bioevent/biogeography patterns in relation to crustal dynamics held at the University of Peshawar in September 1999. There are few references to unpublished reports and postgraduate theses. Not included are numerous articles in which stratigraphy has been incidental to economic geology, mineralogy, structural, tectonic or petrologic presentations, notably for the Kohistan Terrane and the Nanga Parbat Syntaxis (e.g. Khan et al., 2000). Numerous citations of such literature can be found in the excellent overview of the geology and tectonics of Pakistan by A.H. Kazmi & M. Qasim Jan (1997). Useful for older literature and for literature on areas adjoining Pakistan to the east and west are the Bibliography of Indian Geology by La Touche (1917), the Bibliography on Himalayan Geology by Kapoor et al. (1976) and the Bibliography on the Geology of Afghanistan by Kastner (1971). Many of the cited references have not been checked against the original publications-a mammoth task beyond the means of compilers without access to all relevant libraries in Pakistan and India. Because most titles provide a clear indication of content, no attempt has been made to annotate the bibliography. It is hoped, nevertheless that even casual perusal of it will draw attention to many publications, including some long forgotten, which include important data and opinions.

T/101. Tandon, A.N. & Srivastava, H.N., 1975. Focal mechanism of some recent Himalayan earthquakes and regional plate tectonic. Bulletin of Seismological Society of America 65, 963-969.

Focal mechanism solutions of 12 recent earthquakes along the northern boundary of the Indian-Eurasian plates, from Hindukush to Burma, have been determined assuming the double-couple hypothesis. It has been found that the majority of earthquakes are of thrust type with the pressure directions acting at right angles to the faults/mountains, but, for a few of the earthquakes the orientations of the pressure directions are almost along the strike of the faults.

Such observations could be partly explained in terms of the concept of “flake tectonics” as proposed for continent-continent collisions. A number of earthquakes in the eastern Himalayas and Burma show normal dip-slip or predominantly strike-slip movements. These anomalies call for further refinements of the plate theory in this zone of complicated deformation.

T/102. Tandon, S.K., Thakur, V.C. & Jain, A.K., 1974a. Tilloids from N.W. Pakistan. *Geological Magazine* 111, p.568.

This note refers to a recent letter in this journal by Kempe (1973) wherein he has recorded a “Tilloid” occurrence near Warsak and advanced the line of the known Himalayan localities of subcontinental tillites more than 200 km. It may be pointed out that the gneiss; of the Himalayan diamicts is still an open question. Rallan (1913) recognized the Manjir Conglomerate (Chamba Tillites of Powell & Saxena, 1971) to be part of a flysch sequence. In recent years, a debate has also ensued on the origin of the Blaini Conglomerate and related formations (Bhargava, 1972; Bhattacharya & Niyogi, 1971; Casshyap, 1969; Gaur & Dave, 1971; Niyogi & Bhattacharya, 1971; Rupke, 1968; Saxena & Pande, 1969; Valdiya, 1970, 1973). We may also add that many of these controversial 'tillite' horizons form part of different tectonic units and may not all be the Stratigraphic equivalents. The premise of Kempe (1973) regarding the extension of the Himalayan tillite localities has thus to be viewed in the above framework.

T/103. Tandon, S.K., Thakur, V.C. & Jan, A.K., 1974b. Tilloids from Pakistan. Reply by Kempe, R.D.C., *Geological Magazine* 111, 568-569.

Tandon, Thakur & Jain refer above to the tilloids from NW Pakistan (Kempe, 1973), suggesting that this Himalayan diamict should be treated as one of several of which the true origin is still in dispute. I entirely agree. My objective in drawing attention to this unusual rock, which I referred to as a tilloid [which] may thus be the most northwesterly of the known sub-continental tilloids, was in the hope that it would be visited and examined by those who, unlike myself, are familiar with Indian and other tillites and are thus in a better position to decide in such cases on the origin of the rock.

T/104. Tanoli, S.K., 1990. Shallow marine sediments of the Patala Formation of Paleocene age, Kohat area, Pakistan. *Geological Bulletin, University of Peshawar* 23, 111-121.

The Patala Formation in Kohat area consists of four lithofacies which are; PF1 sandstone with shale interbeds, PF2 shale and siltstone with limestone interbeds, PF3 shale with interbeds of siltstone, and PF4 shale and marl interbeds. These facies were deposited in shallow marine shelf environments ranging from upper shoreface to offshore possibly middle to outer shelf environments.

Facies PF1-PF4 in general depict deposition in a continuously deepening or transgressive conditions. The lateral variations in lithology within the Patala Formation are suggested to be mainly related to the local variations in paleogeographic setting.

Key words: Sediments, Paleocene, Patala formation, Kohat.

The Patala Formation in Kohat area is divisible into four lithofacies which are; PF1 sandstone with shale interbeds, PF2 shale and siltstone with limestone interbeds, PF3 shale with interbeds of siltstone, and PF4 shale and marl interbeds. These facies are interpreted to have been deposited in shallow marine, ranging from upper shoreface to offshore, shelf environments. Facies PFI-PF4 in general depict deposition in a more or less continuously deepening basin. The lateral variations in lithology within the Patala Formation are suggested to be mainly related to the local variations in paleogeographic setting.

T/109. Tariq, S., 1992. Geology and clay mineralogy of Patala Formation in Salt Range and Kalachitta Range with reference to Paleo-Environments. M.Phil. Thesis, University of Peshawar, 177p.

The Patala Formation was studied in Salt Range and Kala Chitta range. About 99 samples were collected to investigate clay mineral composition and to understand the paleo-environments and diagenetic/ sedimentological control of the clay minerals. The samples from the Salt Range representing the southern end of the Potwar basin contain mostly kaolinite _illite and a mixed-layer clay mineral (a mixture of general illite/montmorillonite). The chlorite mineral was detected only in five samples from the Nilawahan area (central Salt Range).

The samples from the Kala Chitta Range (Khawri Khawar section) contain mostly illite, chlorite and mixed-layer clay mineral. The kaolinite was found in 12 samples. It was concluded that the illite, chlorite mineral are the detrital clay –minerals which were brought into the depositional basin through erosional and sedimentological processes from a source rock exposed in the south.

The kaolinite from both localities, was found to be partly diagenetic and partly of detrital origin. The mixed-layer clay mineral was observed to be of diagenetic origin. The kaolinite in Khawri Khawar section (Kala Chitta Range) was interpreted as detrital mineral. The comparison of clay composition from the Salt Range and Kala Chitta Range (Khawri Khawar section) indicated that kaolinite decreases in the samples of Kala Chitta Range while illite and chlorite show increase. The mixed-layer clay mineral did not Show any significant variations. The decrease of kaolinite in Kala Chitta Range samples was interpreted as a sedimentological/ depositional control.

The crystallinity indices of illite and kaolinite Show a decrease in crystallinity in the samples from the Kala Chitta Range as compared to the Salt Range samples. It is 0.77 for kaolinite, 0.37 for illite in Kala Chitta Range, and 0.26 for kaolinite and 0.19 (average) for illite in Salt Range. The decrease in crystallinity of illite and kaolinite again verify the transportation of kaolinite and illite from south to north of the depositional basin which was the direction of deepening of the basin.

Key words: Clay, mineralogy, Patala Formation, Salt Range, Kalachitta.

T/110. Tariq, S., 2001. Environmental geochemistry of surface and subsurface water and soil in Peshawar basin, NWFP, Pakistan. Ph.D. thesis, NCE geology, University of Peshawar.

Peshawar Basin is situated at the southern foothills of Himalayas between the longitude 71° 15' and 72° 45' E and latitude 33° 45' and 34° 30' N in the North-West- Frontier Province (NWFP) of Pakistan. Major cities of the basin are Peshawar (capital), Mardan, Charsadda and Nowshera. The E-W flowing Kabul river and its tributaries irrigate the basin and join the Indus at the eastern exit. Peshawar Basin is surrounded by mountain ranges of Khyber in west

and northwest, Attock-Cherat in south and Swat in the northeast. The basin is filled with Quaternary sediments ranging from Pleistocene to recent in age. These sediments overlie rocks of Paleozoic age. The Quaternary sediments of the Peshawar Basin are physio-graphically classified as Peshawar Piermont-sediments, Peshawar lacustrine sediments and Peshawar flood plain/ stream channel sediments.

The sediments present in the foot-hills of the mountains in the western (Khyber Range) and southern Attock-Cherat Range) part of the Peshawar Basin are coarse deposits of sand and gravel. However, the sediments of the central part of the basin contain relatively large proportion of fine material and are characterized as the lacustrine sediments. On the basis of existing lithologies the aquifer of Peshawar Basin has been classified as Peshawar Piedmont aquifer and Peshawar Lacustrine aquifer. The Peshawar Piedmont aquifer has further been divided in to Khyber mountain range piedmont aquifer, Attock-Cherat Range Piedmont aquifer and Lower

Swat Range Piedmont-aquifer.

Fast growing urbanization and industrialization in and around the major cities is threatening the air as well as the surface and subsurface water systems of the Peshawar Basin. In the cities, air is consistently polluted by vehicular emanations, industrial effluents and metals-born dust, which ultimately make their way to surface and underground water. This study is part of a large project concerning surface and groundwater and soil pollution of major and trace elements and heavy metals. The isotopic data of surface and groundwater of the Peshawar Basin has also been evaluated in order to identify the sources of pollution.

The hydro-physical and chemical parameters of the water of Peshawar Basin determined during the present study include pH, Temperature (T) electrical conductivity (Ee), total dissolved solid (TDS) calcium (Ca), magnesium (Mg), potassium (K), chromium (Cr), nickel (Ni), copper (Cu), cobalt (Co), lead (Pb) cadmium (Cd), bicarbonate (HCO₃), sulfate (SO₄) and chloride (Cl). Surface and groundwater of all the aquifers and rivers respectively have been classified as normal alkaline fresh water and alkaline earth fresh water with higher contents of alkalies. This suggest that the cations and anions have played an important role in categorizing the waters of the Peshawar Basin. On the basis of physical parameters (i.e., pH, T, Ee and TDS), the water of all the rivers and aquifers of Peshawar Basin can be generally classified as "fresh", however, "Slightly saline" water is also present at various places. The groundwaters of some areas have pH in acidic range and have high SO₄ contents suggesting the contamination through coal and sulfide seems having metal sulfides. These areas of unsuitable drinking water have been delineated during this study.

In order to establish the chemical contamination in the water of the various aquifers of Peshawar Basin, the above mentioned parameters have been compared among various aquifers and also with the permissible limits of US-EPA and WHO.

Various cations (e.g., Ca, Na, K, and Fe) anions (e.g. SO₄, Cl, HCO₃) and trace elements (e.g., Cu, Pb, Zn, Ni, Cr, Co and Cd) in the drinking water of Peshawar are generally within the permissible limits set by US-EPA and WHO. However, Ca, Mg, Na, K, Fe, Pb, Cr, SO₄, Cl, and HCO₃ at some places exceed the permissible limit. This could generally be attributed to the compositional changes in the lithology of the area. The oxygen isotopic characteristics of both surface and groundwaters of the Peshawar Basin have been determined. The three rivers, Kabul, Swat and Indus have distinct ¹⁸O signature with Indus river being the most depleted, Swat river being the most enriched and Kabul river midway between the two. The oxygen isotopic data for the underground water system of the Peshawar Basin indicate that the aquifers in the Peshawar Basin are recharged both by rainwater and waters from the Kabul and Swat rivers. In this respect the Kabul river remain dominant over the Swat river. This data also indicate that the shallow waters in the basin are more contaminated than the deep water. This suggests that there are chances that any pollution in the surface water can very easily be transferred to the underground water. This study also indicate that the soils of Peshawar Basin have higher contents of few major elements such as MgO, CaO, Na₂O, K₂O and trace elements such as Cu, Pb, Cr and Ni when compared with the normal soil elsewhere in the world. This could possibly be correlated with the surrounding rocks (ultrabasic to acidic nature) of Peshawar Basin.

It is evident from this study that though the waters of the piedmont aquifers are safe both for agricultural and drinking purposes but still the special measures shall be taken to protect the underground water of the area from contamination if the industries are to be established in these areas of the Peshawar Basin in future. In this regard, some recommendations are also given at the end.

Key words: Geochemistry, groundwater, Peshawar basin.

T/111. Tariq, S., Baqri, S.R.H. & Rehman, O., 1997. The distribution of clay minerals in Patala Formation of the Kala Chitta and Salt Ranges: Implications for paleoenvironments. Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 227.

During the Paleocene, the predominantly shaly rocks of the Patala Formation were deposited in an extensive Potwar Basin, stretching from the Salt Range to the Kala Chitta Range. Ninety nine samples were collected to investigate the clay mineral composition and to understand the paleoenvironments and diagenetic sedimentational control of the clay minerals in the basin. The samples from the Salt Range, representing the southern end of the Potwar Basin, contain mostly kaolinite, illite, and a mixed-layer clay mineral consisting of illite and montmorillonite. Chlorite was studied only in samples from the NW area of the central Salt Range. The samples from the Kala Chitta Range contain mostly illite, chlorite and mixed-layer clay mineral.

Kaolinite found in twelve samples. It is concluded that the illite-chlorite mineral and the detrital clay minerals were brought into the depositional basin through erosional and sedimentational processes from a source rock exposed in the south. The kaolinite was found to be partly diagenetic and partly of detrital origin. The mixed-layer clay mineral was observed to be of diagenetic origin. The kaolinite in Kala Chitta Range is interpreted as detrital mineral. The crystallinity of kaolinite and lute minerals were also studied in samples. The comparison of clay minerals composition from the Salt Range and Kala Chitta Range show that kaolinite decreases while illite and chlorite increase with depth towards north in the samples from the Kala Chitta Range. The mixed-layer clay mineral does not show any significant variation. The decrease of kaolinite in Kala Chitta Range samples was interpreted as related to a sedimentational/depositional control, because comparatively coarse grained kaolinite was deposited in abundance in shallower parts and hardly transported into the deeper parts of the basin towards north. The fine grained illite-chlorite minerals were transported and deposited in abundance in the deeper part of the basin. The crystallinity indices of illite and kaolinite show a decrease in crystallinity in the samples from the Kala Chitta Range as compared to the Salt Range samples. It is 0.77 nm for kaolinite, 0.37 nm for illite in Kala Chitta Range, and 0.26 nm for kaolinite and 0.19 nm for illite in Salt Range. The decrease in crystallinity of illite and kaolinite minerals again verify the transportation of these minerals, and deepening of the depositional basin from south to north.

Key words: Sediments, clay, Paleocene, Patala formation, Kalachitta, Salt Range.

T/112. Tariq, S., Baqri, S.R.H. & Rehman, O., 1998. The distribution of clay minerals in patala formation of the potwar basin: implications for palaeo environments. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 193-195.

During the Paleocene, the predominantly shaly part of the Patala Formation was deposited in Potwar Basin, stretching from the Salt Range in the south to the Kala Chitta Range in the north. The paleoenvironments interpreted by the diagenetic sedimentational control of the clay minerals in the basin by analysing the clay mineral composition in 99 samples. The samples contain kaolinite, illite, chlorite and a mixed-layer clay mineral of illite/montmorillonite. It is concluded that the kaolinite/ illite and chlorite minerals are the detrital clay minerals, brought into the depositional basin due to erosion of the source rocks exposed in the south of partly diagenetic origin. The clay minerals composition from the south to north show that the kaolinite decreases while illite and chlorite increase. The decrease of kaolinite in Kala Chitta Range is most likely due to sedimentational/ depositional control, because coarse-grained kaolinite was deposited in abundance in shallower parts and hardly transported into the deeper parts of the basin towards north. The fine-grained illite and chlorite minerals were transported and deposited in abundance in the deeper parts of the basin. No significant variation observed in mixed-layer clay mineral. The crystallinity indices of illite and kaolinite decrease in the Kala Chitta Range as compared to the Salt Range. The decrease in crystallinity in clay mineral again verify the transportation, and deepening of the depositional basin from south to north.

T/113. Tariq, S., Hamidullah, S. & Shah, M.T., 1998. Preliminary environmental geochemistry of surface and subsurface waters from Peshawar Basin, north Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume 13th Himalayan-Karakoram-Tibet International Workshop, 195-196.

The Peshawar Basin is semi-circular low-lying broad depression ($\approx 8000 \text{ km}^2$) situated at the southern margin of foot hills of Himalayas and north-west of the Indus Plain. Unplanned urbanization and industrialization due to a very high rate of population increase have affected the major cities of N.W.F.P., particularly those situated in Peshawar

Basin. Air is highly polluted in the major cities and industrial estates and both surface and underground water are also facing a significant threat. This study is part of a large project concerning with the investigation of surface and subsurface water pollution related to major and trace elements, particularly heavy metals in Peshawar Basin. Here we present the major element chemistry of the various types of water from the basin. On the basis of stratigraphic correlation five types of semi-confined aquifers, namely, Khyber piedmont aquifer (west and south-west), Attock-Cherat piedmont aquifer (south and south-east), Lower Swat-Bunner piedmont aquifer (north and north-east), floodplain and lacustrine aquifers in the central part of the basin have been identified. A total of 112 water samples collected from surface (river) and subsurface water (shallow, dugwell; deep, tubewell) have been analyzed. Majority of the surface and subsurface water samples appear to be hydrogencarbonatic (Ca-Mg-HCO_3 type) and sulfatic (Cl-SO_4 type) of the alkaline earth fresh water with high contents of alkalies.

Sodium-chloride (NaCl) and magnesium-sulfate (MgSO_4) are the major ionic pairs in these waters. Based on the major ions comparison with Quality Standards of Drinking Waters, most of the waters of the Peshawar Basin are classified as normal waters. Few dugwells (shallow water) from the Khyber and Attock-Cherat piedmont aquifers (Zahairabad and Ghari Chandan respectively), a dugwell and two tubewells from lacustrine aquifer of the central part of the basin (Amman Kot) indicate relatively higher concentration of sodium, calcium, magnesium, potassium, iron, chloride, sulfate, and total dissolved solid (TDS) as compare to the standard Maximum Contaminant Level (MCL) of potable water. The high concentration of these radicals at these locations, in the basin, can be attributed to, a) the presence of evaporites at the depth, e.g. gypsum, limestone, dolomite and halite etc., b) water logging and salinity, c) greater use of fertilizers. Therefore no contamination from a source related to industrialization and urbanization was found in waters of these areas.

The magnetostratigraphy of eleven new sections in the Khaur area of northern Pakistan is presented. All specimens have been subjected to thermal demagnetization. The sections, taken in adjacent ravines incising the Siwalik formations nearly perpendicular to strike, form a temporal framework in which to interpret the biological and lithological information. A composite section is constructed from several long sections and is correlated to the magnetic polarity time scale (Chron 6 to Chron 15), providing absolute age information for the biostratigraphic zonations of Barry et al. (1982). Detailed sections along the strike of major stratigraphic marker beds document an

isochronous horizon and form the basis for paleoenvironmental reconstructions. The preservation of a polarity transition in fluvial sediments suggests continuity of sedimentation on a time scale of 10^3 – 10^4 years.

Using teleseismic data from the Himalaya and surrounding regions plus observations from local seismic networks located on both side of the Yarlung Zungbo River during 1975-1979, both large and small earthquake fault plane solutions are obtained, and the relationship between the seismicity of the plateau and plate tectonics is investigated. Shallow earthquakes are dominant on the Qinghai-Xizang (Tibet) Plateau, whilst intermediate earthquakes are common at the east and west extremities of the arc. In the central part of the arc intermediate depth shocks are rare. According to the fault plane solutions the directions of compressive stress are mainly north and northeast, i.e., basically perpendicular to the strike of the arcuate system. The extremely thick crust and other geophysical data

fields in this regions suggest that the stress field is caused by the collision and compression of the Indian and the Eurasian plates.

T/133. Theobald, W., 1880. On some Pleistocene deposits of the northern Punjab and the evidence they afford of an extreme climate during a portion of that period. Geological Survey of India, Records 13(4), 221-243.

Theobald provided fairly detailed information about the geographic distribution, lithology and size of the Punjab erratics. Many blocks are located on the east bank of the Indus River in the territory between Indus and Haro rivers and the Grand Trunk Road, particularly near Attock, south of Haji Shah, near Attock city, and Lawrencepur. More blocks occur further north near old Tarbela village, and in the valley of the Dor River, and also on the eastern bank of the Indus river south of the Kala Chitta Range near Nara, Jand and Pindi gheb. The blocks are mostly of granite, gneiss, basalt, and limestone, and range from angular to surrounded in shape, with dimensions up to 20 m³. The blocks rest on a terraced surface suspended some 10 m above the present course of the Indus, about 300-400 m above sea level. Based on lithology, the boulders are considered to have been brought from the north. Theobald states that the erratics were carried and deposited directly by the glaciers or by fallen ice blocks in the ancient Indus and looks upon them as proof of the expansion of the Pleistocene glaciers as far as the foot of the mountain range, below 600 meters.

T/135. Thewissen, J.G.M., Gingerich, P.D. & Russell, D.E., 1987. Artiodactyla and Perissodactyla (Mammalia) from the early-middle Eocene Kuldana Formation of Kohat (Pakistan). University of Michigan, Contributions from the Museum of Paleontology, 27, 247-274.

Chorlakkhi, yielding approximately 400 specimens (mostly isolated teeth and bone fragments), is one of four major early-to-middle Eocene mammal localities on the Indo-Pakistan subcontinent. On the basis of ungulates described in this paper we consider the Chorlakkhi fauna to be younger than that from Barbora Banda older than the Kalakot fauna, and possibly comparable in age to the Ganda Kas/Lammidhan fauna. Artiodactyls are abundant in the Chorlakkhi fauna. Two families are represented: Dichobunidae and Raoellidae. A new dichobunid, *Pukibune chorlakkhiensis* n. gen. et sp., and a new raoellid, *Indohyus majar* n. sp., are described. A new diagnosis of Raoellidae is given here. Perissodactyls are rare at Chorlakkhi. However a few elements identified as isctolophid tapiroids brontotheriids and hyracodontids are known.

Raoellidae is endemic to the Indo-Pakistan subcontinent and may be related to European Dacrytheriidae. Pakistan dichobunids too seem to have European affinities. The perissodactyls are possibly more closely related to Eocene taxa from the rest of Asia than to those from Europe.

T/136. Thewissen, J.G.M., Hussain, S.T. & Arif, M., 1994. Fossil evidence for the origin of aquatic locomotion in archaeocete whales. Science 263, 210-212.

Recent members of the order Cetacea (whales, dolphins, and porpoises) move in the water by vertical tail beats and cannot locomote on land. Their hindlimbs are not visible externally and the bones are reduced to one or a few splints that commonly lack joints. However, cetaceans originated from four-legged land mammals that used their limbs for locomotion and were probably apt runners. Because there are no relatively complete limbs for archaic archaeocete cetaceans, it is not known how the transition in locomotory organs from land to water occurred. Recovery of a skeleton of an early fossil cetacean from the Kuldana Formation, Pakistan, documents transitional modes of locomotion, and allows hypotheses concerning swimming in early cetaceans to be tested. The fossil indicates that archaic whales swam by undulating their vertebral column, thus forcing their feet up and down in a way similar to modern otters. Their movements on land probably resembled those of sea lions to some degree, and involved protraction and retraction of the abducted limbs.

Key words: Palaeontology, mammalia, Eocene, Kuldana Formation, Kohat.

T/137. Thewissen, J.G.M., Hussain, S.T., Arif, M., Aslan, A., Madar, S.I. & Roe, L.J., 1997. The origin of the modern orders of mammals within the context of Paleogene deposition in the northern Pakistan. Abstracts, 3rd GEOSAS Workshop on Siwaliks of South Asia, Islamabad. GSP, Records 109, 80-84.

One of the greatest enigmas of the evolution of life is the origin of the modern orders of mammals. Many recently mammal orders appear in the fossil record abruptly, and no morphologically-similar ancestors are known. Krause and Maas (1990) have proposed that Indo-Pakistan could be the birth place for many of these orders and that investigation of Paleocene and Eocene sediments of the subcontinent could solve these enigmas. Collaborative investigations of teams from Howard University, the Northeastern Ohio Universities College of Medicine (NEOUCOM), and the GSP have resulted in significant collections of Eocene mammals, elucidating the origin of several orders of modern mammals. The most primitive artiodactyl in the world is *Diacodexis* and one of its species, *D. pakistanensis* has been found in Kohat District (Thewissen et al., 1983). Thewissen and Hussain (1990) suggested that it is the most primitive member of its genus. Spectacular fossil discoveries have been made with respect to the origin of cetaceans (whales and their relatives). The oldest known cetaceans, so called pakecetids, are known from Punjab and NWFP (West, 1980; Gingerich and Russell, 1981). Important new fossil material of these animals has been found in the Kala Chitta Hills, allowing a better understanding of the evolution of underwater hearing (Thewissen et al., 1992) and the ability of whales to drink sea water (Thewissen et al., 1996B). A complete skeleton of another cetacean, *Ambulocetus natans* from Punjab, is the only cetacean known to preserve much of the hands and feet of the ancestral cetaceans and allows the study of locomotion of amphibious whales (Thewissen et al., 1994, 1996A). Anthracobunids, a group only known from Pakistan and India, played an important role in the origin of siremans and proboscideans (Wells and Gingerich, 1981; West, 1981), and true siremans have been recovered in several areas of Punjab (Gingerich et al. 1995). New fossil material for Eocene primates (Thewissen et al., in press) and hyaenodontid creodonts, may solve important biogeographical questions of these orders of mammals, and some of the earliest rodents are known from NWFP (Hussain et al., 1978).

Understanding of the depositional environment of Punjab and NWFP is of great importance in the recovery of early mammals. The Cretaceous-Tertiary Boundary of the Kohat-Potwar Province (Punjab and NWFP) is characterized by an unconformity which is commonly expressed as a taterite near the northern edge of the Potwar Plateau. Paleocene deposits of the Kohat-Potwar Province are marine and can be more than 1000m thick (Meissner and Rahman, 1973). These deposits have been interpreted as documenting a continental shelf and deep sea basin sequence (Wells, 1983), and Gardezi et al (1976) identified Paleocene clastic deposits that may document a more near-shore environment. Beck et al. (1995) interpreted the Paleocene rocks as having been deposited immediately after the collision between the Indian and Asian continents. This is consistent with magnetostratigraphic data (Klootwijk et al., 1994).

In the early Eocene, shallow water sedimentation dominates, resulting mainly in extensive limestone deposits that are part of the Ghazij Group of Pivnik and Wells (1996). In the Potwar Plateau area, these include the Margala Hill and Chor Gali Formations which are generally considered to be Ypresian in age (Fatmi, 1973).

Early Eocene marine sedimentation is followed by deposition of continental sediments that are the regressive part of the Laki sequence. These are usually referred lower Kuldana Formation in Punjab or the Mami Khel formation in North-West Frontier Province. Meissner et al. (1974) recovered Foraminifera indicating an early Eocene age for these beds in Kohat District. The lower Kuldana Formation consists mainly of red muds, but occasional indurated conglomerates and sandstones are also present. It is the Kuldana Formation that has yielded most of the important paleontological discoveries of Eocene Indo-Pakistan.

The faunas of the two lithologies of the lower Kuldana Formation differ. Most of the collections described by Dehm and Oettingen-Spielberg (1958) were collected in the muds. The fauna here contains a large number of perissodactyls, especially tapiroids and brontotheres. Wells (1984) interpreted these muds as overbank deposits.

The conglomerates of the lower Kuldana Formation are laterally restricted (several meters) and thin (usually less than 1 m beds). Individual grains are cemented by calcite and commonly show concentric rings in cross-section. They have been interpreted by Wells (1983) as soil nodules that were reworked into channels representing lag deposits. Wells (1984) proposed that the nodules were formed in soils during alternating warm-wet and warm-dry conditions, and that occasional torrential rains may have concentrated them into channels. The faunas found in different conglomerates vary greatly, but are generally different from those of the muds in the low numbers of perissodactyls, especially brontotheres.

Howard-GSP Locality 62 in the Kala Chitta Hills is an example of a conglomerate. The preservation of the fossils is unusually good (Asian and Thewissen, in press), fossils from this site include such delicate elements as braincases and scapulae. This suggests that no high-energy transport has taken place. On the other hand, no articulated elements are known from this locality, suggesting that all soft tissues were destroyed before diagenesis. Pakicetids and anthracobunids are the most common taxa among the recovered mammals, and perissodactyls are extremely rare. Freshwater fish and aquatic turtles are also common, and it is likely that the depositional environment of Locality 62 is aephemeral pond. Asian and Thewissen (in press) proposed that the sediments at this locality were deposited in a short time, possibly less than 1,000 years.

Another fossiliferous conglomerate occurs near Barbora Banda in Kohat District. The fauna at this site consists nearly exclusively of two forms. By far the most common is *Diacodexis pakistanensis*, but some individuals of an iscetolopkid tapiroid are also known (Thewissen et al., 1983). Articulated partial skeletons are common for both taxa at this locality (Thewissen and Hussain, 1990). Wells (1983, 1984) studied the genesis of this conglomerate and suggested that a catastrophic flood swept a group of animals in to a channel and buried them with soil nodules that were eroded from the floodplain. Some scavenger activity is also apparent (Thewissen and Hussain, 1990).

Lower Kuldana sediments are followed by a variety of thin beds including varicolored shales, limestones (sometimes dolomitic), and silts. These beds are sometimes described as the upper Kuldana Formation (Wells, 1983), or included in the Mami Khel formation (Meissner et al., 1974; Pivnik and Wells, 1996). We follow Shah (1977) and include the Mami Khel clays in the Kuldana Formation. There is a quick succession of different lithologies, including both freshwater and mare beds. Given the differences in depositional environment, faunal variation is significant. Terrestrial faunas include primates, hyaenodontids, mesonychians, and brontotheres, whereas aquatic faunas include anthracobunids and cetaceans. Wells (1984) interpreted the upper Kuldana deposits as representing coastal plain and near shore deposits, including brine pools, freshwater lakes, marshes, lagoons and bays. There is also evidence for paleosol development (Aslan and Thewissen, in press).

The top of the Kuldana Formation is conformable with the overlying Kohat Formation. A thick (approximately 1 m in the Kala Chitta Hills) mud with many bivalves and gastropods marks the boundary between the formations. It is underlain by green silts with occasional marine snails and bivalves. The vertebrate fauna of silts and oysterbed includes cetaceans, sirenians, bony fishes, and sharks. Abundant plant remains occur in some sites, and induration varies. These deposits represent the transition from paralic to restricted marine environments (Wells, 1984). *Ambulocetus* was found at a locality near the top of the Kuldana Formation.

The Kohat Formation consists of grey muds and limestones with locally abundant benthic foraminifera. Shah (1977) proposed a later Early or early Middle Eocene age for the Kohat Formation. The Kohat Formation is topped by an unconformity after which Miocene freshwater sediments of the Murree Formation are deposited. The base of the Murree Formation commonly consists of a conglomerate that includes reworked Eocene rocks (the Fatehjang Beds).

T/143. Tilman, H.W., 1949. *Two Mountains and a River*. Cambridge University Press, Cambridge. 233p. 18 plates, 6 maps.

A scarce book, this is one of the classic mid-twentieth century texts for mountaineers, explorers and adventurers, in which the author treks and climbs including Kashgar, Tashkurgan, Rakaposhi, the Kukuay Glacier, The Fainyor Nallah, Muztagh Ata, Kashgar, the source of the Oxus, Sarhad, Gilgit, and Ishkashim (where the author was arrested!), and others. The book has the noted Tilman qualities, sense of place, descriptive powers, never-failing humor, affection for many kinds of men, and a not too intolerant hate for a few. A unique work by a noted traveler, writer, and raconteur.

From the dustjacket:

When a couple of years ago Mr Tilman left with us a MS. of his book *Mount Everest*, 1938, he arranged for his own executors to deal with proofs, pictures, maps and index, and went out of civilization. He returned to England some months later. Few of his friends knew what he had been up to. This new book, *Two Mountains and a River*, now reveals everything.

It appears that he and two Swiss mountaineers went together to the Gilgit region of the Himalaya with the ambitious project of an attack on Rakaposhi (25,550 ft.). Rakaposhi beat them.

After defeat Tilman went on alone to Chinese Turkistan, having an appointment with an old Everest colleague, Mr E. E. Shipton, British Consul at Sinkiang, for a private attempt on the *Father of Ice-Mountains* which Sven Hedin had four times attempted. They did not reach the summit of their mountain, both got frost-bitten toes, and they had to give up that part of their ambition; but they did some heavy travelling among strange towns, which provided Tilman with just the travel copy he handles and photographs best.

Finally, Tilman alone took an alternative return route, which included a crossing of the frontier of Afghanistan (for which he had no visa) where he had an anxious and angering setback, being arrested as a spy by strange Afghan officials, and handed on under guard from town to town, until his final release.

The book has the Tilman qualities, sense of place, descriptive powers, never-failing humour, affection for many kinds of men, and a not too intolerant hate for a few. It is risky to say that Tilman reminds one of Borrow, but there is no doubt that this book will maintain his unique reputation as a traveller, writer, and raconteur.

Divided into the following sections:

- Food and equipment
- Karachi to Abbottabad
- The approach march

- Gilgit - arrival and departure
- The Jaglot approaches
- The two ridges
- The Dainyor Nallah
- The Kukuay glacier
- Chalt to Misgar
- Misgar to Tashkurghan
- Muztagh Ata
- To Kashgar
- Another way home
- The Oxus source
- Sarhad to Ishkashim - open arrest
- Ishkashim - close arrest
- Destination unknown
- Faizabad and freedom

T/144. Tilman, H.W., 1951. China to Chitral. Cambridge University Press, Cambridge.

A story of travel into China's mysterious inner massif where mountains rival Everest's height and the native tribesmen still have a time-suspended life unchanged since Genghis Khan's Golden Horde swept the civilized world. Tilman, a young Englishman, started out from Shanghai, took some easy stages by plane, then descended to earth and oxcart, then truck, to cross the deep interior into Sinkiang or Chinese Turkestan-the long, fabulous back of the beyond that lies north of the Himalayas. There he observed curiously costumed tribesmen, Turkish-bazaar towns, curly-roofed houses designed to keep devils out, and he achieved the ascent of some of the world's highest- and roughest- mountains. This hasn't a magic text to speed it along, but some maps, along with 69 photographs, will attract the travelogue fancier.

T/145. Tilton, G.R., Bryce, J.G. & Mateen, A., 1998. Pb-Sr-Nd isotope data from 30 and 300 Ma collision zone carbonatite in northwest Pakistan. *Journal of Petrology* 39, 1865-1874.

We present isotope data for the synorogenic Sillai Patti and Loe Shilman (30 Ma) and the pre-orogenic Koga and Jhambil (300 Ma) carbonatites, of the Indus Suture Zone. The younger carbonates are foliated-banded sheet-like bodies in the metamorphosed belts of the Higher and Lesser Himalaya, within the Indus Suture Zone. They appear to be collision related and have no relationship to the silicate rocks in the complex. The initial isotope ratios are: ϵ_{Nd} -3.1 to -3.8; $^{87}Sr/^{86}Sr$ 0.70463-0.70486 (ϵ_{Sr} +2.4 to +5.6); $^{206}Pb/^{204}Pb$ 19.01-21.35; $^{207}Pb/^{204}Pb$ 15.54-15.67; $^{206}Pb/^{204}Pb$ 38.29-40.63. The pattern is atypical given that carbonatites generally yield positive ϵ_{Nd} and negative ϵ_{Sr} . The Nd, Sr, and least radiogenic Pb isotope ratios also fit the pattern of carbonatites from the East African Rift, suggesting derivation from similar sources. In that case a lithospheric source for the 30 Ma Pakistan carbonatites was probably transported with the Indian Plate during migration from East Africa to the collision with the Asian continent. Intrusion of the carbonatites into rocks of the Himalayan orogenic zone apparently affected only the Pb isotopes on some of the plutons. Nd, Sr and Pb isotope patterns for the 300 Ma Pakistan plutons fit those for most intra-plate carbonatites, with positive ϵ_{Nd} and negative ϵ_{Sr} , showing that neither transport nor collision noticeably disturbed their isotope patterns.

T/156. Tongiorgi, M., Milia, A. de, Le Fort, P. & Gaetani, M., 1994. Palynological dating (Arenig) of the sedimentary sequence overlying the Ishkarwaz Granite, upper Yarkhun valley, Chitral, Pakistan. *Terra Nova* 6, 595-607.

A sedimentary sequence overlying a granite pluton near Ishkarwaz (upper Yarkhun valley, Chitral, Pakistan; Karakorum Microplate) contains abundant, but poorly preserved, acritarchs probably referable to the late early Arenig-early late Arenig interval. The palynological assemblages of Karakoram show a marked similarity to the cold water Peri-Gondwana assemblages; i.e. to those of Li Jun's *Arbusculidium*-*Coryphidium*-*Stiafoheca* 'Mediterranean' Bioprovince. Biogeographical and geological comparisons suggest that, before the accretion of Cimmerian microplates to the Eurasian continent, the Karakorum Microplate was located along the northern margin of Gondwana in a latitude intermediate between the Mediterranean region and South China (Yangtze Platform).

T/158. Treloar, P.J., 1989. Imbrication and unroofing of the Himalayan thrust stack of the North Indian plate, north Pakistan. *Geological Bulletin, University Peshawar* 22, 25-44.

The northern part of the Indian Plate in North Pakistan is dominated by a crustal scale south-verging thrust stack composed of a number of thrust nappes, each of which is stratigraphically distinct. Major nappes recognized in the Swat to Kaghan area of north Pakistan are the Besham, Swat, Hazara, Banna, Lower Kaghan and upper Kaghan nappe. Metamorphism was synchronous with early ductile stages of Himalayan deformation, the metamorphic pile being subsequently disrupted during the development of the thrust stack which marks the last phase of southeasterly directed Himalayan thrusting. Within each nappe the metamorphic grade increases upwards, an overall inversion that represents post-metamorphic imbrication within individual nappes, synchronous with the main phase of nappe stacking, rather than an originally inverted metamorphic gradient. As a result of this "within-nappe" imbrication each thrust slice within any particular nappe contains rocks of a higher metamorphic grade than those in the slice below, with sharp metamorphic breaks across the imbricating thrusts as well as across the major shears that bound the individual thrust nappes. Exhumation and unroofing of the rocks within the thrust stack was rapid. The assembly of the stack triggered rapid erosion, record in the Oligocene and Miocene molasse basins, and regional extension that included significant northward extension within the Main Mantle Thrust zone. Cooling ages imply that peak metamorphism was completed by 40 Ma ago, or within 15 to 20 Ma of collision; that the post-metamorphic thrust stack had been assembled by 25 Ma ago, and that much of the subsequent exhumation was completed by 18 Ma ago.

Key words: Tectonics, structure, stratigraphy, metamorphism, Indian plate, Himalaya.

T/159. Treloar, P.J., 1990. Collision processes in the NW Himalaya: Evolution of the Indian plate thrust stack, Pakistan Himalaya. In: Abstract volume, 5th Himalaya-Karakoram-Tibet Workshop, Milano, p.62.

In NW Pakistan Himalayan collision was between the Kohistan Island Arc (accreted to Asia about 100 Ma ago) and the Indian Plate, with Kohistan thrust south over India along the Main Mantle Thrust (MMT). In the crystalline internal zones of the Indian Plate, metamorphism, at temperatures of up to 650°C, was synchronous with ductile simple shear regionally developed in the MMT footwall. The metamorphic pile was subsequently imbricated within a crustal-scale south-verging thrust stack formed of a number of internally imbricate nappes, each lithologically distinct. The thrusts, which imbricate these nappes each, have higher-grade rocks in their hanging wall than in footwalls generating an overall inversion of the metamorphic sequence. It is stressed that this inversion results from

a post- metamorphic disruption of the metamorphic pile rather than from an originally inverted metamorphic gradient.

Internal zone evolution can hence be divided into two periods of deformation, each of which resulted in a, subsequently eroded, topographic high: an early period of thickening of India under Kohistan culminating in the metamorphic peak and a second phase of post-metamorphic stacking. Ar-Ar, K-Ar, Rb-Sr and fission track geochronology enables us to date these different events. The first period predates 40 Ma (the time of cooling back through the hornblende blocking temperature). Thermal modeling suggests that the crustal thickening, which drove the metamorphism, must have predated 60 Ma, which is earlier than the normally accepted timing of Himalayan collision. Post-metamorphic stacking of the internal zones was largely accomplished between 35 and 25 Ma ago subsequent to which this second topographic high was exhumed by a combination of extension in upper levels of the Indian plate and the overlying MMT zone, and rapid erosion reflected by molasses deposition in the foreland basins. Eocene and Miocene molasses sequences respectively date the erosion of these two mountain fronts. Since 25 Ma the crystalline zones have acted as rigid block transported southward over the foreland basin sequences.

Shortening estimates can be derived for different structures within the internal and external zones, geochronological date allowing us to date both when these structures were operative and the rates at which they accommodated shortening. Although total shortening across the zone is of the order of 500-kms, giving a time-averaged rate of ca. 1cm/yr, shortening rates varied throughout the post-collisional period. Within the internal zones the two deformation periods were separated by a phase of little or no apparent shortening. Shortening rates of 2 to 4 cm/yr can be estimated for the period of post-metamorphic stacking. Within the external zones similar variations can be observed. There is, however, little evidence of shortening between 25 and 12 Ma, after which shortening rates, as recorded by sequentially developed structures, varied from <1 to ca. 5 cm/yr.

Key words: Tectonics, metamorphism, MMT, Indian plate, Himalaya.

T/160. Treloar, P.J., 1991. P-T-t paths of metamorphism, Pakistan Himalaya: implications for crustal subduction and staking. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Auris, France, 93-94.

One of the main contributions that metamorphic petrology can make to our understanding of the tectonic evolution of orogenic belts is by contributing hard data pertaining to the P-T-t paths of crustal thickening, metamorphism and exhumation. This involves a consideration not just of thermodynamically calculated metamorphic Ps and Ts, but the use of inclusion suite thermobarometry and the forward modeling of P-T trajectories based on chemical zonations. Such trajectories, when coupled with microstructural analysis of fabric-porphyroblast relationships and Ar-Ar and fission track mineral cooling chronologies, enable the construction of well-defined P-T-t-deformation.

Within the crystalline internal zones of the Indian Plate, west of the Nanga Parbat syntaxis, fabric-porphyroblast relationships demonstrate that metamorphism was synchronous with early stage of ductile deformation. This deformation was related to the development of the first Himalayan mountain front. It is now well established that this metamorphic pile was subsequently deformed within a post-metamorphic thrust stack which contains a number of individual thrust nappes, each with tectonically controlled metamorphic inversions. This period of post-metamorphic thrust stack, which contains a number of individual thrust nappes, each with tectonically controlled metamorphic thrust stacking documents the development of a second Himalayan mountain front.

In the Upper Kaghan, Hazara and Swat nappes forward modeling of garnet zonation profiles in low variance assemblages, as well as changes in inclusion suite parageneses from core to rim (especially ilmenite in garnet cores and rutile in garnet rims in rocks saturated with plagioclase and kyanite), both indicate that the main period of metamorphic mineral growth was along a path of increasing T and P. maximum Ps of 9 to 12 kbar are routinely recorded, with ΔP s during metamorphism of ≥ 6 kbar. These substantial syn-metamorphic pressure increases reflect thickening of the Indian Plate crust during active subduction beneath Kohistan.

Within the Upper Kaghan and Swat nappes, near rim Ca zonation in garnets and the mantling of matrix rutile by ilmenite testify to a phase of pressure decrease, although still at elevated pressures, which must represent early stages of exhumation of the deeply buried rocks. This exhumation is recorded in the late Eocene molasse sediments of the Murree Formation. That no extensive down temperature and pressure cooling path recorded in the zonation profiles suggest extremely rapid cooling that can only have been accommodated by rapid unroofing such as uplift-driven erosion and upper crustal extension on the hanging wall of a major S-verging thrust located beneath the currently exposed crystalline rocks. That this cooling, from $>600^\circ\text{C}$, was rapid is indicated by mineral cooling ages that date cooling through 500°C at ca. 40 Ma. In passing we may note that this early timing of metamorphism and post-metamorphic cooling is inconsistent with a combination of the normally accepted timing of Himalayan

collisions and one-dimensional conductive models of the thermal evolution of thickened crust. They imply that either Himalayan collision was earlier than normally predicted, or that frictional processes of heating are more important in deformation zones than hitherto suggested.

Apart from the growth of calcic rims on garnets in the garnet and staurolite zones of the Hazara nappe there is little evidence for metamorphic overprinting during post-metamorphic stacking. These calcic rims are, though, important. Modeling across the zonations demonstrate that they record abrupt pressure increases, equivalent to about 10-kms of new tectonic burial. Inside the rim regions, the garnets record normal growth patterns relating to metamorphism during development of the first mountain front. The calcic rims relate to tectonic thickening during the second mountain building phase. Within the post-metamorphic stack, the ductile nature of the shear fabrics and K-Ar geochronology suggest that temperatures were >350°C throughout the period of stacking.

Within the post-metamorphic stack there is a systematic increase in metamorphic pressure from the structurally lowest to the structurally highest nappes. This is most clearly shown in the Kaghan Valley where pressures range from ca. 5 kbar in the lowermost nappes to eclogite conditions in the highest ones, as David Spencer has recently, and most excitingly, shown. This is convincingly firm evidence that, following subduction-related metamorphism, the subducted slab was acutely telescoped, largely by crustal scale thrusting that was entirely confined to sequences on the MMT footwall. That the uppermost nappes are essentially composed of cover sequences has important implications for processes of cover basement decoupling during continental subduction. Displacement amounts for those rocks originally most deeply subducted, and now structurally uppermost in the internal zones, must have been substantial and imply that total shortening amounts for the Indian Plate are well in excess of the 500-km or so generally assumed.

Consequently the full metamorphic story for the Indian Plate internal zones involves: pre 50 Ma, and associated with the growth of the first mountain front, syn-subduction metamorphism (were the heat for this metamorphism not largely driven by frictional heating the collision and crustal thickening must have pre-dated 60 Ma); rapid, pre-40 Ma, exhumation-driven, cooling; pre-25 Ma, and during the growth of the second mountain front, the telescoping and stacking of the cooled and partly exhumed subducted slab with tectonic metamorphic inversions; a second phase (pre-15 Ma) of extension and erosion-driven cooling.

Key words: Tectonics, orogeny, metamorphism, P-T-t path, Indian plate, Nanga Parbat syntaxis.

T/161. Treloar, P.J., 1992. Tectonic of the Himalayan collision between the Indian Plate and the Afghanistan Block: Regional Implication. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 132.

The tectonic history of Afghanistan is complex but can be simplified into deformations related to two main orogenic events. In the earlier of the two, the Triassic to Jurassic aged Kimmerian orogeny, blocks of Gondwanan affinity were sutured to the Asian Plate. Two ophiolitic sutures (Hari-rud and Panjao) can be traced eastward into, respectively, the Jingsha and Banggong sutures of Tibet. A calc-alkaline arc sequence, developed on the southern part of the Asian Plate *sensu stricto*, to the north of the Herat Fault, represents the magmatic products of the subducted intervening oceanic plate. Subsequent to the Kimmerian the Afghan block behaved as a part of Greater Asia.

Prior to Himalayan collision, subduction of the Tethyan oceanic plate beneath Afghanistan saw the development of volcanic arc plutonic sequences of Late Cretaceous age within the Helmand and SW Pamir blocks of the Afghan continental margin, and within the Nuristan extension of the Kohistan-Ladakh island arc. These plutons, and associated volcanics, represent the western end of the Trans-Himalayan batholith.

An important ophiolite emplacement event occurred during the Paleocene. This included emplacement of the Khost, Muslimbagh, Zhob and Waziristan ophiolites onto the western margin of Greater India, as well as ophiolite emplacement onto the Kabul block. The Kabul Block is interpreted here as being of great significance in the pre-Himalayan tectonic evolution of the NW Himalaya. Not only were ophiolitic units emplaced onto it from the northwest, but subsequent to the ophiolite emplacement events, the Kabul block remained separated from Greater India by oceanic crust to its east and southeast. Eocene to Oligocene flysch sediments of the Katawaz basin were deposited onto this oceanic crust subsequent to the ophiolite emplacement events. The Kabul block therefore appears to represent a sliver of continental crust separated from Greater India by a narrow slice of oceanic crust.

Timing of Himalayan collision is uncertain, but there is an increasing body of data which suggests that peak metamorphism in the NW Himalaya must have predated 40 Ma ago, and that metamorphism and leucogranite emplacement may have been as early as 51 Ma ago. If these ages predate true India-Asia collision, as seems likely, then we need to find a mechanism by which the northern margin of Greater India may have been telescoped and

thickened prior to India-Asia collision. Such a mechanism could involve the collision of the leading edge of India with an independent slice of continental crust, subsequently subducted beneath Kohistan and southern Asia. The Kabul Block may be the southwestern, and only remaining exposed, part of this strip of continental crust. The early metamorphism may, therefore, represent thermal relaxation following this pre-Himalayan collision between India and “Kabulistan”.

True India-Afghanistan collision did not take place until the mid- to late-Oligocene, the oceanic crust and overlying flysch sediments, that separated the Kabul Block from the Indian Plate, remaining intact until then. Dating of this collision is derived from the ages of: molasse sediments that postdate thrusting in the Sulaiman Ranges of West Pakistan; flysch sediments folded within the Katawaz Flysch Basin; Paleogene sediments deformed in basins within the Herat Fault zone; and Oligocene sediments and volcanics folded during deformation of the Farah Block of Afghanistan. Significant counter-clockwise rotation of northern Afghanistan took place as, following oblique collision, Afghanistan climbed onto the western margin of the Indian Plate.

The degree to which continental extrusion, accommodated by strike-slip faulting, has taken place in Afghanistan following the Oligocene is uncertain. The Herat and Chaman Faults cannot have acted together to accommodate such expulsion as the former was mainly active during the early Miocene, and the latter after that. Instead, much of the shortening consequent on collision and the continued indentation of India into Asia may currently be being taken up by the northwestward thrusting of the Hindu Kush Mountains over the Afghan-Tadzhik Basin.

T/163. Treloar, P.J., 1995b. P-T-t Paths and the relationship between collision, deformation and metamorphism in the NW Himalaya. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

In recent years, an increasing amount of attention has been given to the thermal controls of metamorphism and the P-T-t paths followed by evolving regional metamorphic terrains. One-dimensional models of conductive heat transfer within orogenically thickened crust clearly demonstrate that in the absence of the sudden injection of heat through magmatic processes, time-scales over which prograde regional metamorphism occurs should be measurable in tens of millions of years. As such, it has become commonplace to consider that the regional metamorphism of thickened crust is a lengthy process, with short lived regional metamorphic episodes being limited to regions, possibly of limited extent, that are characterised by the magmatic advection of heat from the mantle to the crust. In this paper I wish to explore mechanisms which may explain why areas of apparently large regional extent, can undergo regional metamorphism over short time-scales but in the absence of any magmatic heating. An area ideal for this study is the chlorite- to sillimanite-grade metamorphic pile developed on the leading edge of the Indian Plate in northern Pakistan, in the NW Himalaya.

Early Tertiary tectonic and metamorphic evolution of the Indian Plate in N Pakistan.

Within the NW Himalaya, collision was between the leading edge of the Indian Plate and the Kohistan-Ladakh island arc. The Kohistan arc, sutured to Asia at between 100 and 85 Ma ago (Treloar et al 1989a), was the last exotic terrain to be accreted to the Asian Plate prior to Tertiary collision between the Indian and Asian Plates. Prior to collision between the Indian Plate and Kohistan, a series of ophiolitic sheets were obducted onto the northern and western margin of the Indian Plate. Structural data from various ophiolites suggest ophiolite emplacement to have taken place about 65 Ma ago (Searle 1986, Beck et al 1995). When collision between the Indian Plate and the Kohistan island arc commenced, Kohistan was obducted onto the leading edge of the Indian Plate along the Main Mantle Thrust (MMT), a major north-dipping thrust fault that is the true westward continuation of the Indus-Tsangpo Suture Zone. Within the crystalline internal zones, the Indian Plate can be divided into three lithostratigraphic units. At the base is a Proterozoic complex comprised of biotite gneisses intruded by undeformed granites. Hornblende and zircon ages from the gneisses are about 1850 Ma (Treloar & Rex 1990a, b). The gneisses are overlain by a series of late Precambrian to early Cambrian sediments intruded by the Cambrian Mansehra

granite, and which underwent a Paleozoic low grade metamorphism (Baig et al 1989). Unconformably overlying these units is a sequence of pelites, calc-pelites, marbles and amphibolites which constitute the Carboniferous to Triassic Panjal Sequence of the Kaghan Valley and the Alpurai Schist sequence of the Swat Valley (Di Pietro et al 1993, Greco & Spencer 1993). These units must have been overlain, prior to collision, by a sequence of Mesozoic to Eocene continental margin limestones and sandstones, up to 4km thick.

Metamorphism on the footwall of the MMT, within the Indian Plate cover sequences, was synchronous with ductile deformation associated with collision with Kohistan (Treloar et al 1989b, c, d; DiPietro 1991). Spiral garnets, garnets with curving inclusion trails, and garnets with inclusion trails discordant to developed crenulation cleavages are all consistent with growth of metamorphic porphyroblasts early in the deformation history. Subsequent to the main phase of metamorphism, the metamorphic pile was disrupted within a S-vergent thrust stack which imbricated thrust nappes composed of basement rocks with thrust nappes composed of cover rocks. Within individual nappes, N-dipping thrusts placed rocks of a higher metamorphic grade on top of rocks of a lower metamorphic grade, thus generating a tectonically inverted metamorphic sequence, with metamorphic grade increasing both northward and structurally upward. The thrusts and shears which controlled this stacking disrupted the peak metamorphic assemblages and thus post-date the main phase of metamorphism. Although Tertiary cooling ages are readily retrieved through hornblende and mica Ar-Ar data from the Upper Kaghan, Swat and Hazara nappes, there is no evidence for a substantial Tertiary heating of the basement rocks, from within which undisturbed hornblende Ar-Ar spectra yield ages of ca 1850 Ma (Treloar & Rex 1990a, b). This implies either that the cover sequences, metamorphosed during the early Tertiary, were transported great distances during the post-metamorphic thrust stacking, or that the early Tertiary metamorphism was restricted to the upper part of the Indian Plate.

Geochronologic data from a variety of sources indicate that peak metamorphism predated 47Ma with cooling back through 5000C by 40 Ma (Treloar et al 1989a; Treloar & Rex 1990a, b; Zeitler & Chamberlain 1991; Tonarini et al 1993; Smith et al 1994). By contrast, timing of Himalayan collision between the Indian and Asian plates is poorly constrained although most reasonable estimates place it at between 65 and 50 Ma ago (Klootwijk et al 1992; Patriat & Achache 1984). However the timing of collision is defined, there is still an absolute maximum of 15 Ma between initial collision and the attainment of peak metamorphic conditions within the leading edge of the Indian Plate in Pakistan. This is insufficient to permit the attainment of middle amphibolite-facies temperatures by purely conductive heating of cold rocks following continental thickening, unless they had extremely high internal heat generating properties. Possible solutions to this dichotomy are either that the metamorphism predated the Tertiary collision of India, which appears unlikely, or that the driving force for metamorphism involved more than simply conductive heating following crustal thickening. Here I wish to assess the second of these possibilities.

Metamorphism in the Indian Plate. Metamorphic conditions have been derived for much of the internal zones of the Indian Plate exposed to the west of the Nanga Parbat syntaxis (Treloar et al 1989b, c; DiPietro 1991; DiPietro & Lawrence 1991; Pognante & Spencer 1991). For the Swat region, kyanite-grade rocks were metamorphosed at 625 + 500C and 9 + 2 kb. For the Hazara area, staurolite-grade rocks were metamorphosed at 480~620a(2 and 5-10kb, and kyanite-and sillimanite- grade rocks at 600-7400C and 7-12 kb. Kyanite- and sillimanite-grade rocks of the upper Kaghan Valley, on the hanging wall of, the Batal Thrust, were metamorphosed at ca. 650 + 500C and 9 + 2 kb. In addition, eclogitic rocks within the Upper Kaghan nappe yield P-T estimates of 650 + 500C and 14.5 + 2.5 kb. In the Lower Kaghan Valley, on the footwall, and to the south of, the Batal Thrust garnet-grade rocks yield P-T estimates of 540 + 400C at 10 + 2 kb.

Pressure-temperature-time (PTt) paths have been estimated for rocks from each of the major thrust nappes. Within the Swat region, garnet cores contain an assemblage including zoisite, calcite and ilmenite, and garnet rims contain an assemblage that includes kyanite and rutile. The transition from ilmenite in garnet cores to rutile in garnet rims and in the matrix is consistent with a pressure increase from core to rim. For the Hazara and Upper Kaghan region, PTt paths have been calculated through forward modelling of garnet zonation profiles. Calculated core to rim paths invariably involve increasing pressure trajectories, with little evidence from marginal rim compositions for a significant late pressure decrease.

Thus, in North Pakistan, metamorphism of the Indian Plate sedimentary cover was along a path of increasing pressure, synchronous with ductile shearing, consistent with metamorphism having occurred during active subduction of the leading edge of continental India beneath Kohistan. Peak metamorphism of the cover sediments was achieved by no later than 50 Ma, with cooling back through 5000C at 40 Ma. Subsequently, the rocks were stacked within an imbricate thrust pile within which higher grade rocks are always stacked on top of lower grade rocks. Any model that attempts to explain the metamorphic history of this part of the Indian Plate has to be able to account for the rapidity of heating and subsequent cooling, the syn-metamorphic path of increasing pressure, the subsequent tectonic stacking of the metamorphic sequence; and why, on the footwall of the MMT, it is largely the cover, and not the basement, sequences that show the effects of Tertiary metamorphism.

A Model for the early Tertiary thermal evolution of the NW Indian Plate.

Much of the numerical modelling of the thermal evolution of metamorphic terrains has been involved with explanations for the evolution of inverted thermal gradients across crustal-scale structures. Within 1-dimensional systems, it is easy to generate an inverted thermal gradient across a thrust fault by assuming instantaneous thrusting. However, such an instability will decay within a few Ma due to conductive heat transfer across the fault. Using 2-dimensional modelling, it can be shown that, at thrust displacement rates of $< 5 \text{ cm a}^{-1}$ and in the absence of dissipative shear heating, conductive cooling during thrusting would prevent the development of an inverted thermal gradient, even in the immediate vicinity of the fault (Ruppel & Hodges 1994). Even at thrust rates of $> 5 \text{ cm a}^{-1}$ a steady state temperature inversion cannot be maintained due to cooling of the hanging wall block by continued underthrusting of cold layers on the top of the footwall block: the so-called subduction refrigeration effect (Peacock 1987). To preserve a record of the inverted thermal gradient, it is necessary to accrete the metamorphosed footwall rocks onto the base of the hanging wall, and then to tectonically uplift them. By contrast, dissipative shear heating can generate an inverted temperature gradient on the footwall of the thrust, but with the temperature maximum on the thrust plane itself (Molnar & England 1990; England & Molnar 1993). The effects of dissipative shear heating will override any incipient cooling of the upper block, within which a stable geothermal gradient will be achieved after initiation of faulting at a time determined by the displacement rate along the fault and the thermal diffusivity.

The possible effects of dissipative shear heating along the fault that separated Kohistan from the Indian Plate have been modelled using equations 23 to 30 of England & Molnar (1993). Shear stresses have been calculated, using dips of 15 and 30° for the fault surface and displacement rates along the fault of 10 and 15 cm a^{-1} , for two different sets of P-T conditions (7250 at 10 Kb and 650°C at 10 Kb) that equate to kyanite to sillimanite bearing rocks of the Hazara nappe and the kyanite-bearing rocks of the Swat nappe respectively) and thus approximate to temperatures attained in the uppermost part of the Indian Plate on the footwall of the MMT. Derived shear stresses are a function of the angle of dip of the subduction thrust and the convergence rate, with high dips and high convergence rates favouring high shear stresses. The relatively low angles of dip of the subduction thrust are taken to account for the fact that buoyant continental, rather than dense oceanic, crust was being subducted beneath Kohistan. Displacement rates are based on early Eocene convergence rates between India and Asia. For these input parameters, shear stresses developed along the thrust at depths of 25 to 50 km are in the order of 57 to 116 MPa.

Using the calculated shear stresses, temperature gradients developed on both the hanging wall and footwall of the thrust can be retrieved. A steady state geotherm of $\text{Ca. } 20^\circ\text{C km}^{-1}$ will be attained in the hanging wall within about 5 Ma of the initiation of thrusting. For the footwall, and for depths of 35 km, a negative geothermal gradient of between -83 and -178°C km^{-1} will be attained. Thus, if the effects of dissipative shear heating along the MMT are considered, it is clear that at about 5 Ma after initiation of collision significant negative thermal gradient could have been established beneath Kohistan in the Indian Plate rocks on the footwall of the MMT, with temperatures on the immediate footwall $> 550^\circ\text{C}$.

Discussion.

Given the likely inverted gradients that developed during thrusting, it becomes possible to construct an approximate model for metamorphism on the footwall of the MMT, which might have developed within approximately 5 Ma of the initiation of collision between India and Kohistan. As the major isogratic reactions are temperature dependent, the temperature inversion developed on the footwall of the MMT should be matched by a metamorphic inversion. In order to be preserved, such inverted metamorphic sequences need to be accreted to the base of the over-riding fault block and brought rapidly back towards the surface. To do this the main zone of shearing has to step downward into the footwall so that the initially metamorphosed rocks can be uplifted on the hanging walls of new thrusts developed on their footwall. This accretion process is likely to achieve a thrust-type imbrication of the metamorphosed zone as a result of which rocks metamorphosed deeper within the thrust zone will be stacked on top of rocks metamorphosed at shallower levels within the thrust zone. These imbricating faults will be sub-parallel to the master fault, although with an anastomosing geometry, will stack higher pressure (and thus higher temperature/grade) rocks on top of lower pressure (and thus lower temperature/grade) rocks, and will tectonically thicken the metamorphic complex.

A number of predictions arise from this model. Firstly, the metamorphic pile will be relatively thin and concentrated in the upper part of the footwall block. This means that, as in N. Pakistan, the main metamorphism will be concentrated in the cover sequence of the downgoing plate, with the basement rocks insulated from the thermal effects of the thrust-related metamorphism. Secondly, to be preserved, the rocks that underwent rapid metamorphism during active shearing on the thrust footwall must be brought rapidly back towards the surface, and hence, as in N. Pakistan, will show rapid post-peak metamorphic cooling histories and only a brief residence at high temperatures and pressures. Thirdly, the thrust imbrication that develops during accretion and uplift should stack high-grade rocks on top of lower grade rocks, as is seen in N. Pakistan, thus re-enforcing the original syn-thrusting inverted metamorphic gradient. In the internal zones of N. Pakistan, there is no evidence for older rocks being stacked upon

younger rocks. Rather, the geometry is of rocks that had been deeper in the subduction zone being stacked upon rocks that have never been as deep. This implies that deeper rocks accreted onto the hanging wall first with increasingly shallower packages accreted onto their base during their tectonic exhumation. Exhumation of the metamorphic tectonites developed on the immediate footwall of the MMT would have been by a combination, firstly, of imbrication of the metamorphic rocks during their accretion onto the footwall of the MMT, and, secondly, by uplift of the MMT and the imbricated metamorphic rocks on the hanging walls of S-vergent thrusts developed as deformation stepped downward into the Indian Plate. This uplift would have been accompanied by erosive unroofing of Kohistan. The imbrication of the metamorphic rocks during accretion onto the MMT footwall thus provides a mechanism for producing a regional metamorphic signature of large areal extent, as a thin metamorphic “aureole” becomes tectonically thickened by intense subsequent imbrication.

The thermal models presented here are clearly approximations. At the subduction rates used here a zone with inverted thermal gradient could also be modelled on the MMT footwall through simple one-dimensional thermal modelling. However, it is clear that dissipative shear heating may be a significant factor in controlling metamorphism within thrust systems, and provides a mechanism by which areas of apparently large regional extent can undergo regional metamorphism over short time scales, but in the absence of any magmatic heating.

Key words: Tectonics, collision, deformation, metamorphism, Himalaya.

T/164. Treloar, P.J., 1995c. Short time scale events: are they the key signature of early stages of orogenesis? A framework for discussion. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

That the Himalaya form a wonderful (scenically and scientifically) open air laboratory within which to study orogenic processes is indisputable. What is maybe more debatable is the extent to which they form an ideal basis on which to build analogies for the evolution of old orogenic belts. If we accept the broad tenets of the Law of Uniformitarianism, it is obvious that modern day processes should form the key by which we understand the past. This is clearly demonstrated by recent papers by de Wit et al (1992) and Windley (1993) which utilise modern tectonic processes as analogues for Archaean and Proterozoic tectonism in the Limpopo Belt. As an example, I admit to a Tibetan analogy for the late Archaean tectonic evolution of the Limpopo Belt and adjoining Zimbabwe and Kaapvaal cratons (Treloar et al 1992), a model relatively uncritically accepted by southern African geologists, yet one with such serious flaws that it has to be viewed as untenable (Treloar & Blenkinsop, in press). One of the problems in applying Tibetan-Himalayan analogies to the Archaean, for instance, is in the time scales involved. In many cases, the errors on geochronologically dated apparently simultaneous events are almost as large, or even greater than, the total elapsed time since the initiation of the India-Asia collision!

Two features really form the gist of this discussion: time scales and rates of orogenic processes. Through a combination of isotope, fission track, palaeomagnetic and palaeontologic dating techniques it is now possible to constrain the timing of most of the critical events within the history of the Himalayan orogeny, and the rates at which those events took place. Ironically, the least well constrained event is the timing of initial collision between India and Asia (mais, c'est la vie!). What this chronology tells us is not only that a tremendous amount has happened within a relatively short time scale (< ca. 60 Ma), but that it happened quickly. Given that the initial India-Asia convergence rate was in the order of 20 cm a⁻¹, this may not be surprising, but it does raise a number of questions.

As a young metamorphic petrologist I, amongst many others, was influenced by the seminal papers of England & Richardson (1977) and England & Thompson (1984). Amongst the first to attempt to model the thermal evolution of tectonically thickened crust, these papers demonstrated the efficiency of purely one-dimensional conductive thermal relaxation of thickened crust in driving regional metamorphism and the fact that for most thickened crustal sections metamorphic P-T-t paths are of a “clockwise~ sense (if one assumes that pressure on the P axis of a P-T plot increases upwards. Geophysicists would likely describe these, probably correctly, as counterclockwise paths!) What these early attempts at thermal modelling showed, and this may be the critical message that struck home to a thousand hearts, is that time scales of regional metamorphism are LONG, measurable in many tens of millions of years. An unstated implication of the England & Thompson models, as well as other similar ones, is that regional metamorphism should be, BY DEFINITION, static. Thickening of the metamorphic pile occurs synchronously with deformation, but the peak metamorphic temperatures are attained many millions of years later. There is geochronological support for this. Both Burton & O'Nions (1991) and Vance & O'Nions (1992) have shown that growth periods of individual garnets may be measurable in terms of up to about 10 million years. However, the exciting, seminal and sometimes controversial work of Tim Bell and his colleagues (Bell 1985, Bell et al 1986, Bell and Johnson 1989, 1992) poses a major question to this simple assumption. Bell will aver that porphyroblast growth

in metamorphic rocks is synchronous with deformation. If we look at papers that describe metamorphic tectonites from the Himalaya, what do we see? Spiral garnets, garnets with curving inclusion patterns etc (e.g. Treloar et al 1989a, b). Whether one wishes to resort to “Zwartian” or “Bellian” classifications of porphyroblast-matrix relationships, these textures have to be consistent with syn-deformational growth of metamorphic porphyroblasts, the only thing that is logically not predicted by standard one-dimensional thermal modelling.

Let us take as an example, the early Tertiary metamorphism of the leading edge of the Indian Plate in the NW Himalaya of N Pakistan. It is clearly demonstrable that peak metamorphism there had occurred by between 47 and 50 Ma (Zeitler & Chamberlain 1991, Tonarini et al 1993, Smith et al 1994) and that subsequent cooling back through 5000C was achieved by 40 Ma (Treloar & Rex 1990a, b). Depending on how one constrains the timing of collision, peak metamorphism was within between 5 and 15 Ma of initial India-Asia collision. What price long time scales of regional metamorphism now? In a parallel paper to this (Treloar, this volume) an answer to this conundrum is provided, which builds on the numerical experiments of Molnar & England (1989) and England & Molnar (1993) in invoking dissipative shear heating as the driving thermal impetus for early Tertiary regional metamorphism in the NW Himalaya.

But, this rapid Early Tertiary regional metamorphism is not the only short-lived event that we recognise within the Himalaya. In no particular order of importance or chronology the following far-from-exhaustive list includes:

The synchronicity of thrusting along the Main Central Thrust, extension along the Zaskar Shear Zone/South Tibetan Detachment Zone granite generation and emplacement within the High Himalayan Crystallines (HHC) at about 22 to 20? Ma (references to numerous to mention! but see Searle et al., 1993, England & Molnar 1993). The near synchronicity of metamorphism, melting and granite emplacement within the HHC (a above) uplift and erosion of the HHC and deposition of derived sediments within the Himalayan foreland basins (Najman et al 1993) and the Bengal Fan (Copeland & Harrison 1990) and beyond (France-Lanord et al 1993). The rapid late Oligocene to early Miocene cooling of the internal zones of the Pakistan Himalaya (from > 350° to < 100°C in <8Ma in direct response to erosional and extensional unroofing of the pile (Treloar et al 1991).

The rapid (instantaneous?) late Miocene uplift of the Tibetan plateau (England & Houseman 1988).

The rapid uplift of the Nanga Parbat (Zeitler 1985, Treloar et al 1991) and Hazara syntaxes (Bossart 1988).

Lateral variations in the rapid rate of sediment accumulation in the foreland basins. In Kohistan, there is a possible linkage between probably short-lived regional scale metamorphism and lower arc melting and massive advective heat input from the mantle associated with emplacement of the Chilas body at ca 85 Ma.

There have to be many more examples of rapid metamorphism, sedimentation, exhumation, which as a group of Himalayan geologists we can identify, in discussion, at this meeting. It is true that it is not only just in the Himalaya that short-lived events are important in crustal evolution. As an example, emplacement of granitoid plutons into the Mesozoic arc developed along the western margin of continental South America in the Chilean Andes was not a continuous process. Instead a number of distinct short-lived pulses of pluton emplacement have been identified by precise hornblende Ar-Ar geochronology. Essentially pluton emplacement was controlled by intermittent periods of extensional activity within the trench parallel Atacania Fault system (Grocott et al 1994). When the fault system was not in extension, no space was available within the crust for magmas to stall and create plutons, hence periods of plutonism are separated by distinct periods of volcanism. Similar, highly responsive, relationships between changes in regional deformation and magmatic styles have been identified elsewhere (Glazner 1991). Harte & Dempster (1987) and Ridley (1989) have argued that lateral changes in metamorphic history and style within orogenic belts are a function of active tectonic boundaries, across which there may be significant lateral heat fluxes, and that prominent metamorphic zones within orogenic belts may be the product of tectonic boundary conditions and thus not necessarily representative of the overall thermal history of the belt. They inferred that these tectonic boundary zones and associated heat fluxes may be long-lived. However, Himalayan examples demonstrate that this may not necessarily be the case.

I do not wish to deny that there are a plethora of data that support the thesis that orogenic deformational and metamorphic features are long-lived. Particularly relevant here are the way that granulite terrains show evidence for long time-scales of high temperature, static annealing and metamorphism (Mezger et al 1990). It is clear that any overthickened crust, if left long enough, would follow the one-dimensional conductive thermal relaxation paths of England & Thompson (1984) and, over a long time scale, heat up and experience a long term, static regional metamorphism. There is little doubt, in my mind, that rocks currently located at depths of >40 km below the topographic surface in Tibet and the Himalaya are currently following the path of purely conductive heating and regional metamorphism. My picture of the lower crust beneath Tibet and the Himalaya is of zones of slowly heating isotropic granulites separated by fine-grained mylonitic shear zones. Dissipative heating along these shear zones may contribute fundamentally to the evolving thermal budget in these deep crustal regions. The significance of the above probably comes down to two points. Firstly, the role of shear zones, thrusts and faults in controlling many of

the processes witnessed within the Himalayan belt. These include crustal thickening, uplift, tectonic exhumation, space creation for pluton emplacement, a dissipative shear heating contribution to metamorphism, fluid access for retrogression and/or melt fluxing, all of which processes will be enhanced by high displacement rates. Secondly, that short-lived events within the Himalaya are important due to high convergence rates, and hence rapid displacement rates along shear zones and faults at all crustal levels. Implications of this include the following. Are short-lived events of less importance in orogenic belts in which strain rates are lower? Will short-lived events within the Himalaya-Tibet region become less significant as the convergence rate between India and Asia decreases? To answer these questions we probably need to consider what the late stages of orogeny involve and what will the Himalaya-Tibet region look like fifty or a hundred million years hence. Most of the features that we see now will have been re-distributed as sediment in the oceans to south and east. The thickened crust which currently underlies the High Himalaya and Tibet will probably have returned to a more normal crustal thickness by a number of processes (delamination, extension, but increasingly dominantly through isostatically driven erosion) such that rocks now at depth will be exposed at surface. Those rocks will show evidence for a long thermal history at depth, consistent with England & Thompson's (1984) early models. Evidence for the shear zones which accommodated much of the Tertiary thickening will be limited to annealed granoblastic rocks with little microstructural information, and the Ar and fission track cooling histories will tell us little about the major orogenic processes. It is probable that preserved deformation features will be dominated by those generated during the later stages of orogeny, when convergence rates, and hence strain rates, were lower.

My contention, which we should discuss at this meeting, is that, although over the duration of an orogeny, it may appear that long time scales of metamorphism, magmatism, erosion and uplift are the norm (and if we look at orogens such as the Appalachians, the Cadomian or the Caledonides where we see the roots of the eroded orogen this may appear a sensible conclusion) the reality is that short lived, and possibly localised, thermal, magmatic, metamorphic, erosive and sedimentary processes that result from short-lived faulting (thrusting and extensional) events (brittle at surface, ductile at depth) characterised by high displacement rates, are an important contributor to early stages of orogeny. Thus, if it is these short-lived, rapid events which dominate early orogenic processes the Himalaya are only really a true analogue for the early stages of orogenies characterised by high convergence rates, and we should not attempt to force too far analogies that explain the waning, late-stage orogenic processes recorded in many of our deeply eroded orogenic belts.

T/165. Treloar, P.J., 1997. Thermal controls on early-Tertiary, short-lived, rapid regional metamorphism in the NW Himalaya, Pakistan. *Tectonophysics* 273, 77-104.

During Tertiary collision in the NW Himalaya, the leading edge of the Indian Plate was subducted beneath the Kohistan island arc along the Main Mantle Thrust (MMT). Metamorphism within Indian Plate cover sediments was synchronous with ductile shearing, and took place along a path of increasing pressure during subduction beneath the island arc. Initial collision cannot have pre-dated 65 Ma and probably shortly pre-dated 50 Ma. Radiometric data constrain the metamorphic peak as shortly post-dating 50 Ma. As, firstly, initially subducted units are now probably located beneath Tibet, secondly, the subduction thrust separating the Kohistan arc terrane from the Indian Plate was probably cooled by continued underthrusting and, thirdly, the heat-producing Indian Plate cover sediments were delaminated from the basement during collision, metamorphism was more rapid than can be predicted by purely conductive models of thermal relaxation. Although dissipative shear heating along the MMT doubtless contributed to early stages of heating of the footwall rocks, the temperatures attained in the footwall are too high to support the shear stresses required to generate them solely through shear heating. A model is derived to account for both the rapid regional metamorphism and the equally rapid post-metamorphic cooling. Dissipative shear heating along the MMT generated an early inverted thermal profile in the upper units of the Indian Plate. As the hanging wall mafic rocks have a low thermal conductivity, they would have acted as a thermal reflector and the heat would have been conducted away only slowly. As footwall temperatures increased through the brittle-ductile transition, the role of dissipative shear heating decreased and continued heating became a function of internal heat generation within the footwall rocks, together with hanging wall thermal reflectivity. The metamorphic inversion was reinforced by imbrication of the metamorphic stack as it accreted onto the MMT footwall during early stages of uplift and exhumation. Dissipative shear heating within thrust systems provides a potentially important mechanism by which areas of large regional extent can undergo regional metamorphism over short timescales, in the absence of magmatic heating.

T/166. Treloar, P.J., 1999. Exhumation of high-grade Indian Plate rocks in North Pakistan: Mechanical implications of a multi-phase process. *Terra Nostra* 99 (Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany), 157-158.

Although syn-convergent extension has been described from many compressional orogens, evidence that it may partition into multiple discrete phases is less clear, even though extension is predicted as continuing for as long as shortening once a critical crustal thickness is attained. Geochronological and structural data from the Indian Plate of North Pakistan, to the west of the Nanga Parbat syntaxis, as well as from the structurally overlying Kohistan arc, permit construction of a model for Indian Plate exhumation that demands two discrete, short-lived phases of rapid exhumation separated by long periods of erosive exhumation with low unroofing rates. Here, the evidence for this is summarized, and the mechanical implications assessed.

Data collated from a variety of sources date peak metamorphism in the Indian Plate internal zones, that post-dated thrusting of Kohistan onto the Indian Plate along the Main Mantle Thrust, at $c. 47 \pm 3$ Ma at $T' > 6000^\circ\text{C}$ and P of 10 - 15 kbar (see review in Treloar, 1997). That maximum pressures were higher yet is indicated by the recent discovery of coesite in the Kaghan eclogites (O'Brien et al., this volume). Metamorphism was followed at $c. 40$ Ma. by rapid decompression-related cooling to $ca 5000^\circ\text{C}$ (Treloar & Rex 1990; Tonarini et al. 1993), much of it probably between 43 - 40 Ma at a cooling rate of 500°C/Ma . This cooling resulted from rapid exhumation of all the metamorphic rocks; not just the highest pressure ones. That all of the earliest formed metamorphic rocks were partially exhumed at this time, and that the highest pressure rocks are located in cover sediments rather than basement gneisses excludes the application of a simple Chemenda-type model for this period of exhumation and cooling (c.f. Anczkiewicz et al., 1998). Instead of uplift being driven by the rapid rise of a positively buoyant, deeply subducted basement slice, it is more likely to have involved accretion of metamorphosed cover rocks onto the base of the arc and uplift of the whole sequence on the hanging wall of structurally underlying south-vergent thrusts. K-feldspar Ar-Ar data from southern Kohistan date rapid cooling there at $ca 40-42$ Ma (Krol et al., 1996). This indicates that the Eocene-aged cooling and exhumation consequent on uplift was largely accommodated by extension in the upper, brittle, parts of the over-riding Kohistan arc slab. Although synchronous erosion of the Kohistan slab is recorded in the base of the Murree Formation in the Hazara syntaxis (Bossart & Ottiger, 1989), it is unlikely to have been fast enough to accommodate the extremely rapid cooling indicated by the Geochronological data.

A period of slow cooling in the upper Indian Plate followed until $ca. 22$ Ma when ductile through to brittle extensional displacement was initiated along N-vergent structures developed along the Main Mantle Thrust (MMT), and in rocks immediately above and below. This extension, coeval with renewed deposition in the foredeep, resulted in $ca 300^\circ\text{C}$ cooling at a rapid rate of $ca 600^\circ\text{C/Ma}$ in rocks on the MMT footwall (Burg et al., 1996; Vince & Treloar, 1996). Both of the discrete exhumation events can be linked to short-lived phases of ductile thrusting at the, then active, base of the thrust wedge. In the former case, this imbricated the metamorphic complex on the MMT footwall. In the latter, it transported the metamorphic complex south along the Panjal Thrust. Each thrust event had the effect of thickening the thrust wedge and can be coupled with the development of north-vergent extensional faulting in the upper part of the thickened crust. In the former case, the locus of brittle extensional faulting was at a high level within the Kohistan arc. In the later, extensional faulting, which spanned the ductile to brittle transition, developed within the Main Mantle Thrust zone. Both extensional events are coeval with sedimentary pulses within the foredeep. This suggests that they are the direct result of the erection of a topographic high as a result of ductile thrusting and imbrication at the base of the evolving thrust wedge. Extensional faulting in the Pakistan Himalaya, developed near the brittle-ductile transition, is a mechanical consequence of the requirement to maintain the critical taper of a wedge being thickened by ductile processes at its base. Not only does thrusting propagate downward within the wedge, but extension also steps downward following the brittle-ductile boundary. Periods when extension is dominant over erosion are the result of over-thickening of the orogenic wedge, possibly due to short-lived high rates of thrusting at the base of the wedge. Since the Miocene, the Pakistani topographic high has been reduced by erosion rather than extension. Although thrusting has continued at the base of the wedge, growth of high mountains has been retarded by the presence of an Eocambrian salt layer within which the basal thrusts are now located. As a result, critical taper of the wedge is now maintained by out-of-sequence thrusting at the rear of the wedge, rather than thickening at its frontal base.

T/167. Treloar, P.J., Brodie, K.J., Coward, M.P., Jan, M.Q., Khan, M.A., Knipe, R.J., Rex, D.C. & Williams, M.P., 1990. The evolution of the Kamila shear zone, Kohistan, Pakistan. In: Salisbury, M.H. & Fountain, D.M (Eds.), *Exposed Cross-Sections of the Continental Crust* Kluwer Academic, the Netherlands, 175-214.

The Kamila Shear Zone is a deep to mid crustal structure developed within the Kohistan island arc complex of North Pakistan prior to Himalayan collision: between Kohistan and India. Meta-gabbros of the Chilas complex were transported southwards across the shear zone onto a stack of high pressure rocks that had been assembled in the hanging wall of the Tethyan subduction zone. The shear zone is constituted by an anastomosing array of amphibolite facies ductile high strain zones within which fabric intensity varies although mylonitic zones are common. Shear criteria and kinematic indicators have a consistent SW-vergence. Little microstructural evidence for the high temperature ductile shearing is preserved, fabrics having been over-printed by post-deformational processes of recrystallisation, annealing and grain growth. A subsequent history of exhumation during decreasing temperature is documented by a progressive sequence of down temperature retrogression and deformation in superimposed shear zones which predominantly affected coarse grained rocks unaffected by the earlier crystal plastic deformation. The shearing involved dominantly cataclastic amphibolite to greenschist facies deformation culminating in lower greenschist facies shearing and mylonitisation, and the development of a distributed network of minor cataclastic and gouge-filled fault rocks.

South of the Main Mantle Thrust in north Pakistan, rocks of the northern edge of the Indian plate were deformed and metamorphosed during the main southward thrusting phase of the Himalayan orogeny. In the Hazara region, between the Indus and Kaghan Valleys, metamorphic grade increases northwards from chlorite zone to sillimanite zone rocks in a typically Barrovian sequence. Metamorphism was largely synchronous with early phases of the deformation. The metamorphic rocks were subsequently imbricated by late north-dipping thrusts, each with higher grade rocks in the hanging wall than in the footwall, such that the metamorphic profile shows an overall tectonic inversion. The rocks of the Hazara region form one of a number of internally imbricated metamorphic blocks stacked, after the metamorphic peak, on top of each other during the late thrusting. This imbrication and stacking represents an early period of post-Himalayan uplift.

T/169. Treloar, P.J. & Coward, M.P., 1991. Indian plate motion and shape: constraints on the geometry of the Himalayan Orogen. *Tectonophysics* 191, 189-190.

Sea-floor palaeomagnetic data that reflect variations in rate and vector of Indian Plate movement and rotation suggest that initial collision between India and Asia occurred at about 50–55 Ma ago. As the pre-collisional Indian Plate was diamond shaped, with the northern margin comprised of two oblique boundaries, collision was earliest where these boundaries meet, or in what is now the northwest Himalaya. Oblique convergence along each of these two boundaries would generate rotation of thrust sheets as they climb on to the Indian Plate. The oroclinal shape of the main Himalayan chain to the east of the northwest Himalayan syntaxes reflects a combination of the effects of oblique convergence, post-collisional anticlockwise rotation of the Indian Plate, and the pinning of the main thrusts at their northwestern terminations by crust thickened during the earliest collisional stage. The Indian Plate rotation enhances a strike-slip component of movement along the western oblique margin, with the transpressively sinistral Chaman fault zone now acting as a continental escape structure.

In North Pakistan the dominant transport direction throughout Himalayan collision has been to the S or SSE. Southward propagation of thrusts within the thickened Indian Plate has, however, been impeded by interference with SW-verging thrusts in Kashmir, at the western end of the main Himalayan oroclinal chain. As a result of this interference, thrusts within both the Pakistani and Kashmiri systems have become pinned at their lateral terminations. Lineation and palaeomagnetic data document substantial rotations of whole thrust sheets, of up to 40° around the pinned terminations, anticlockwise in Pakistan and clockwise in Kashmir. Although such rotations are best seen within the Pliocene to Recent structures of the external zones, similar rotations can be determined within Oligocene structures in the internal zones. The NW Himalayan syntaxes are crustal scale folds which have grown within the zone of convergence between the two thrust systems. The main Himalayan thrust system is interpreted as having been pinned within the Himalayan chain, rather than at its western termination, due to early thickening of the northwestern Indian Plate having acted as a mechanical impediment to the lateral propagation of the main Himalayan thrusts.

(Eds.), *Himalaya and Tibet: Mountain roots to mountain tops*. Geological society of America Special Papers 232, 137-152.

India collided with the northern Kohistan/Asian plate at about 55 Ma. Subsequently, Asia has overridden India, developing a wide range of thrust slices at the top of the Indian plate. Balanced sections in the imbricated sedimentary cover of the Indian plate indicate a minimum displacement of more than 470 km since collision. This requires the Kohistan region to the north to be underlain by underthrust middle to lower Indian crust, the internal ductile deformation and thickening of which accounts for the main overall crustal thickening beneath Kohistan. In the Besham area of north Pakistan, a stratigraphy can be documented for the northern part of the Indian plate that includes basement sequences of quartz-feldspathic gneisses of the Besham Group, and of Precambrian schists of the Tanawal Formation intruded by the Swat-Mansehra granite. The basement rocks are unconformably overlain by carbonate-rich Paleozoic sedimentary rocks. Sedimentary rocks of both the basement and cover sequences were metamorphosed at an early stage of the Himalayan deformation during tectonic burial associated with crustal thickening. Structures just south of the suture related to this crustal thickening include a sequence of ductile mylonites thickened by thrust-related folding, a folded thrust stack involving basement rocks imbricated with cover strata, and late cross-folds. Much of the thickening of the Indian plate in the footwall of the Main Mantle Thrust can be related to the necessary changes in thrust wedge shape as it climbs through the crust.

T/172. Treloar, P.J., George, M.T. & Whittington, A.G., 2000. Cross-cutting mafic sheets from Indian plate gneisses in the Nanga Parbat Syntaxis: their significance in dating crustal growth and metamorphic and deformation events. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 25-50.

Indian plate, granulite facies, migmatitic basement gneisses exposed within the Nanga Parbat syntaxis host at least two generations of mafic sheets. In the southern part of the syntaxis, concordant sheets yield Palaeo-Proterozoic model ages of 2.2-2.6 Ga, which probably date early stages of continental growth. In the northern part of the syntaxis the sheets include a suite of discordant, silica-saturated or oversaturated sub-alkaline basalts extracted from a slightly depleted sub-continental mantle. Nd model ages and an imprecise Sm-Nd isochron yield an age of emplacement at between 1.6 and 1.8 Ga. That these dykes crosscut granulite facies migmatitic fabrics implies that peak metamorphism in the Indian plate gneisses was, at latest, Meso-Proterozoic and not Tertiary in age. Zircon and

amphibole ages published elsewhere suggest that this metamorphism was probably c. 1850 Ma in age. That the basement gneisses were refractory by the Tertiary has implication for the derivation of leucogranite sheets during the Neogene. Although the gneisses experienced a Tertiary-aged metamorphism, it was to lower temperatures than the Meso-Proterozoic metamorphism. Unless the gneisses were rehydrated during the Tertiary, the leucogranites need to have been soured from more fertile rocks underplating the granulite facies basement complex.

T/174. Treloar, P.J., O'Brien, P.J. & Khan, M.A., 2001. Exhumation of early Tertiary, coesite-bearing eclogites from Kaghan valley, Pakistan Himalaya. *Journal of Asian Earth Sciences* 19, p.68.

The preservation of coesite in ultra high pressure eclogites now at surface raises questions about the structural mechanisms by which they were exhumed. As UHP rocks metamorphosed early in an orogenic cycle probably come to surface through more than one exhumation phase, often few structures remain that relate to the early part of the exhumation path that brought them to "mid"-crustal depths. Here, part of that early path is revealed for coesite-bearing eclogites from the Indian Plate internal zones of N. Pakistan. Metamorphism, at $725 \pm 25^\circ\text{C}$, 28 - 30 kbar, at c. 50 Ma, shortly post-dated subduction of the leading edge of continental India beneath Kohistan.

Structural restorations, field and petrographic data, show the eclogite-bearing rocks are flanked by thrusts below and extensional shears above and that thrusting, extension and the amphibolite to greenschist facies transition were synchronous. The eclogites lie immediately above a top-side-S thrust, S-C' fabrics related to which are overprinted by greenschist facies albite porphyroblasts. The dominant microstructures, though, are S-C' shear bands, penetratively developed throughout the eclogite facies metasedimentary sequences, which document a phase of pervasive top-side-N extension. Hornblende crystals locally parallel stretching lineations related to this extension. Albite porphyroblasts up to 10 cm in diameter overgrow extension related fabrics, although elsewhere they are flattened and stretched within those fabrics.

Top-side-S thrusting predated cooling through the amphibolite greenschist transition at 40 Ma, at which time the pervasive top-side-N extension was operating. This implies exhumation from metamorphic peak to greenschist facies within a few million years. It is likely that both the thrust and extensional sense shear zones represent the late-stage of a deformation continuum which commenced at UHP and brought the eclogites back to "mid" crustal levels. Subsequent Miocene extension brought the rocks near to surface.

T/175. Treloar, P.J., Petterson, M.G., Jan, M.Q. & Bignold, S.M., 1995. A re-evaluation of the Stratigraphy and Early Evolution of the Kohistan Arc Sequence: Implications for Magmatic and Tectonic Arc Building Processes. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

The NW Himalaya are atypical of the Himalayan chain due to the separation of the Asian and Indian Plates by the Kohistan-Ladakh island arc. The arc was initiated during the mid-Cretaceous, offshore of Asia above a N-dipping subduction zone. The arc was sutured to Asia along the Shyok (or Northern) Suture at between 102 and 85 Ma (Treloar et al 1989). Thickening of the arc along S-vergent shear zones accompanying suturing. Subduction of Tethyan oceanic crust beneath the arc continued until about 55 Ma ago when Indian Plate continental rocks began to be underthrust beneath the arc along the N- dipping Main Mantle Thrust (MMT). Most of the penetrative shearing deformation within the arc is related to Cretaceous suturing to Asia rather than the early Tertiary collision with India (Treloar et al 1990). Extrusive volcanic activity spanned the mid-Cretaceous to Eocene, with the last phases of volcanism postdating the initiation of collision with continental India. On the basis of geochemical and

geochronological data, granitoids of the Kohistan batholith, intrusive into the volcanic sequence, have been divided into three. Stage 1 plutons, predate suturing of Kohistan to Asia. Post-suture stage 2 and 3 plutons, dated at 85 to 26 Ma, show a change from gabbroic to granitic types with time (Treloar et al 1989). Petrogenetic and structural models suggest that the infant arc was an extract from Cretaceous mantle and that the subsequent magmatic evolution was a function of the tectonic history. Sr and Nd isotope data document a change in magma source following suturing to Asia and associated arc thickening. The early post-suturing gabbro-diorites have a dominantly mantle-derived isotopic signature. With time, however, magmas emplaced into the arc show evidence for an increasing crustal input as the immature crust of the lower arc began to melt. The crust to mantle input ratio increased with time, such that the last stage magmas were entirely crustally derived (Pettersson & Windley 1990; Pettersson et al 1993). The full sequence thus shows characteristics that change from those of the juvenile stages of an island arc through those of a thickened volcanic arc accreted to a continental margin, to those of an arc underplated by continental crust.

Here we wish to present new field and structural data which enables us to redefine and clarify the stratigraphy of, and order of events within, the Kohistan arc; to this stratigraphy with an evaluation of the newly available geochemical data, not all of which is consistent with the hypothesis that the arc represents a simple calc-alkaline subduction related system, to derive a model for the tectono-magmatic evolution of the infant arc; and to comment on processes that may be generally relevant to early arc development.

A REVISED ARC STRATIGRAPHY.

We have mapped four sections across the southern part of the Kohistan arc: along the Indus Gorge from the MMT northward to the schists that outcrop to the north of the Chilas complex; a north-south section through Chilas that crosses the Indus Valley section; and along the Swat and Dir valleys from the MMT to north of the Chilas complex. The field relations that we recognise define the nature of the contacts of the Chilas body and this, together with the recognition of a regionally extensive sequence of sedimentary and volcanic rocks to the north of the Chilas body, enable us to redefine the basal arc stratigraphy.

The Kamila amphibolite belt. The southern margin of the arc is marked by a series of ultrabasic layered intrusions of which the Jijal body is the best known. The belt separates the Jijal and Chilas bodies, and can be divided into two. The southern part of the belt is marked by the variably sheared rocks of the Kamila Shear Zone, the only major crustal scale structure within the arc (Treloar et al 1990). The belt contains a mixture of variably deformed metabasalts and meta-gabbros, although the ratio of meta-basaltic to meta-plutonic material varies both along and across strike. Metamorphic grade is of amphibolite facies, with metamorphism synchronous with shearing. Hornblende Ar-Ar cooling ages of ca. 85 Ma from sheared rocks indicate that the main phase deformation and metamorphism is probably linked to suturing with Asia. On the basis of trace element and rare earth data that the mafic rocks can be divided into two (Khan et al 1993): a Ti-rich HFSE and HREE enriched subset and a Ti-poor HFSE and HREE depleted subset. The Ti-rich subset have remarkably flat REE and incompatible trace element diagrams. This chemistry is untypical of subduction-related magmatism, and is transitional between E- and N-type MORB. These basalts have an oceanic rather than a subduction-related affinity and closely resemble intra-oceanic plateau basalts such as the Ontong-Java, plateau basalts of the Pacific. By contrast, the Ti-poor subset have a transitional tholeiitic to calc-alkaline chemistry with a negative Nb anomaly and LILE/HFSE ratios more typical of subduction zone magmas and represent the early stages of development of a calc-alkaline arc constructed on the magmatically thickened oceanic crust.

The Jaglot schist belt. We identify schists, interbedded with volcanics, outcropping immediately N of the Chilas gabbro-norites wherever we have been able to access that contact. This belt of rocks extends from E to W right across the arc, and we identify it as a major Kohistan-wide stratigraphic unit located to the N of the Chilas complex which has not previously been formally defined. We propose that it be termed the Jaglot Schist Group. On the S side the Group is intruded by the Chilas gabbro-norites, on its N it is overlain by the Chalt volcanics. The Jaglot schist group is bimodal with greenschist facies metabasalts, sometimes pillowed, and volcanoclastic schists interbedded with metasedimentary schists. The schists are dominantly quartz-rich pelites with some psammitic and calc-silicate horizons. The sediments are similar to greywacke dominated lithologies, and probably represent input of terrigenous material into medium to deep water marine basins. Turbidity currents formed graded units. Where basalts crop out, they tend to dominate with a low proportion of sedimentary material. Sedimentation is evidence for crustal stretching and basin development in close proximity to a subaerial source for abundant amounts of terrigenous material. Such a setting would be consistent with a model of basaltic volcanic eruptions within an arc basin which was acting as a depo-centre for both sedimentary and volcanic rocks. Thus we favour deposition within a medial to distal basin developed behind the main frontal arc during active uplift and erosion of the arc. Basalts with both ocean plateau type and subduction type signatures outcrop within the belt, suggesting that the transition to full arc magmatism occurred during deposition of the Jaglot Group. In both the Indus and Dir Valley sections pillows have

been strongly stretched. The schists everywhere carry a strong tectonic fabric and are intruded by Stage 1 plutons (a mixture of gabbro-diorites and granodiorites), which have also been strongly deformed. The most southerly of the deformed stage 1 plutons crop out within half a kilometre of the northern margin of the Chilas body.

The Chalt, Hunza, Western and Shamran volcanics. Volcanic rocks crop out to the N of the schist belt along the northern margin of the arc over an area, which extends from the Hunza Valley east to Chitral. These form what has been previously termed the Chalt Formation. On the basis of geochemistry we divide this volcanic terrane into two: the Cretaceous Chalt or Hunza Valley volcanics, *sensu stricto*, which outcrop mainly in the E in the Hunza Valley, and the Western and Shamran Volcanics in the W. The Hunza Valley volcanics are overlain by the Yasin Group of turbiditic sediments, fossils within which yield Albian-Aptian ages (Pudsey 1986). The Chalt volcanics are strongly deformed with, in the Hunza Valley, stretched pillows common. There is a bimodal distribution into basaltic to andesitic lavas and rhyodacitic lavas, although the latter are volumetrically minor. Basalts and andesites of the Chalt volcanics have a tholeiitic trend and high MgO (6-15%), Cr and Ni contents with chemistries typical of boninites and, in extreme cases, basaltic komatiites. They have negative Nb-anomalies, high LILE/HFSE ratios and (Ce/Y)_N ratios close to unity, all similar to low-K tholeiites (Petterson et al 1990). The Western volcanics are calc alkaline in type, with high LILE/HFSE ratios, negative Nb anomalies and Ce/Y ratios consistent with high LREE/HREE ratios (Petterson et al 1990). They can be correlated geochemically with the Shamran volcanics which yield an Eocene Ar-Ar hornblende age of 58 ± 1 Ma (Treloar et al 1989) and both the Utror volcanics (Sullivan et al 1993), and the Drosch volcanics.

The Dir Group. Eocene volcanic rocks of the Dir Group outcrop in the Dir and Kalam regions. The Dir Group is divided into the volcanoclastic Baraul Banda Formation and the Utror Volcanics, and comprises a diverse assemblage of coarse volcanoclastic material, basaltic-andesite flows and porphyroclastic material. The lavas consist of a variably altered suite of tholeiitic to calc-alkaline lavas that range in composition from basaltic andesite to high silica rhyolite. They show selective enrichment of LIL elements with respect to the HFS elements, and LREE enrichment relative to the HREE with Ce/Yb ratios in the range 2.3 to 9.9 (Sullivan et al 1993). These trends are typical of subduction related volcanics. The Dir Group overlies granitic plutons dated at ca 75-78 Ma and is intruded by younger plutons dated at 45-48 Ma (Treloar et al 1989). Deposition of the Dir Group was as a marine fore-arc sequence following collapse of the continental margin.

The Chilas complex which marks the core of the arc, is a massive body of, locally layered, calc-alkaline gabbro-norites up to 50km wide and 300km long. The calc-alkaline magmas are similar in trace element composition to those of the low-Ti, HFSE depleted plutons within the amphibolite belt, in that they display a distinct negative Nb anomaly and high normalised LILE/HFSE ratios. The gabbro-norites were probably derived from partial melting of a mantle diapir emplaced during initial stages of arc splitting (Khan et al 1989, 1993). On its northern margin, the Chilas body is intrusive into meta-sediments intercalated with metavolcanics of the Jaglot Schist Group. The intrusive nature of the contact is clearly indicated by the presence of abundant schist xenoliths within the northern part of the Chilas body. Unlike the rocks of the schist belt to the north and the amphibolite belt to the south, both of which were strongly deformed and sheared during the crustal thickening event which postdated suturing of the arc to Asia, rocks of the Chilas complex are generally undeformed although cut by isolated narrow shear zones. Locally, though, the gabbro-norites are intensely deformed. No granodiorites are intrusive into the gabbro-norites. U-Pb ages on zircon separates from Chilas gabbro-norites in Upper Swat fall on a concordia of 84 Ma which would be consistent with a post-suturing emplacement of the Chilas Complex.

DISCUSSION.

To construct a model for the evolution of the Kohistan arc which has general relevance to early arc evolution scenarios, we need to consider the relative timing of volcanic and plutonic events, the significance of the changes in magma chemistries, the role of the repetitive switching from extension to compression in controlling magmatism, the effects of suturing of the arc to Asia in the late Cretaceous with subsequent arc thickening.

On field criteria, geochemistry and geochronology, we can identify a number of distinct units within the Kohistan arc. Although the contact between the Jaglot Schist Group and the Kamila Belt volcanics and intrusive gabbroic rocks is never exposed, the two being always separated by the Chilas gabbro-norite body, we argue that they are lithologically distinct. The greywackes present in the former are absent in the latter, and the mafic plutons present in the latter are absent in the former. On the basis of consistent northward dips within the volcano-sedimentary sequences, we argue that Kamila Amphibolites underlie the basalts and turbiditic sediments of the Jaglot schist belt. The mid-Cretaceous Chalt volcanics overlie the Jaglot Schist Group. The Western, Shamran and Utror volcanics, postdate suturing and are thus younger than the other three units.

Within the arc, we can define a number of geochemically distinct magma types in both the volcanic and intrusive sequences. The volcanic rocks of the Kamila Belt show a change from oceanic plateau to subduction type chemistry with time. The tholeiitic type, transitional between N-MORB and E-MORB, with High TiO₂ contents, low

LILE/HFSE ratios and flat REE and spidergram patterns, are typical of ocean plateau basalts and we interpret this basement volcanic sequence one of oceanic crust magmatically thickened within an intraoceanic setting. These are superceded by a calc-alkaline type with high LILE/HFSE and LREE/HREE ratios which include the bulk of the basic rocks in the Kamila amphibolite belt, and the Chilas gabbro-norites. A third type are the low TiO₂, high MgO low-K boninite and basaltic komatiites of the tholeiitic Chalt volcanics. This is a chemistry typical of extensional regimes. Fourthly, are the more silicic calc-alkaline magmas of the Kohistan batholith and of the basalts, andesites and rhyolites of the Utror and Western volcanics, which have high LILE/HFSE ratios. It is clear that, although the batholithic granitoids and some of the volcanic rocks are calc-alkaline in type with subduction zone type chemistries, many of the pre-suture volcanic rocks are not so. The first true calc-alkaline arc type rocks are the second stage low-Ti basalts within the Kamila amphibolite belt and the calc-alkaline plutons intrusive into the Kamila volcanics. Early parts of the Kohistan sequence are, therefore, NOT arc related. The timing of the final transition from ocean (plateau) to subduction related arc magmatism is uncertain but we infer it to have been during deposition of the Jaglot Schist Group.

There is clear evidence for at least three phases of rifling within the arc. The first of these involved the development of the back-arc(?) or intra-arc(?) basin within which the Jaglot Schist Group was deposited. It is likely that the sediments of the schist belt have an arc source, the remnants of which are visible in the plutonic rocks of the Kamila amphibolite belt. Thus the sediments and basalts of the schist belt may be contemporaneous with the later stage calc-alkaline plutonism of the amphibolite belt which marks the initiation of true arc style calc-alkaline activity. This period of crustal stretching probably continued until the extrusion of the Chalt volcanics and deposition of the turbiditic Yasin Group, with the peak of rifling being represented by extrusion of the primitive boninitic rocks of the Clink volcanic sequence. A second rifting event was linked to the emplacement of the Chilas body. The size of the Chilas complex and the transition from calc-alkaline gabbro-norites to the tholeiitic UMA association are both consistent with emplacement of the body into a tensional environment. The deformation state of the complex suggest emplacement after arc suturing to Asia. The third phase of rifling was accompanied by deposition of the Eocene Dir Group.

Rifling phases were separated by compressive phases. One such was related to suturing of Kohistan to Asia, accompanied by arc thickening. That thickening of the arc accompanied suturing is indicated by the deformed nature of the Stage 1 plutons but not of the Stage 2 plutons. The Kamila Shear Zone, deformation within which is dated as pre-80 Ma, is the major regional expression of this shortening. A second phase of compression is documented from the Dir area. Here, early Stage 2 batholiths (75-78 Ma) were eroded and exhumed prior to the unconformable extrusion of the Utror Volcanics onto their eroded surfaces and the subsequent intrusion of further plutons into the Dir Group at 48-45 Ma. For significant granite emplacement to take place within a volcanic arc, the over-riding plate must be in a state of either orthogonal tension or of transtension with plutonism inhibited during compressive phases. The clear hiatus in plutonism within the arc between 75 and 50 Ma would be consistent with a period of compression, during which intrusion was inhibited and regional uplift and erosion occurred, separating periods of extension or transtension. At about 55 Ma, arc regional extension replaced compression as the dominant strain with the resultant development of the fore-arc basin into which the Baraul Banda Slates and Utror Volcanics were deposited.

Thus we suggest a tectonic model within which the magmatic evolution of the Kohistan arc can be viewed. Arc evolution of the Kohistan was dominated by extensional tectonics with periods of tension separated by significant phases of shortening during which plutonism would have been inhibited. The earliest magmatism was related not to subduction driven arc growth but to magmatic thickening of oceanic crust, possibly within an ocean plateau setting. The earliest stages of arc growth were located on this magmatically thickened oceanic crust. Once subduction was initiated, extension in the back-arc developed, possibly in response to roll-back of the subduction zone. This extension included the development of the basin in which the Jaglot sediments were deposited and the extrusion of the boninitic Chalt volcanics, which may represent melting of upwelling asthenosphere beneath the zone of lithospheric thinning. This first phase culminated with melting of the lower arc crust generating the Stage 1 plutons of the Kohistan Batholith immediately prior to suturing of the arc to the Asian Plate. Subsequently, the arc returned to a state of active (trans?)-tensional rifling during which the Chilas Complex was emplaced. The thermal and magmatic history of Kohistan shows the initiation of the Stage 2 plutonism at about 85 Ma, essentially synchronous with the emplacement of the Chums Complex at about 84 Ma. Amphibole Ar-Ar data date regional cooling through ca 500°C at about 80 Ma. We infer that emplacement of the Chilas body, as a result of asthenospheric upwelling resulting from active extension and rifling in the arc, and the associated massive advection of heat from the mantle to the base of the arc crust, would have had a significant thermal effect on the volcanic rocks of Kohistan. In particular, sufficient heat may have been released to melt the base of the arc in the Kamila belt, drive the widespread regional metamorphism and initiate deep arc melting and subsequent stage 2 pluton creation. The cessation of this

period of extension is dated by erosive exhumation of the Stage 2 batholiths in the Dir and Swat region although what caused this is uncertain. Renewal of extension at c. 60 Ma, involving fore-arc collapse, resulted in extrusion of the Shamran and Dir volcanics and the deposition of the Baraul Banda Formation in a major extensional basin at about 60 Ma.

T/176. Treloar, P.J., Petterson, M.G., Jan, M.Q. & Sullivan, M.A., 1996. A re-evaluation of the stratigraphy and evolution of the Kohistan arc sequence, Pakistan Himalaya: implication for magmatic and tectonic arc-building processes. *Journal of the Geological Society of London* 153, 681-693.

New field mapping and structural data, combined with published geochemical data, from the Kohistan arc in the NW Himalaya, enable a re-evaluation of the arc stratigraphy. Key lithological units and their relationships are more clearly defined, permitting the construction of a revised magmatic-tectonic history for the arc. The oldest units are transitional oceanic-type basalts, which form the basement to the subduction related sequence. Arc-type gabbroic sheets and plutons intrude the oceanic basalts; together these form the Kamila Amphibolite Belt. Metasediments and basaltic lavas were deposited, within an extensional basin, onto the Kamila Amphibolite Belt basement. This sequence, exposed across the arc, forms a distinct stratigraphic unit which is formally defined here as the Jaglot Group. Sediment-charged turbidity cements transported material into the basin, whilst submarine eruptions contributed the basaltic component. This period of extension culminated in the eruption of high-Mg boninites of the Chalt Volcanic Group which overlie the rocks of the Jaglot Group. The earliest granitoids of the Kohistan Batholith predate suturing and intrude the Jaglot and Chalt sequences. At c. 100 Ma Kohistan sutured to Asia, suturing being accompanied by thickening of the arc with the development of major intra-arc shear zones and a penetrative, regionally developed steep cleavage. At c. 85 Ma intra-arc rifting permitted the emplacement into the arc of the voluminous gabbro-norites of the Chilas Complex which clearly intrudes the Kamila Amphibolite Belt to the south and the Jaglot Group to the north. The Chilas Complex has been regarded as part of the pre-suturing, juvenile arc sequence. Field evidence summarized here show this to be not so. Heat advection associated with emplacement of the Complex caused amphibolite facies regional metamorphism, melting of the lower arc and plutonism. Some of the resultant granitoid plutons were unroofed and eroded during a compressional phase at between 80 and 55 Ma, before emplacement of further plutons and extrusion of basaltic through to rhyolitic volcanic rocks at between 55 and 40 Ma. At least three phases of extension and rifting, each separated by short lived phases of compression, characterized arc evolution. Much of the magmatism is controlled by extensional tectonics within the overriding plate of the kind commonly associated with a retreating subduction zone.

T/177. Treloar, P.J., Potts, G.J., Wheeler, J. & Rex, D.C., 1991. Structural evolution and asymmetric uplift of the Nanga Parbat syntaxis, Pakistan Himalaya. *Geologisches Rundschau* 80, 411-428.

The Nanga Parbat syntaxis, in the NW Himalaya, is a still growing crustal-scale north-trending antiformal structure in the core of which Indian Plate gneisses have been uplifted from beneath the overthrust rocks of the Kohistan island arc. Isotopic and fission track geochronology show that uplift rates within the syntaxis have increased to present day rates of > 6 mm/yr. Uplift has been accommodated by a combination of initial northwest verging thrusting on the western margin of the syntaxis, followed by crustal scale folding within the syntaxis and latterly by dextral reverse faulting on the western margin. This thrusting, folding and faulting is the effect of deformation at the north-western lateral tips of the main Himalayan thrusts where they interfere with the south-southeast verging thrusts of the northwest Himalaya.

Amphibole and mica K-Ar, Ar-Ar and Rb-Sr geochronology for the crystalline internal zones of the Indian Plate define both an extensive pre-Himalayan thermal history and a post-Himalayan metamorphism cooling history. South of the Main Mantle Thrust, near Besham, hornblende Ar-Ar ages from basement gneisses record an ca. 1850 Ma mid-Proterozoic thermal event. Hornblende, muscovite and biotite cooling ages from cover sequences metamorphosed during the Himalayan orogeny are 35 ± 4 , 30 to 24, and 29 to 22 Ma respectively. The mica ages, together with those derived from zircon and apatite fission track data (Zeitler, 1985) demonstrate a rate of cooling, of about 30°C/Ma, during the late Oligocene to early Miocene that was greater than that either before or since. This rapid cooling was initiated during the post-metamorphic evolution of the Indian Plate south-verging crustal-scale thrust stack, during which cover sequences metamorphosed during the Himalayan orogeny were imbricated with basement rocks thermally unaffected during that event. Most of the cooling, which happened during the stripping of some 10 ± 2 km of overburden, reflects exhumation due to a combination of erosion, recorded in the Miocene molasse sediments of the foreland basin, and major crustal extension within the MMT zone. Both erosion and extension were the direct consequence of the evolution of the thrust stack.

A post-metamorphic Himalayan cooling history for the crystalline internal zones of the northern Indian plate is defined by amphibole and mica K-Ar and Ar-Ar geochronology. Hornblende, muscovite and biotite cooling ages from cover sequences metamorphosed during the Himalayan orogeny are 35–40, 30 to 23, and 29 to 23 Ma respectively. The mica ages, together with those derived from zircon and apatite fission track data demonstrate a cooling rate of about 30°C/Ma during the late Oligocene to early Miocene. This rapid cooling was initiated during the post-metamorphic development of the Indian Plate south-verging crustal-scale thrust stack. Most of the cooling occurred during the stripping of some 10 ± 2 km of overburden through a combination of erosion, recorded in the Miocene molasse sediments of the foreland basin, and major crustal extension within upper levels of the Indian Plate and the Main Mantle thrust zone. Both erosion and extension were the direct consequence of the evolution of the thrust stack.

T/181. Treloar, P.J., Rex, D.C., & Williams, M.P., 1991. The role of erosion and extension in unroofing the Indian plate thrust stacks, Pakistan Himalayas. *Geol. Mag.*, 128, 465–478.

In north Pakistan cooling history data show that metamorphism within the Indian Plate predated 40 Ma, and that the post-metamorphic thrust stack developed within the crystalline internal zones had cooled to less than 100 °C by c. 18 Ma. Much of this cooling occurred during late Oligocene to early Miocene time and can be equated to substantial unroofing of the metamorphic pile. This unroofing was by a combination of erosion, recorded in Lower Miocene molasse deposits within the foreland basins, and by large scale hinterland (northward) directed extensional normal faults developed within the upper parts of the Indian Plate and within the Kohistan-India suture zone and operative as late as 20 Ma. As up to 20 km of material was removed during exhumation, substantial uplift must have been synchronous with exhumation. Part of this may be accounted for by isostatic rebound of the thickened Indian Plate, and part by uplift in the hanging wall of major south-verging thrusts developed at the base of the crystalline pile.

T/182. Treloar, P.J., Rex, D.C., Guise, P.G., Coward, M.P., Searle, M.P., Windley, B.F., Petterson, M.G., Jan, M.Q. & Luff, I.W., 1989. K-Ar and Ar-Ar geochronology of the Himalayan collision in NW Pakistan: constraints on the timing of suturing, deformation, metamorphism and uplift. *Tectonics* 8, 881-909.

Mica and hornblende K-Ar and Ar-Ar data are presented from each of the three crustal components of the Himalayan collision zone in North Pakistan: the Asian plate, the Kohistan Island Arc, and the Indian plate. Together with U-Pb and Rb-Sr data published elsewhere these new data (1) date the age of suturing along the Northern Suture, which separates Kohistan from Asia, at 102-85 Ma; (2) establish that the basic magmatism in Kohistan, which postdates collision along the Northern Suture, predates 60 Ma, and that the later granite magmatism spanned a range of 60-25 Ma; (3) show that uplift amounts within Kohistan are greater toward the Nanga Parbat syntaxis than away from it and that rate of uplift near the syntaxis increased over the last 20 Ma to a current figure of about 5.5 mm a year; (4) show that much of southern Kohistan had cooled to below 500°C by 80 Ma and that the major deformation which imbricated Kohistan probably predated 80 Ma and certainly predated 60 Ma and was related to the Kohistan-Asia collision rather than the Kohistan-India one; (5) imply that uplift along the Hunza Shear in the Asian plate together with imbrication of the metamorphics in its hanging wall took place at about 10 Ma and was associated with breakback thrusting in the hanging wall of the Main Mantle Thrust; (6) suggest that the Indian plate has a lengthy pre-Himalayan history with an early metamorphism at about 1900 Ma, major magmatism at 500-550 Ma and early Jurassic lithospheric extension or inversion; and (7) show that the Indian plate rocks were metamorphosed shortly after the collision within Kohistan, which occurred at circa 50 Ma, and subsequently cooled back through 500°C at circa 38 Ma and 300°C at 30-35 Ma with ages of cooling through 200°C and 100°C (as determined by fission track data) locally controlled by Nanga Parbat related uplift tectonics.

T/183. Treloar, P.J., Rex, D.C., Guise, P.G., Wheeler, J., Hurford, A.J. & Carter, A., 2000. Geochronological constraints on the evolution of the Nanga Parbat syntaxis, Pakistan Himalaya. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds) *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 137-162.

New amphibole, muscovite and biotite Ar-Ar and K-Ar data and zircon and apatite fission track data are presented from the western margin of the Nanga Parbat syntaxis as well as from the Indus and Astor valley section which cross the syntaxis. Amphibole data date a regional cooling through 500°C at 25±5 Ma and are inconsistent with earlier suggestions that the peak of regional metamorphism was Neogene in age, although there is no doubt that some rocks were still at upper amphibolite facies temperatures as recently as 5 Ma. The data can be used to constrain structural models for syntaxis uplift. After an initial phase of crustal-scale buckling, bodily uplift of the syntaxis was along subvertical shear zones developed along its margins, although with a significantly higher time-averaged strain rate for shears developed along the western margin than along the eastern margin. The latter may be antithetic to the former. These shears were operative from 10 to <1 Ma. In the southwestern part of the syntaxis, this subvertical uplift was superseded, since 6 Ma, by uplift along moderately SE-dipping NW-vergent shears on the hanging wall of which are located Neogene-aged migmatites.

T/184. Treloar, P.J., Rex, D.C. & Hurford, A.J., 1992. Geochronology of the Indus Gorge Section through the Nanga Parbat Syntaxis: Constraints on uplift history Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 92.

The Indus Gorge provides a constant altitude east-west section across the north-trending Nanga Parbat syntaxis. The syntaxis is a structural half window, within the core of which Indian Plate gneisses are updomed from beneath a cover of overthrust volcanics of the Kohistan-Ladakh island arc complex. This section provides an opportunity for detailed, structurally constrained, sampling for both P-T-t path analysis and geochronology. Here we present data

from this traverse that enable us to constrain the uplift history of the syntaxis. 70 samples were collected for analysis by hornblende and mica Ar-Ar and K-Ar techniques, and by zircon and apatite fission track techniques. When those data of Zeitler (1985) and Zeitler and Chamberlain (1989) are included we have a copious, closely spaced data set.

A marked break in cooling ages occurs across the western margin of the syntaxis. This margin is marked by the Raikot-Sassi Fault Zone, a complex fault system with an overall oblique sense of displacement that includes both right lateral and thrust type displacements. The data imply that significant displacements have occurred along this zone within the last 1 to 2 Ma.

The eastern margin is marked by neither a significant fault zone nor a marked step in cooling ages. Instead cooling ages gradually decrease westward across the margin into the syntaxis, a decrease explained by exhumation during the growth of a large scale antiformal fold located within the syntaxis. Hornblende and mica ages are both younger within the western half of the syntaxis than in the eastern half. This is consistent with the recognition of a series of domal structures within the syntaxis not all of which grew synchronously. Within the Indus Gorge section, the data are consistent with the growth of an antiform within the eastern part of the section before 5 Ma ago, and the subsequent growth of a similar structure, at Ca. 3 Ma ago, in the western part of the section.

Neither zircon nor apatite ages show this age difference from east to west, indicating that folding may have become of secondary importance to uplift controlled by faulting along the eastern margin after about 2 Ma ago. Although a combination of early folding followed by later oblique slip thrusting along the western margin may explain the uplift and cooling history of the Indus Gorge section, it may be unwise to extrapolate this model without qualification to the rest of the syntaxis. The internal structure of the Syntaxis is best modeled as a series of nested domes. More detailed geochronology is required to demonstrate the extent to which these developed diachronously as well as their temporal relationships to thrusting along the western margin.

Total exhumation and overall uplift rates are difficult to quantify given the vertical telescoping of isotherms due to rapid uplift and unroofing, and the emplacements as recently as 2 Ma ago, of leucogranite dykes and bodies to high structural levels. However, due to the constant altitude of the Indus Gorge section, the antecedent nature of the river and the magnitude of the unroofing indicated by the cooling history data, we feel confident that exhumation amounts approximately equal bulk uplift amounts. As such, it is hard to escape the conclusion that fold amplification was exponential, or that recent uplift rates have been as high as 6mmyr⁻¹, as suggested by Zeitler (1985).

In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds) Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya. Geological Society, London, Special Publication 170, 1-6.

Often described as a natural laboratory, the Himalaya are probably the ideal place in which to study ongoing continent-continent collision. This volume focuses on the geology of the northwestern part of the Himalaya which provides the most complete and best-exposed transect across the range. Here, in northern Pakistan and in Ladakh in northwest India, the full profile across the south Asian continental margin, and the north Indian margin is superbly exposed in mountains reaching as high as K2 (8611 m) and Nanga Parbat (8125 m). The south Asian geology is exemplified in the Karakoram and Hindu Kush ranges along the north and northwestern frontiers of Pakistan. The

unique Kohistan-Dras island-arc terrane is sandwiched within the Tethyan suture zone between India and Asia. Rocks of the northern margin of the Indian Plate are exposed in both the Zaskar and the Pakistan Himalaya. The northern sedimentary carbonate platform of the Indian Plate, magnificently exposed in the mountains of Zaskar and Ladakh, is largely missing in Pakistan where the Kohistan arc has been obducted southward onto the metamorphosed rocks of the internal crystalline zones of the Indian Plate. The Nanga Parbat syntaxis represents an orogenic bend developed within a convergent zone in the thrust belt where the south-vergent thrusts of the central and eastern Himalaya swing around through 300 degrees.

The history of geological research in the Himalaya extends back to some of the earliest explorers and climbers who visited the region. Two significant problems have affected mapping of the topography and geology of the Himalaya. The first of these is the sheer logistical problem of attaining access to extremely rugged terrain. The second is a political problem. In the NW Himalaya, access to rocks along the disputed border between India and Pakistan is largely forbidden to foreigners. Similarly, easy access northward across the Chinese-Pakistan border has only been possible since the opening of the Khunjerab Pass in 1986. It is arguable that prior to the Russian invasion of Afghanistan in 1980, the geologically best known of the Himalayan nations was Afghanistan, largely through the detailed mapping of Wittekindt & Weipper (1973) and Wolfart & Wittekindt (1980). Since then, advances in understanding of the geology of Afghanistan have been limited to re-interpretations based on satellite imagery or increases in knowledge of the geology of surrounding states such as Pakistan. As a result of these problems, many regions of the Himalayan chain remain poorly mapped or completely unmapped. Containing many new maps, this volume goes part of the way towards addressing this shortfall.

Despite the problems of access, the Himalaya and adjoining mountain ranges continue to be a magnet to earth scientists. The geology of northern Pakistan was largely unknown until about 20 years ago. Until then much of what was known of the region was due to the work of the Geological Survey of India, especially Hayden (1915) and Wadia (1931, 1932). Some aspects of the geology were summarized in volumes that dealt with the geology of the whole of prepartitioning India (e.g. Wadia 1919). Some geology was carried out by geologists attached to major expeditions to the Karakoram (e.g. Desio 1930; Auden 1938). However, really detailed regional scale work truly commenced only in the 1970s during which R. A. K. Tahirkelli from the University of Peshawar carried out much pioneering work in the northern part of the Indian Plate, the Hindu Kush and Karakoram mountains of the southern part of the Asian Plate and what is now recognized as the Kohistan arc. This work was summarised in 1982 in a superbly illustrated Geological Bulletin of the University of Peshawar (Tahirkelli 1982) as well as in Tahirkelli et al. (1979). A then useful summary of the broader effects of the Himalayan orogeny was given in Farah & De Jong (1979). In 1980 the Karakoram Highway (KKH), that stretches from Islamabad in Pakistan through to Kashgar in China, was opened and this stimulated an extraordinary influx of geoscientists into the region. The KKH straddles not just the northern margin of the Indian Plate and the southern margin of the Asian Plate, but also the Cretaceous Kohistan island arc sandwiched between the two. An early synthesis of the geology along the Pakistani section of the KKH was given in the proceedings of an international expedition that traversed the KKH immediately on its completion (Miller 1982). A recent literature audit showed that between 1980 and 1997, over 200 papers had been authored or coauthored on the region traversed by the KKH by British, French and German geoscientists alone. A complete reference list up to 1996 and synthesis of the geology of N. Pakistan is given in Kazmi & Jan (1997). This volume builds upon this recent explosion of geological knowledge.

The essential geological framework of the Pakistan Himalaya is summarized briefly below. The Kohistan-Dras island arc was initiated offshore of Asia during the late Jurassic or early Cretaceous. The arc sutured to the southern margin of the Asian Plate at between 102 Ma, the age of emplacement of the pre-suturing Matum Das pluton (Pettersen & Windley 1985) and 85 Ma. The later age is derived from an c. 84 Ma U-Pb zircon age (Zeitler et al. 1981) for undeformed gabbro-norites of the Chilas complex, which contain xenoliths of Gilgit Formation gneisses that had been deformed during suturing. The age is compatible with a Rb-Sr age of 87 $\pm$ 19 Ma (Mikoshiba et al. 1999) assuming that their sample 92CH60 is included in the regression. After suturing the arc behaved as an Andean-style volcanic arc. Thickening of the arc accompanied suturing. Most of the deformation and metamorphism in the arc appears to have post-dated suturing, but predated collision with India. Deformation and metamorphism within the southern margin of the Asian plate appears to have been diachronous with tectonothermal events during the late Cretaceous (after suturing with Kohistan) and the Tertiary. A full review of the Cretaceous through to Tertiary history of the Asian Plate in Pakistan is given in Searle et al. (1999) and of the Kohistan arc in Treloar et al. (1996) and Searle et al. (1999). Collision between the arc and continental India followed closure of neo-Tethys. The age of collision is not precisely determined, although on the basis of the sedimentary record is likely to have been at about 55 Ma (see discussions in Garzanti et al. 1996, Pivnik & Wells 1996, Rowley 1996 and Treloar 1997). A late Cretaceous to Paleocene ophiolite emplacement event predated final closure of Neotethys (Searle 1986; Beck et al. 1995; Searle et al. 1997). Since collision the leading edge of the Indian Plate has undergone deformation, burial,

metamorphism and exhumation. In contrast to the main Himalayan chain to the east, peak metamorphism in the Pakistan Himalaya was Eocene in age (Treloar & Rex 1990). Exhumation during the early Miocene was by a combination of north-vergent extension (Burg et al. 1996; Vince & Treloar 1996) and erosion with sediments deposited in the foreland basins to the south of the topographic high (Burbank et al. 1996). Deformation of these sedimentary basins continues to the present day.

The northwest Himalaya differ from the main Himalayan chain for three main reasons. Here the Asian and Indian plates are separated by the Kohistan-Dras island arc, peak metamorphism was Eocene rather than Miocene in age, and the south-vergent thrust systems are deformed by the West Himalayan syntaxes. First recognized by Wadia (1931, 1932), the syntaxes are crustal scale, north-trending antiformal structures which are essentially half windows. The Hazara syntaxis to the south deforms thrusts of the external zones. Within its core, foreland basin sediments on the footwall of the Main Boundary Thrust have been tectonically uplifted (Bossart et al. 1988). The Nanga Parbat syntaxis deforms thrusts of the internal zones. Within its core, crystalline rocks of the Indian plate have been tectonically exhumed from beneath their cover of volcanic rocks of the Kohistan-Ladakh arc sequence that had been thrust onto the Indian Plate early in collision. Present day uplift rates within the Nanga Parbat syntaxis may be as high as 6 mm a⁻¹ (Zeitler 1985). Mechanisms of uplift and its deformational effects, timing of uplift, and the magmatic effects of rapid uplift and exhumation have been the focus of exhaustive research within the Nanga Parbat syntaxis during the last ten years. A number of British scientists funded by the Natural Environmental Research Council and the Royal Society have been working in the syntaxis. At the same time, a team from the USA under the leadership of P. K. Zeitler has been working in the area with funding from the National Science Foundation. Papers from both of these groups are included in this volume.

In setting the regional scene for the volume, Caporali describes the gravity field of the Karakoram Mountain Range and surrounding areas. He demonstrates the gravimetric low associated with the Nanga Parbat syntaxis which is a function of the rapid differential uplift within the syntaxis as well as the presence of large negative anomalies between the Karakoram Fault and the Main Karakoram Thrust. The relationship between crustal scale geological features (sutures, thrusts and syntaxes) and gravitational potential is clear when plotted on a regional scale geology map (Caporali, fig. 3).

The next seven papers deal with the Nanga Parbat syntaxis. In the first of these, Treloar et al. outline the significance of field relationships in defining long term geological histories. Mafic sheets within Indian plate gneisses within the Nanga Parbat syntaxis clearly document a polyphase deformation and metamorphic history. In stressing the importance of recognising complex histories, the authors recall the seminal work of John Sutton and Janet Watson in the Lewisian Complex.

The next papers relate to the structural and topographic evolution of the syntaxis. Butler revisits his earlier studies (Butler & Prior 1989a, b; Butler et al. 1989) on the western margin of the syntaxis to refine, in the light of recent field-work, an interpretation of the structures that accommodated bodily uplift of the syntaxis along west-vergent thrust faults. Edwards et al. describe structures exposed along the south-west of the syntaxis (i.e. to the south of those described by Butler). Uplift here was along steep, east-side up shear zones. Whereas Butler and Edwards et al. describe structures that accommodated uplift along the western margin of the syntaxis, Argles describes the structural evolution of part of the eastern margin of the syntaxis. Butler et al. describe a structural section that crosses the syntaxis and incorporate data presented here and elsewhere to derive a model for the structural evolution of the syntaxis as a whole. This model should be viewed in connection with that published by Schneider et al. (1999). As geochronological data were first used to hint at the speed of syntaxial growth (Zeitler 1985), it is appropriate that a more profound data set should be used in an attempt to constrain uplift mechanisms. To this end, Treloar et al. use geochronological data to outline firstly, that peak metamorphism within the syntaxis is Eocene-Oligocene, rather than Miocene, in age, and also to indicate how geochronological data can be used to refine the regional scale features that accommodated uplift within the syntaxis. This set of five papers provide a benchmark on which future structural studies of the syntaxis can be built. The Nanga Parbat massif encompasses greater than 6000m of relief. This relief is a function of the rapid Neogene uplift and results in rapid erosional unroofing of the crystalline basement complex. Shroder & Bishop explore aspects of this unroofing and demonstrate that late Pleistocene processes were sufficiently rigorous to produce the present-day pronounced relief. Whereas elsewhere in the Himalaya, extensional unroofing has played an important part in exhumation, at Nanga Parbat, where exhumation is most rapid, it appears not to have done so, a point also made by Edwards et al., Bishop & Shroder argue that accelerated uplift and erosion are part of a feed-back loop with tectonic uplift. They also use remotely sensed imagery to derive a hierarchical order of topographic complexity that is a function of erosion dynamics. The use of remote sensing is probably the prime way in which the topography of the Himalaya will be mapped in future. Large crustal-scale structures like the Nanga Parbat syntaxis should encourage debate. Two papers here do just that. In a far-reaching paper Burg & Podladchikov model the evolution of the Himalayan syntaxes numerically, (the

Nanga Parbat syntaxis and the Namche Barwhe syntaxis at the eastern end of the Himalayan chain). Their numerical modelling indicates that pure shear thickening and symmetric buckling accommodate shortening until, at a certain strain, an asymmetric thrust-like flow pattern occurs on a crustal to lithospheric scale and it is on this that the syntaxes grow. A side-effect of the model is that syntaxial growth is accompanied by the growth of marginal basins, in the case of the Nanga Parbat syntaxis these are the Kashmir and Peshawar basins. That these basins may be the result of syntaxial uplift is in contradiction to previous models which infer them to be piggyback basins developed above late-stage thrusts such as the Main Boundary Thrust. Whittington et al. use isotopic data to demonstrate that the crystalline Indian Plate rocks contained within the core of the Nanga Parbat syntaxis are typical of the Lesser Himalaya rather than of the Higher Himalaya. The implications of this are profound as they stress the differences between the Pakistan Himalaya and the Indian and Nepalese Himalaya, and indicate that models that suggest that the syntaxis is developed above the lateral tip of the Main Central Thrust may be incorrect.

The remaining papers in this volume provide a cross section across the Himalayan collision zone from the Asian plate through the Kohistan arc to the Indian plate. It has long been known that, prior to collision, the southern margin of the Asian plate was a tectonic collage formed of a series of exotic blocks sequentially accreted to the southern margin of continental Asia. The Kohistan-Dras arc was the last of these blocks to be accreted to Asia. Zanchi et al. describe one of the suture zones that encompassed the southward growth of Asia during the late Mesozoic and show how the Tirich Mir Fault Zone can be described as a suture on the basis of the presence of ophiolitic peridotites. Also on the Asian Plate, Hildebrand et al. describe the geological evolution of the Hindu Kush in the NW Frontier of Pakistan. They document a major late Mesozoic deformation probably related to suturing of Kohistan to Asia as well as an Oligocene-Miocene metamorphism-deformation event that was likely related to indentation of Kohistan into Asia following collision of Kohistan and India. This paper comes together with an important new geological map of a large part of the Hindu Kush.

Three papers deal with aspects of the Kohistan arc sequence. Yamamoto & Nakamura and Anczkiewicz & Vance date peak metamorphism within the Kamila amphibolite belt at the structural base of the arc at c. 95 Ma with amphibolite facies retrogression at c. 85 Ma (see Treloar et al. 1989). Arbaret et al. describe a variety of SW-vergent structures within the Kamila amphibolite belt that range from magmatic through sub-magmatic to amphibolite facies. This deformation spans the period documented geochronologically by Yamamoto & Nakamura and Anczkiewicz & Vance. What remains unclear is to what these deformation, magmatic and metamorphic events relate. Arbaret et al. interpret the magmatism and deformation as having occurred at the base of the arc during ongoing subduction of the Tethyan oceanic lithosphere beneath Kohistan. An alternative solution is that the deformation documents a change in subduction dynamics following on from suturing of Kohistan to Asia.

Three papers deal with the sutures that bound the arc. Weinburg et al. describe the suture zone between Asia and the Ladakh part of the Kohistan-Ladakh arc sequence and show that closure must have pre-dated 68 ± 1 Ma. Robertson and DiPietro et al. discuss the evolution of the suture between the Mesozoic arc and the Indian Plate. Robertson finds the Indus Suture Zone in Ladakh to be a zone of complex multi-stage processes involving deformational features which span the time interval from subduction through emplacement to post-collisional shortening. DiPietro et al. provide a detailed account of the Main Mantle Thrust (MMT) which separates the Kohistan arc from the Indian Plate and which is the true western continuation of the Indus-Tsangpo Suture Zone. They highlight the fact that the MMT is constituted of a number of strands of various ages. Although clearly a major early Tertiary tectonic feature, the MMT has been transposed many times during the Tertiary. Three papers detail the geology of the internal zones of the Indian Plate. Corfield & Searle describe the geology of the north Indian continental margin in Zaskar. They include an important new map and estimate shortening amounts across the north Indian margin. These estimates incorporate both late Cretaceous to Palaeocene ophiolite emplacement events and subsequent post-collisional shortening. Lombardo et al. describe the occurrence of glaucophane and barrosite-bearing eclogites from the Upper Kaghan Valley. Fontan et al. also describe high-pressure rocks from Indian plate sequences in the Neelum Valley. Although eclogites have previously been described from Indian Plate sequences of north Pakistan (Pognante & Spencer 1991), it is only recently that the high pressure nature of these rocks has been recognized (O'Brien et al. 1999). The full significance of these rocks is as yet unclear. Abassi & Friend explore the significance of exotic conglomerates in the Neogene Siwalik succession and relate them in part to growth of the Nanga Parbat syntaxis. They show the Pliocene-aged Janak conglomerate to be derived from a topographic high, with erosion shedding into the Neogene foreland basin. Finally, Badshah et al. provide a detailed map of part of the Pakistan-Afghanistan border. This important map forms a link between those of Jones (1960), Wittekindt & Weippert (1973) and Bender & Raza (1995) and with these documents an important part of the collision zone between the Indian Plate and the Afghanistan Block (see Treloar & Izatt 1993).

Key words: Tectonics, Nanga Parbat syntaxis, Himalaya.

T/188. Treloar, P.J., Wheeler, J. & Potts, G.J., 1993. Metamorphism and melting within the Nanga Parbat syntaxis (Pakistan) Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 54.

Metamorphism within the Indian Plate gneisses within the Nanga Parbat syntaxis reached kyanite-bearing granulite facies in which the assemblage quartz-plagioclase-orthoclase-garnet-biotite-kyanite (or sillimanite) -rutile was stable. Calculated peak metamorphic conditions were at about 10 kbar and 800°C achieved after a period of prograde metamorphism along a P-T path with positive slope. A leucogranite melt is intimately associated with the main fabric, within the plane of which is contained a south trending lineation. This melt is considered to be an in situ anatexitic melt derived by vapour absent melting during the main phase of south verging thrusting. Melt reaction topologies imply that such melting should be decompressive in nature and this may imply that late stages of the peak metamorphism were consistent with some unroofing of the metamorphic pile. Similar trends of regional metamorphism during pressure increase with some decompression at the metamorphic peak have been documented elsewhere in the Pakistan Himalaya.

That all these fabrics are folded by the large scale folds that dominate the Nanga Parbat syntaxis, and which date from syntaxial growth, as well as being cut by large garnet-tourmaline bearing leucogranite sheets poses a problem. Do these anatexitic melts date from a peak metamorphic phase that substantially predates syntaxial evolution or do they document early stages in that evolution? The lineation data within the layered anatexites is critical here, as it indicates that the fine scale anatexitic layering dates from a different tectonic environment from that of the syntaxial growth, that of southward thrusting rather than east-west shortening. Thus we infer the presence of two melt phases within the syntaxis. The first, under granulite facies conditions, dates from the main phase Himalayan metamorphic-deformation event which, elsewhere in Pakistan, reached its peak during the Eocene although reasons of structural geometry indicate that this could have been somewhat delayed within the Nanga Parbat region. The second is Neogene in age and is related to decompressive vapour-absent melting during active uplift and unroofing of the syntaxis.

T/189. Treloar, P.J., Wheeler, J. & Potts, G.J., 1994. Metamorphism and melting within the Nanga Parbat syntaxis, Pakistan Himalaya. *Mineralogical Magazine* 58A, 910-911.

The Nanga Parbat syntaxis, in the northwest Himalaya, is a region of increasingly rapid neotectonic uplift. Synchronous with uplift has been the emplacement into the syntaxis, within the last 10 Ma, of leucogranite sheets and bodies enriched in radiogenic Sr, the generation of which has been linked to processes of decompressive, vapour-absent melting of a continental crustal source (George et al., 1993; Zeitler et al., 1993; Smith et al., 1992). Recently published age data on monazites (Smith et al., 1992), zircons (Zeitler et al. 1993) and amphiboles (Treloar et al., in prep) demonstrate that parts of the syntaxis experienced high (> 500~ temperatures during the Neogene, interpreted by Smith et al. (1992) as a regional scale high grade metamorphism associated with granite generation and emplacement. If this argument follows, there is a causal link between Neogene high temperature metamorphism, melting and, granite emplacement during regional uplift and metamorphism. Here, we question some of the assumptions implicit in this model, in particular in relation to the timing of high grade metamorphism and melting. In the northwest Himalaya, collision was between the Kohistan island arc and the Indian Plate, Kohistan being thrust southward onto the leading edge of the Indian Plate. The Nanga Parbat syntaxis is a north trending structural half window, within the core of which Indian Plate gneisses have been uplifted from beneath the structurally overlying arc rocks. The tectonics responsible for this uplift have been outlined by Treloar et al. (1991). The Indian Plate rocks exposed within the core of the syntaxis include early Proterozoic biotite-rich quartzo-feldspathic basement gneisses, and late Proterozoic cover sediments intruded by Cambrian granites. Both sequences carry intense S-, L- and S-L-tectonite fabrics, are intruded by basic sheets and Neogene Himalayan leucogranites, and are characterised by variable, often extensive, migmatisation.

T/190. Treloar, P.J., Wheeler, J. & Potts, G.J., 1995. Polycyclic Deformation, Metamorphism and Melting within the Nanga Parbat Syntaxis, Pakistan Himalaya: From whence comes the

Neogene Leucogranites. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

Ever since Sutton & Watson (1951) demonstrated that the early history of the Lewisian basement complex of NW Scotland was divisible into two distinct tectonothermal events separated by a phase of dyke emplacement, geologists studying basement terrains have been conscious of the need to distinguish between different cycles of deformation in crustal sections which may have passed through more than one orogenic event. In a region such as the Himalaya, where it is tempting to ascribe all deformational and metamorphic features to Tertiary-aged orogenesis, the problems of polycyclic crustal evolution are acute. That not all granites within the Himalayan chain are Tertiary in age, has been demonstrated by the recognition, all along the length of the Himalayan chain, of Cambrian aged granites, some of which have been deformed during the Tertiary. In addition, a crustal evolution event at ca. 1850 Ma, which included the formation of a penetrative fabric and concluded with the emplacement of granites which crosscut that fabric, has been documented from within the most internal zones of the Indian Plate (Zeitler et al 1989; Treloar et al (1989). These basement gneisses were subsequently deformed within the Himalayan orogen.

In the NW Himalaya, collision was between the Kohistan island arc and the Indian Plate, with Kohistan thrust south onto the leading edge of the Indian Plate. The Nanga Parbat syntaxis is a N-trending structural half window, within the core of which Indian Plate gneisses have been uplifted from beneath the overlying arc rocks. The extreme youth of this increasingly rapid neotectonic uplift, which has been accommodated by a combination of NW- to W-vergent thrusting along the western margin of the syntaxis and large wavelength buckle folding within the core of the syntaxis (Butler et al 1988 1992; Madin et al 1989; Treloar et al 1991), is clearly demonstrated by extremely young mica Ar-Ar and zircon and apatite fission track ages within the core of the syntaxis (muscovite 3 Ma, zircon 2 Ma, apatite 0.4 Ma) which are significantly younger than those preserved in the rocks which flank it (e.g. some 10 km to the west of the syntaxis: muscovite 19 Ma, zircon 10 Ma and apatite 6 Ma) (Zeitler 1985; Treloar et al 1989, 1991; George et al 1993; Zeitler et al 1993).

Synchronous with uplift has been the emplacement into the syntaxis, within the last 10 Ma, of leucogranite sheets and bodies enriched in radiogenic Sr. the generation of which has been linked to decompressive, vapour-absent melting of a continental crustal source (George et al 1993; Zeitler et al 1993; Smith et al 1992). The youngest of these sheets are about 2 Ma old (Zeitler & Chamberlain 1991). Pb-Pb age data on monazites (Smith et al 1992) and zircons (Zeitler et al 1993) and Ar-Ar data on amphiboles (Treloar et al, in prep) demonstrate that parts of the syntaxis were at high (>500°C) temperatures until about 10 Ma ago. The monazite data have been interpreted as implying that the rocks exposed within the syntaxis experienced a Neogene, high grade regional metamorphism which was associated with granite generation and emplacement. If this argument follows, there is a causal link between Neogene high temperature metamorphism, melting and, granite emplacement during regional uplift and metamorphism. However, that the main metamorphic fabrics in the Indus and Astor Gorges are cut by dykes of probable pre-Tertiary age leads us to infer that models which attempt to constrain the timing of high grade metamorphism and melting within the syntaxis without considering the polycyclic nature of these rocks are oversimplifications.

Pre-Neogene deformation and metamorphism.

The pre-Tertiary metamorphic history of the Indian Plate rocks exposed within the core of the syntaxis has been described elsewhere (Wheeler et al., submitted; Treloar et al 1994). The Indian Plate rocks include early Proterozoic biotite-rich quartz-feldspathic basement gneisses (true Isclere gneisses), an a late Proterozoic cover sediments (the Shengus gneisses) intruded by Cambrian granites. Both sequences have been affected by pre-Tertiary deformation, metamorphic and magmatic events, are intruded by basic sheets and Neogene Himalayan leucogranites, and are characterised by variable, and often extensive, migmatisation. Within the Shengus para-gneisses, the main metamorphic paragenesis is quartz-plagioclase-orthoclase-garnet-biotite-kyanite and/or sillimanite-rutile. Over much of their outcrop the Shengus paragneisses are migmatitic, with a stromatic leucogranite melt segregated from the restitic pelite fabric. Field relations imply this to be an in situ anatexitic melt. The presence of kyanite and garnet in equilibrium with the melt is consistent with vapour-absent melting, initially of muscovite and latterly of biotite. The common absence of muscovite implies that muscovite was completely destroyed during melting. The presence of kyanite rather than sillimanite in equilibrium with the melt is consistent with high pressures and temperatures of melting. Petrogenetic grids constrain peak metamorphic conditions to about 10 Kb and 800°C.

That this high grade metamorphism is pre-Tertiary is demonstrated by field relationships. A series of basic dykes clearly cross-cut the layered rocks of the migmatite complex and contain xenoliths of migmatitic material. In places these sheets contain undeformed relicts of an ophitic plagioclase-clinopyroxene assemblage, with the pyroxenes rimmed by a corona-like development of fine-grained hornblende. Elsewhere, the sheets have been almost

completely amphibolitized with a metamorphic assemblage of hbde-bt-qtz-pl-(grt). Thus, the sheets have undergone a post-emplacement amphibolite facies metamorphism. On the basis of their mineralogy they have not experienced the granulite facies metamorphism recorded within the migmatitic rocks. Hornblende Ar-Ar cooling ages of ca. 20 Ma (Treloar et al. in prep) document a Tertiary age for the latest cooling.

Due to post-metamorphic deformation, the peak metamorphic assemblage is rarely preserved in an undeformed state. The migmatites show evidence for ductile shearing with the development of an intense mylonitic fabric that post-dates the peak metamorphism. In outcrop, this fabric appears as a series of intense S-, L- and S-L-tectonite fabrics, within which lineations plunge gently to either N or S, consistent with a southerly transport direction of Kohistan onto India. Although the basic dykes are commonly discordant to the S-tectonite fabrics, they locally carry an internal L-S tectonite fabric sub-parallel to that of the migmatite complex. In some of the sheets this fabric is penetratively developed throughout the sheet; in others it is limited to the margins. Thus although they postdate the main phase metamorphism and migmatization, the dykes predate the ductile shearing which pervasively deforms the metamorphic complex. We argue that this S-L fabric is Himalayan in age. The ductile shearing is itself postdated by a later thermal event, as indicated by the presence of sillimanite bundles which overprint the main tectonic fabric. Although the main metamorphism was pre-Tertiary, that sillimanite bundles overprint the main tectonite fabrics demonstrate a Tertiary-aged regional re-metamorphism during the Himalayan orogeny, after which the migmatite complex cooled back through 5000C at between 20Ma and 10 Ma (Smith et al 1992; Treloar et al, in prep).

The planar fabrics have been folded and define a series of N-trending domal structures (Madin et al 1989; Treloar et al 1991; Butler et al 1992). The simplest interpretation of the structures is that the L-S fabrics represent ductile simple shear deformation during the S-vergent thrusting of Kohistan onto the leading edge of the Indian Plate during early stages of the Himalayan collision, with folding of the S-surfaces dating from the large scale buckling that accompanied syntaxis growth (Treloar et al 1991), fold axes being sub-parallel to the earlier stretching lineation. That the fabrics which deform, and thus post-date, the formation of the migmatite complex also pre-date the initial stages of syntaxial uplift implies that the main phase migmatization cannot be the result of late-Himalayan Neogene-aged decompressive melting. All of these fabrics are cut by the garnet-tourmaline bearing leucogranite sheets dated by Zeitler et al (1993) as <10 Ma old.

Discussion.

The prime temptation when studying rocks within the internal zones of an orogenic belt is to ascribe the metamorphism to that orogenic event. Thus, it would appear logical to ascribe the high grade metamorphism and melting within the Nanga Parbat syntaxis, which is the most internal part of the Himalayan orogen exposed anywhere, to be of Tertiary age. The Pb-Pb data presented by Zeitler et al (1993) and Smith et al (1992) have been interpreted by them as suggesting a Neogene age for high grade metamorphism and melting. However, field relationships demonstrate that, although this may be true for the leucogranite sheets which cut the migmatite complex, it is not so for the migmatite complex itself.

It is clear that two melting events have affected the Nanga Parbat region. The first, under granulite facies conditions, pre-dates dyke emplacement and is, at latest, Triassic in age. The second, which is Neogene in age, is most likely related to melting during uplift and unroofing of the syntaxis. This second melt event presents a significant problem: what is the source for the leucogranite melts. Having melted once, and thus being infertile, the migmatite terrain cannot have been the source for the Himalayan leucogranite sheets which cut it, unless Tertiary metamorphism was at higher temperatures than the pre-Tertiary metamorphism, a suggestion excluded by the amphibolite-facies mineralogy of the basic sheets. Here we consider possible source regions for the Neogene-aged melts.

In the absence of extreme temperatures, the rocks currently exposed within the core of the syntaxis, and which had undergone a dehydrative pre-Tertiary melting event, can only have melted a second time if their fertility had been recharged. There are two possible mechanisms by which this may have been achieved. The first is related to the late stages of the main metamorphism and migmatization. The preservation of centimeter-scale leucosomes within the metapelites demonstrates that melt extraction was inefficient. Crystallization of the retained pockets and layers of melt caused some back reaction within the restites. Textural relationships within the Shengus gneisses are consistent with a back reaction such as: $grt + kfs + melt = bt + kya + qtz$.

Similarly, the growth of small muscovite flakes within feldspar and crosscutting biotite may indicate an analogous muscovite generating back reaction. Muscovite is though rarely present in large quantities within the Shengus gneisses. Within the Iskere gneisses, mica content varies. Some are biotite -rich with no muscovite, whereas others contain both biotite and muscovite. Assuming that these migmatitic gneisses have been to the same elevated temperatures as the Shengus gneisses, we infer that the fabric forming muscovite present is the result of a migmatitic back reaction of the type: $bt + als + kfs + melt = ms + pla + qtz$.

The muscovites then recrystallised during early Tertiary simple shear. If high enough temperatures were attained during the Neogene, then some melt could be produced by vapour-absent melting of muscovite produced through

melt related back reactions. However, few of the rocks within the Indus and Astor Gorges contain significant muscovite contents and this process does not appear capable of generating significant melt quantities.

A second mechanism of re-fertilizing the Nanga Parbat gneisses would be by rehydrating them through a process of focussed fluid flow. Some samples contain mats of muscovite, which overprint the peak metamorphic assemblages. These mats reflect the growth of muscovite during the influx of water at temperatures sufficient to destabilise the orthoclase-kyanite present in the peak metamorphic assemblage. It is worth noting that Neogene aged monazites dated by Smith et al (1992) are often contained within fabric parallel (?) muscovites. As the major tectonic fabrics are probably early Tertiary in age, it is difficult to see how they can contain Neogene-aged monazites. However, if the muscovite mats within which the monazites are contained reflect new mineral growth in zones of fluid flow channelised through the dry granulites of the Nanga Parbat massif, rather than a regional scale Neogene-aged prograde metamorphism, this dichotomy can be resolved.

That there are localised pockets of Neogene-aged metamorphism (Smith et al. 1992; Zeitler et al. 1993) is indisputable. Cordierite-bearing low pressure granulites, intruded by cordierite-bearing leucogranites dated by Neogene-aged monazites have been described from the Fairy Meadows area (Zeitler et al 1993; Smith et al 1992). These rocks are not readily explicable in terms of the structure of the whole massif. Similar rocks are not widespread across the syntaxis. They must represent either a suite of the low-pressure rocks imbricated within the main granulite suite, or a localised re-metamorphism of an older higher-pressure granulite terrain. If the latter is correct, the cordierite gneisses may represent a Neogene re-metamorphism associated with locally pervasive fluid flow on the hanging wall of the thrusts developed along the W margin of the syntaxis, along which the syntaxis has been uplifted.

What is the source of the channelised fluids? Due to the continuing northward movement of India, previously unmetamorphosed and thus wet Indian Plate sediments are currently being underthrust beneath the Nanga Parbat syntaxis. Metamorphism of these sediments through dehydration reactions will lead to fluid release and it is likely that at least some of this fluid will pass up through the overlying dry granulites of the Nanga Parbat syntaxis. Thus, at least some of the leucogranite generation may be due to hydration rather than decompression. If metamorphism of these underthrust Indian Plate shelf sediments was at sufficiently high temperatures, then they also provide an alternative source for the leucogranite melts which intrude the Nanga Parbat massif.

It is commonly assumed that leucogranite generation within the Nanga Parbat syntaxis is through decompressive melting. Treloar et al (1991) argued that the uplift recorded within the syntaxis could be explained solely in terms of the folding and thrusting mapped by them and others. This would be consistent with decompressive melting within the upper crustal layers. However, melting in the presence of channelised fluid flow derived from underthrust units does not need decompression. In addition, if the underthrust fertile sediments are the source of the Neogene leucogranite melts, and if these granites are truly decompressive, they provide a constraint on uplift mechanisms for the syntaxis. Thrusting and folding effectively thicken units observed at surface and thus would increase the pressure on the underthrust fertile sediments where melting is inferred to be taking place. If this melting is decompressive, and that needs still to be demonstrated, it follows that syntaxial uplift cannot be accommodated solely in terms of thin skinned thrusting and folding of the upper crust, but needs to be modelled in terms of deep crustal processes, such as delamination, with the upward velocity more than compensating for the extra loading on the melting zone caused by compressional tectonics across the syntaxial arc.

T/192. Treloar, P.J., Wheeler, J., Potts, G.J., Rex, D.C. & Hurford, A.J., 1993. Geochronology of the Indus Gorge and Astor valley sections through the Nanga Parbat syntaxis: Constraints on uplift history. Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 79-80.

The Indus Gorge provides a constant altitude east-west section across the north-trending Nanga Parbat syntaxis. The Astor Valley, to the south, provides a second section, this one NW-SE trending, through the syntaxis, although not a constant altitude one. The syntaxis is a structural half window, within the core of which Indian Plate gneisses are updomed from beneath a cover of overthrust volcanics of the Kohistan-Ladakh island arc complex. These sections

provide an opportunity for detailed, structurally constrained, sampling for both P-T-t path analysis and geochronology. Here we present data from these traverses that enable us to constrain the uplift history of the syntaxis. 120 samples were collected for analysis by hornblende and mica Ar-Ar and K-Ar techniques, and by zircon and apatite fission track techniques. When those data of Zeitler (1985), Zeitler and Chamberlain (1989), Smith et al (1992) and George et al (1993) are included we have a copious, closely spaced data set.

A marked break in cooling ages occurs across the western margin of the syntaxis. This margin is marked by the Raikot-Sassi Fault Zone, a complex fault system with an overall oblique sense of displacement that includes both right lateral and thrust type displacements. The data imply that significant displacements have occurred along this zone within the last 1 to 2 Ma.

The eastern margin is marked by neither a significant fault zone nor a marked step in cooling ages. Instead cooling ages gradually decrease westward across the margin into the syntaxis, a decrease explained by exhumation during the growth of a large scale antiformal fold located within the syntaxis.

Within the Indus Gorge section, hornblende and mica Ar-Ar ages are both younger within the western half of the syntaxis than in the eastern half. This is consistent with the recognition of a series of domal structures within the syntaxis not all of which grew synchronously. Within the Indus Gorge section, the data are consistent with the growth of an antiform within the eastern part of the section before 5 Ma ago, and the subsequent growth of a similar structure, at Ca. 3 Ma ago, in the western part of the section. Neither zircon nor apatite ages show this age difference from east to west, indicating that folding may have become of secondary importance to uplift controlled by faulting along the eastern margin after about 2 Ma ago. Locally hornblende and monazite ages indicate $T > 500^{\circ}\text{C}$ as recently as 9-10 Ma and in the case of muscovite Rb-Sr ages as recently as 5 Ma. Some of these very young ages may be due to localized thermal perturbations due to melt emplacement.

Within the Astor Valley section, a different cooling profile is recorded with mica ages increasing towards the west, a pattern shown less well by the fission track ages. The tectonic significance of this variation is, as yet, uncertain.

Although a combination of early folding followed by later oblique slip thrusting along the western margin may explain the uplift and cooling history of the Indus Gorge section, it may be unwise to extrapolate this model without qualification to the rest of the syntaxis, as shown by the data from the Astor Valley. The internal structure of the syntaxis is best modeled as a series of nested domes. Folds within the Indus Gorge plunge south, whereas those within the Astor Valley plunge north. More detailed geochronology is required to demonstrate the extent to which these developed diachronously as well as their temporal relationships to thrusting along the western margin.

Total exhumation and overall uplift rates are difficult to quantify given the vertical telescoping of isotherms due to rapid uplift and unroofing, and the emplacement, as recently as 2 Ma ago, of leucogranite dykes and bodies to high structural levels. However, due to the constant altitude of the Indus Gorge section, the antecedent nature of the river and the magnitude of the unroofing indicated by the cooling history data, we feel confident that exhumation amounts approximately equal bulk uplift amounts. As such, it is hard to escape the conclusion that fold amplification was exponential, or that recent uplift rates have been as high as 6mmyr^{-1} , as suggested by Zeitler (1985).

T/193. Treloar, P.J., Wheeler, J., Potts, G.J., Rex, D.C. & Hurford, A.J., 1995. Geochronology of the Indus Gorge and Astor Valley Sections through the Nanga Parbat Syntaxis: Constraints of Uplift History. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

The Indus Gorge provides a constant altitude east-west section across the north-trending Nanga Parbat syntaxis. The Astor Valley, to the south, provides a second section, this one NW-SE trending, through the syntaxis, although not a constant altitude one. The syntaxis is a structural half window, within the core of which Indian Plate gneisses are updomed from beneath a cover of overthrust volcanics of the Kohistan-Ladakh island arc complex. These sections provide an opportunity for detailed, structurally constrained, sampling for both P-T-t path analysis and geochronology. Here we present data from this traverse that enable us to constrain the uplift history of the syntaxis. 120 samples were collected for analysis by hornblende and mica Ar-Ar and K-Ar techniques, and by zircon and apatite fission track techniques. When those data of Zeitler (1985), Zeitler and Chamberlain (1989), Smith et al (1992) and George et al (1993) are included we have a copious, closely spaced data set.

A marked break in cooling ages occurs across the western margin of the syntaxis. This margin is marked by the Raikot-Sassi Fault Zone, a complex fault system with an overall oblique sense of displacement that includes both right lateral and thrust type displacements. The data imply that significant displacements have occurred along this zone within the last 1 to 2 Ma.

The eastern margin is marked by neither a significant fault zone nor a marked step in cooling ages. Instead cooling ages gradually decrease westward across the margin into the syntaxis, a decrease explained by exhumation during the growth of a large-scale antiformal fold located within the syntaxis.

Within the Indus Gorge section, hornblende and mica Ar-Ar ages are both younger within the western half of the syntaxis than in the eastern half. This is consistent with the recognition of a series of domal structures within the syntaxis not all of which grew synchronously. Within the Indus Gorge section, the data are consistent with the growth of an antiform within the eastern part of the section before 5 Ma ago, and the subsequent growth of a similar structure, at Ca. 3 Ma ago, in the western part of the section. Neither zircon nor apatite ages show this age difference from east to west, indicating that folding may have become of secondary importance to uplift controlled by faulting along the eastern margin after about 2 Ma ago. Locally hornblende and monazite ages indicate $T > 500^{\circ}\text{C}$ as recently as 9-10 Ma and in the case of muscovite Rb-Sr ages as recently as 5 Ma. Some of these very young ages may be due to localized thermal perturbations due to melt emplacement.

Within the Astor Valley section, a different cooling profile is recorded with mica ages increasing towards the west, a pattern shown less well by the fission track ages. The tectonic significance of this variation is, as yet, uncertain.

Although a combination of early folding followed by later oblique slip thrusting along the western margin may explain the uplift and cooling history of the Indus Gorge section, it may be unwise to extrapolate this model without qualification to the rest of the syntaxis, as shown by the data from the Astor Valley. The internal structure of the syntaxis is best modelled as- a series of nested domes. Folds within the Indus Gorge plunge south, whereas those within the Astor Valley plunge north. More detailed geochronology is required to demonstrate the extent to which these developed diachronously as well as their temporal relationships to thrusting along the western margin.

Total exhumation and overall uplift rates are difficult to quantify given the vertical telescoping of isotherms due to rapid uplift and unroofing, and the emplacement, as recently as 2 Ma ago, of leucogranite dykes and bodies

T/194. Treloar, P.J., Williams, M.P. & Coward, M.P., 1989. Metamorphism and crustal stacking in the north Indian Plate, north Pakistan. *Tectonophysics* 165, 167-184.

The northern part of the Indian Plate in North Pakistan is composed of a number of large-scale crustal nappes, each of which are stratigraphically distinct, and which were stacked late in the main phase of southeasterly directed thrusting associated with the Himalayan event. The major nappes recognised in the Swat to Kaghan area of North Pakistan are the Besham, Swat, Hazara, Banna, Lower Kaghan and Upper Kaghan nappes. Metamorphism was synchronous with early stages of deformation. Within each nappe the metamorphic grade increases upwards, an overall inversion that represents post-metamorphic imbrication within individual nappes, synchronous with the main phase of nappe stacking, rather than a "hot iron" type inversion as described under the MCT in Nepal and India. As a result of this "within-nappe" imbrication each thrust slice within any particular nappe contains rocks of a higher metamorphic grade than those in the slice below, with sharp metamorphic breaks across the imbricating thrusts as well as across the major shears that bound the crustal-scale nappes. Uplift along these imbricating thrusts initiated cooling of the stack. K-Ar mica and hornblende cooling ages imply that much of this uplift was completed by 30 Ma, or within 20 Ma of the collision.

U/2. Ukai, Y. & Kimura, Y., 1965. On the chemical composition of the granitic rocks collected from the Karakoram and Hindu Kush ranges. In: Matsushita, S & Huzita, K. (Eds), *Geology of the Karakoram and Hindukush. Results of the Kyoto University Scientific Expedition to the Karakoram and Hindukush, 1955*, Vol. VII, 121-130. Nippon Printing & Publishing Co., Ltd., Japan.

This is a preliminary, major element, geochemistry of seven granitic rocks from diverse bodies of granitoids. One sample each was collected near Kalam, Diwangar in upper Ushu valley of Swat, Shunji Gol in Ghizar, Urdukas in Baltoro, and upper Hispar, and two between the Indus-Gilgit confluence and Pari. Chemical analyses are accompanied by CIPW norms, Niggli values and cation numbers. Analyses are plotted on Harker diagram and An-Ab-Or triangle. It is "considered that most of these rocks were produced through the granitization of sedimentary rocks".

U/4. Ullah, H., 1983-85. Geotechnical studies of landslide along Murree-Kohala and Murree-Bhurban Road, District Rawalpindi. M.Sc. Thesis, Punjab University, Lahore, 108p.

The Murree Kohala road one of the most important road of the country which provides facilities of communication between Pakistan and Azad Kashrnir, crossing over the Jhelum river at Kohala. This road is also important for defence point of view. The slopes along the Murree Kohala road are very unstable, especially kassari to Phagwalai village. The condition of the Murree -Kohala road is satisfactory where a good driver can drive every type of vehicle at the speed of 40-50 km/hour, except for the landslide areas. At Murree Kohala road three major slides were selected for study namely Kasseni (K0, K1' K2' K3), Norgali (N1' N2) and Eliot (A1, A2). These are between lower topas to Eliot which are also marked on the map. The second road which join Kohala is starting from Jhikkagali via Burban which meet the Murree Kohala road near phagwani Village. There is also a slide near Kashmiri Bazar which is shown on the map. The project area is lying in the Murree Formation which is mainly composed of Shale, mudstone and sandstone. The detailed geological mapping of the active landslides area were carried out on, the map, sandstone, mudstone and shale with specific symbol on the map.

Key words: Geotechnical, landslides, Rawalpindi.

U/5. Ullah, Z., 1981-83. Geology and petrology of Darel valley (District Diamer) with special emphasis on the petrology of diorites and amphibolites of the area. M.Sc. Thesis, Punjab University, Lahore, 63p.

This thesis presents a geological map of the 30 sq .miles of project area (DAREL) on scale 1" = 1 mile. The project area (Darel) lies in Gilgit Agency, district Diamer. The area is located in the centre of Kohistan. Area is disturbed tectonically, being involved in Himalayan orogeny. The area is composed of igneous and metamorphic rocks. The main rock units in the area are Norite, Diorite, Amphibolites and Granodiorites. Mineralogical description and

petrographic analysis of these rock units are reported in detail. An attempt is made to interpret the petrogenesis of rock types. The Thesis presents a detailed geological and petrological investigation of the project area. Norite and amphibolites represent oceanic crust while Diorite and Granodiorite etc. represent plutonic equivalents of arc. To achieve this goal a period of 45 days was spent at the site during July, August 1984.

Key words: Petrology, diorites, amphibolites, Darel, Diamir, Kohistan.

U/6. Untersteiner, N., 1957a. Glazial-meteorologische untersuchungen im Karakorum. I: Strahlung. Archiv fur Meteorologie, Geophysik und Bioklimatologie, Series B(8), 1-30.

Records of radiation in the ablation area of Chogo Lungma Glacier (Karakorum) show that, in comparison with corresponding conditions in the European Alps, the radiation climate in the Karakorums during summer is characterized by high daily totals of global radiation. This is less due to stronger solar radiation but to a slower decrease of global radiation with increasing cloudiness ($\alpha=0.5$). A relation between the daily sums of global, solar, and sky radiation with cloud amount is given. The short wave radiation balance of firn and bare ice is evaluated from numerous measurements of the albedo. Long wave radiation from the atmosphere is computed from an assumed distribution of temperature and moisture in the free atmosphere by means of Elsasser's diagram, as well as from observed surface values with Ångström's formula, what leads to a good agreement. The outgoing radiation from the glacier's surface is computed according to its temperature. From these data the total radiation balance during the period of observations is derived. By far the greatest, and for its mass balance important, variations of the radiative energy exchange of the glacier is caused by variations of the reflectivity of its surface. Finally, the results of several radiation measurements at higher altitude are given. An estimate of the radiation balance at an altitude of 6.000 to 7.000 m shows that assuming an albedo of 0.75, melting of the snow in this climatic regime (no summer monsoon) seems only possible under rare conditions.

Key words: Glaciers, meteorology, radiation, Karakoram.

U/7. Untersteiner, N., 1957b. Glazial-meteorologische untersuchungen im Karakorum. II: Warmehaushalt. Archiv fur Meteorologie, Geophysik und Bioklimatologie, Series B(8), 137-171.

The present paper deals with further glacial-meteorological observations on Chogo Lungma Glacier carried out during the "Frankfurter Himalaya-Expedition 1955". These observations comprise: ablation, wind velocity at 20, 100, and 300 cm height, temperature and humidity at 20 and 100 cm height, surface temperature, temperature gradient between 20 and 100 cm, precipitation, evaporation, as well as the short and long wave radiative heat exchange at the surface as published in a previous paper. The first series of measurements (Station I, altitude about 4000 m) covers the melting of the remains of winter firn (51 cm) in the course of 6 days. The second series (Station II, altitude about 4300 m) covers the ablation of 120 cm of bare ice with an average albedo of 0,30. Both stations were situated below the firn line on the flat glacier tongue. The daily variation of ablation closely resembles that found in the Alps and indicates a very high percentage of radiative ablation. The glacier wind on Chogo Lungma is exceptionally weak which is probably due to its morphological features (Mustagh-Type). An explanation of the daily course of glacier wind is given by considering the temperature difference between air and ice.

The mean vertical distributions of wind velocity, temperature and humidity may well be represented by logarithmic laws. The vertical flux of perceptible and latent heat are calculated by means of the adiabatic "Austausch" coefficient. To account for stability according to Lettau's formula would necessitate the application of non-logarithmic laws for the temperature and humidity distribution in order to give a constant heat flux. However, the deviations in the lowermost decimetres are small. The mean daily heat economy at Stations I and II is given in Table 6. The correspondence between observed and computed ablation is satisfactory and justifies the methods applied. Radiation balance (long and short wave) contributes 88% over firn and 95% over bare ice to the total ablation. As is to be expected, convective heat supply is of the same order of magnitude as on other temperate glaciers. Ablation by evaporation is negligible. The part of evaporation in the glacial heat economy is discussed in connection with the problems of "nieve de los penitentes". It is shown that, under certain conditions, evaporation may achieve some importance in the thermal budget but that its importance in the mass budget (ablation by evaporation) in the ablation area of temperate glaciers will always be negligible compared to the ablation by melting, due to the great amount of heat required for evaporation. Based upon the small local differences of the heat budget of "sun-cupped" firn an explanation is given of the formation of nieve de los penitentes. The possibilities of simplified measurements of heat

economy, especially on expeditions, are discussed. Finally, the glacial heat budget in high, middle, and lower latitudes is compared, and the predominant importance for glacier shrinkage and advance of summer weather (changes of albedo by temporary snow covers, duration of sunshine) is stressed.

U/8. Uppal, I.H., 1972. Preliminary account of the Harichand ultramafic complex, Malakand Agency, NWFP, Pakistan. Geological Bulletin, University of Punjab 9, 55-63.

The Harichand ultramafic complex, in the Malakand Agency, covering about 45 square miles, has been mapped for the first time on a scale of 6 inches to 1 mile and is presented here on a reduced scale of 1 inch to 1 mile. The complex constituents large bodies of harzburgite with small conformable outcrops of dunite rock. The harzburgite-dunite bodies are partially surrounded by peridotite rock, which is serpentinized along its contact with the country rocks, consisting of low-grade schists. Two small bodies of metagabbroic rock are present in the metamorphic formation falling within the mapped area. Chromitite at places is associated with dunite, while orthopyroxenite dykes sporadically traverse the area. Preliminary account based on field observations and petrographic studies is given, while the results of details petrological and chemical work will be presented in a later communication.

Key words: Ultramafics, petrography, Harichand, Malakand.

U/9. Uppal, I.H., 1980. Origin of chromite deposits and associate dunite of the Harichand ultramafic complex, Malakand Agency. Contributions to the Geology of Pakistan 1, 113-120.

The Harichand ultramafic complex, also called the Dargai complex, is a large body of ultramafic rocks, peridotites and dunite. There are sizable bodies of chromite pods, lenses and layers. Those associated with the dunite are described in this paper.

The podiform deposits of chromite associated with the dunite bodies ominously exposed in the Hari Chand Complex have been subjected to investigation. Field observations, petrographic and chemical studies of selective specimens show that the chromite & dunite were formed prior to the crystallization of the host rocks in deep magma chamber to make basement layer of the crystal mush. These were later on mobilized and transported upward into the upper part of magma chamber when the main mass of the ultramafic complex solidified.

V/1. Valdiya, K.S., 1980. The two intracrustal boundary thrusts of the Himalaya. *Tectonophysics* 66, 323-348.

The series of four different, steeply inclined thrusts which sharply sever the youthful autochthonous Cenozoic sedimentary zone, including the Siwalik, from the mature old Lesser Himalayan subprovince is collectively known as the Main Boundary Thrust (MBT). In the proximity of this thrust in northwestern and eastern sectors, the parautochthonous Lesser Himalayan sedimentary formations are pushed up and their narrow frontal parts split into imbricate sheets with attendant repetition and inversion of lithostratigraphic units. The superficially steeper thrust plane seems to flatten out at depth. The MBT is tectonically and seismically very active at the present time.

The Main Central Thrust (MCT), inclined 30° to 45° northwards, constitutes the real boundary between the Lesser and Great Himalaya. Marking an abrupt change in the style and orientation of structures and in the grade of metamorphism from lower amphibolite facies of the Lesser Himalayan to higher metamorphic facies of the Great Himalayan, the redefined Main Central Thrust lies at a higher level as that originally recognized by A. Heim and A. Gansser. They had recognized this thrust as the contact of the mesozonal metamorphics against the underlying sedimentaries or epimetamorphics. It has now been redesignated as the Munsiri Thrust in Kumaun. It extends northwest in Himachal as the Jutogh Thrust and farther in Kashmir as the Panjal Thrust. In the eastern Himalaya the equivalents of the Munsiri Thrust are known as the Paro Thrust and the Bomdila Thrust. The upper thrust surface in Nepal is recognized as the Main Central Thrust by French and Japanese workers. The easterly extension of the MCT is known as the Khumbu Thrust in eastern Nepal, the Darjeeling Thrust in the Darjeeling-Sikkim region, the Thimpu Thrust in Bhutan and the Sela Thrust in western Arunachal. Significantly, hot springs occur in close proximity to this thrust in Kumaun, Nepal and Bhutan. There are reasons to believe that movement is taking place along the MCT, although seismically it is less active than the MBT.

V/3. Valdiya, K.S., 1984. Evolution of the Himalaya. *Tectonophysics* 105, 229-248.

The compression and attendant deformation of a thick and vast sedimentary prism formed since Early Riphean times on the northern continental margin of the Indian craton gave rise to the Himalaya mountains as a result of convergence and collision of the Indian and Asian plates. The oceanic trench-sediments, tectonically implanted with sea-floor material and intimately associated with calc-alkaline volcanics in the narrow Sindhu-Tsangpo belt extending from Kohistan through Dras, Leh, Darchen (Mansarovar) to Shigatse and beyond, represent the subduction-island arc complex which developed south of the dynamic southern margin of the Asian continent and was welded to the colliding Indian plate during the late Eocene to Oligocene period. This complex is fringed to the north by a wide zone of Andean-type granitic bodies. The evolution of the Himalayan orogen is closely connected with the development of the present-day Andaman-Nicobar-Indonesia island arc-subduction system in the southeast and the Makran Ranges-Oman Trench in the southwest.

The evolution of the Himalaya was accomplished in four major phases of tectonic upheaval during the late Cretaceous to Palaeocene (Karakoram phase), late Eocene to Oligocene (Malla Johar phase), middle Miocene to Pontian (Sirmurian phase), and late Pliocene to middle Pleistocene (Siwalik phase). While the Karakoram phase marks the convergence of continents and the Malla Johar phase represents the collision and subduction, it was during the Sirmurian upheaval that the main tectonic features developed and the Himalaya acquired its distinctive structural complexion.

V/11. Verchere, A.M., 1867. Geology of Kashmir, the Western Himalaya, and the Afghan Mountains, with a note on the fossil by M.E. Verneuil. Journal of the Asiatic Society Bengal 35, part 1: 89-133, 159-203; part 2: 9-50, 83-115, 201-229.

Shows that the so-called nummulites obtained in the Kashmir valley by Messrs. Vigne and Flemming were crinoid stems. The author considers that the tertiary 'Murree beds' are crushed against the older rocks of the Kajrag range and that the peaks of the latter are composed of porphyry (granite), probably of igneous origin. The lower part of the Kashmir limestone series is classed as of Carboniferous age, and is shown to rest on amygdaloidal and slaty rocks, some of which are considered to be lavas, other trap-ashes more or less altered, and other again unaltered detrital sedimentaries. The higher beds of the limestone series, for which the name Kothair is proposed, are considered to be possibly of Triassic age. The trap is considered to have altered the limestones of part of the Kashmir valley, and is accordingly regarded as intrusive and of post-Carboniferous age.

V/12. Verma, R.K., 1992. Seismicity, focal mechanism and plate movement along the western margin of the Indian plate. Abstracts, First South Asia Geological Congress, Islamabad, p.44.

Seismically the western margin of the Indian plate extends from the Makran coast in the south (nearly 25° N) to Hindukush (35° N). However the effect of plate collision extends upto north Pamir, S. Tien shan region. Seismically the area which are particularly active are the Kirthar-Sulaiman region, Quetta transverse ranges, Hazara Thrust region, Kohistan region and the North Pamir region. Most of the territory of Pakistan is characterized by strike-slip as well as thrust faulting. This is true to a large extent of the Hindukush and the North Pamir region alos. Over the Hindukush region the seismic zone extends to a depth of nearly 240 km. here a complex system of faulting is also taking place. At a depth of 80-240 the principal stress axis are oriented N to NW as well as S to SE.

Seismically the Hindukush region cannot be explained in term so of a simple plate subduction model. It appears that the lithospheres corresponding to the Indian and the Eurasian plate are moving relative to each other upto a considerable depth.

V/13. Verma, R.K., 1992. Gravity field in NW Himalaya, Kohistan region and the nature of continental-continental plate collision. Abstracts, First South Asia Geological Congress, Islamabad, p.44.

A Bouguer anomaly map of NW Himalaya, N. Pakistan and parts of Kohistan-Hindukush region has been prepared using all available gravity data. The map shows a pronounce gravity high over the Kohistan region. The gravity field has been interpreted along two profiles. The first extending from Gujranwala to Haramosh massif in NNE-SSW direction and the other from Gujranwala to Ghizar through Kohistan region.

Along the first profile the Moho depth is found to increase from nearly 30 km near the edge of the Indian shield to 77 km underneath the Haramosh massif. Along the second profile a high density intrusive in the upper part of the crust and located close to the Main Mantle Thrust is invoked in order to explain the observed gravity field. The intrusive extends to a depth of nearly 20 km and must have come from the upper mantle.

The nature of isostatic compensation prevailing in the Himalaya will be discussed. The results do not support a simple model of plate subduction along the NW Himalayan front. The role of vertical tectonics in the formation of Himalaya is emphasised.

V/16. Verma, R.K., Mukhopadhyay, M. & Bhanja, A.K., 1980. Seismotectonics of the Hindukush and Baluchistan Arc. *Tectonophysics* 66, 301-322.

A seismicity map of that part of the Pakistan-Afghanistan region lying between the latitudes 28° to 38°N and longitudes 66° to 75°E is given using all available data for the period 1890–1970. The earthquakes of magnitude 4.5 and above were considered in the preparation of this map. On the basis of this map, it is observed that the seismicity pattern over the well-known Hindukush region is quite complex. Two prominent, mutually orthogonal, seismicity lineaments, namely the northwestern and the north-eastern trends, characterize the Hindukush area. The northwestern trend appears to extend from the Main Boundary Fault of the Kashmir Himalaya on the southeast to the plains of the Amu Darya in Uzbekistan on the northwest beyond the Hindukush. The Sulaiman and Kirthar ranges of Pakistan are well-defined zones of intermontane seismicity exhibiting north-south alignment.

Thirty-two new focal-mechanism solutions for the above-mentioned region have been determined. These, together with the results obtained by earlier workers, suggest the pre-dominance of strike-slip faulting in the area. The Hazara Mountains, the Sulaiman wrench zone and the Kirthar wrench zone, as well as the supposed extension of the Murray ridge up to the Karachi coast, appear to be mostly undergoing strike-slip movements.

In the Hindukush region, thrust and strike-slip faulting are found to be equally prevalent. Almost all the thrust-type mechanisms belonging to the Hindukush area have both the nodal planes in the NW-SE direction for shallow as well as intermediate depth earthquakes. The dip of P-axes for the events indicating thrust type mechanisms rarely exceeds 35°. The direction of the seismic slip vector obtained through thrust type solutions is always directed towards the northeast. The epicentral pattern together with these results suggest a deep-seated fault zone paralleling the northwesterly seismic zone underneath the Hindukush. This NW-lineament has a preference for thrust faulting, and it appears to extend from the vicinity of the Main Boundary Fault of the Kashmir Himalaya on the southeast of Uzbekistan on the northwest through Hindukush. Almost orthogonal to this NW-seismic zone, there is a NE-seismic lineament in which there is a preference for strike-slip faulting.

The above results are discussed from the point of view of convergence of the Indian and Eurasian plates in the light of plate tectonics theory.

Key words: Seismotectonics, plate movement, Hindukush.

V/17. Verma, R.K., Mukhopadhyay, M. & Roy, B.M., 1977. Seismotectonics of the Himalaya and the continental plate convergence. *Tectonophysics* 42, 319-335.

The relationship between seismicity and tectonics of the northwestern, central and part of the eastern Himalaya lying between longitudes 74–88°E and latitudes 26–35°N has been studied. A seismicity map of the area for the period 1890–1970 is presented. A strain-energy release map of the Himalaya was prepared following the method discussed by Allen et al. (1965). On the basis of this map it is suggested that the Himalaya does not behave as a single unit so far as the seismic activity is concerned. It could be divided appropriately into three different units;

- (1) the Panjab Himalaya;
- (2) the Kumaon Himalaya; and
- (3) the Nepal Himalaya.

It is suggested that the extension of Aravalli structures into the Himalayan regions has played a role in the tectonics of the Kumaon Himalaya, and probably is the cause of the complex nature of seismicity of the region.

In the Kumaon Himalaya the maximum strain-energy release is related to the Main Central Thrust (MCT), whereas in the Panjab as well as in Nepal Himalaya it is related to the activity of the Main Boundary Fault (MBF). The strain-energy release characteristics of the two thrusts show that their mechanisms of storage and release of energy are different. Strain-energy release through the MCT seems to be more uniform as compared to the MBF along which the release of energy has been mostly abrupt, through large magnitude earthquakes.

Focal-mechanism solutions of Himalayan earthquakes located north as well as south of the Indus Suture Zone indicate that the Indian plate is underthrusting the Tibetan plate towards the north, whereas the latter is underthrusting the Indian plate towards the south. P-axes lying to the north as well as south of the Indus Suture Line are shallow dipping. This confirms the view that the present-day seismicity of the area is a result of continental-continental collision and not of lithospheric subduction.

From the seismic point of view, the territory of Pakistan which lies between latitude 23°–37° N and longitude 61°–75° E is one of the most active zones in the world. The importance of this area lies in terms of movements of the Indian plate with respect to Eurasia on the west. Seismicity, as well as focal mechanism- solutions, throws a considerable light on the nature of forces acting in the area. All the available solutions, along with 12 new ones, have been considered for the present study. Their relationship to major faults in the area is discussed. The majority of the solutions in the central and northern parts show strike-slip faulting with a left-lateral sense of motion, followed by thrust faulting; few show normal faulting. This suggests that the Indian plate is moving with respect to the Eurasian plate along the Chaman fault, Quetta transverse zone, Sulaiman Ranges and the Hazara thrusts region joining the Hazara/Kashmir syntaxis. The orientations of P and T axes have been studied. It is seen that in a large number of cases compressive stress is acting nearly in NNW-SSE to N-S directions. The Hazara thrust region appears to be the most complex. Here, the influence of the Himalayan thrust front is evident to a large extent. The nature of faulting along the Chaman fault and Quetta transverse zone is to some extent similar to that of the San Andreas fault system of California. So far as the energy release is concerned, the maximum energy is being released in the form of strike-slip movements close to the Chaman fault and Quetta transverse ranges.

V/22. Vicary, M., 1851. On the geology of the upper Punjab and Peshawar. *Geological Society of London, Quaternary Journal* 7, 38-46.

Introductory Remarks by Sir R. I. Murchison. In communicating the enclosed letter from Major Vicary to myself, I beg to observe that he obtained his knowledge in an arduous campaign, which led the British forces into regions ordinarily inaccessible to geologists. Independently of the description of an extensive range of those younger tertiary deposits in the Sewalik hills, Avith the contents of which we have been made acquainted through the letters of our associates Falconer and Cautley, Major Vicary now calls our attention to Palaeozoic fossils derived from the mountains which separate British India from Cabul. It appears that Dr. Falconer had previously obtained possession of fossils establishing this point, and I would now state that when I last visited Edinburgh, the Rev. Dr. Fleming showed me *Producti* and *Sjnriferi* collected by his son Dr. A. Fleming, of the Company's Service, in the vicinity of the salt range at Musakhail on the east bank of the Indus, which seemed to be identical with carboniferous forms well known in the British Isles. Being unaware at that time of any similar discovery, I urged my friend, the Rev. Dr. Fleming, to make his son's researches known to the scientific world, and to compare exactly the species collected in Western India with those of Scotland, with which he is so conversant. Having since shown these fossils to M. de Verneuil, he has identified five out of eight or nine species with forms well known in rocks of this age in other parts

of the world, viz. *Productus Cora*, D Orb. *Orthis crenistria*, Phill. *costatus*, Sow. *Terebratula Royssii*, L'Eveille, and *seve- Flemingii*, Sow. = *P. lobatus*, Sow. and other species of this genus.

Now these fossils have already been known to have an enormous geographical range; the *Productus Cora* occurring in Peru, Spitzbergen, Northern Europe, and the Sierra Morena of Spain; whilst two or three of the other species have an almost equally extensive distribution. The observations of Major Vicary are thus augmented in value by the discoveries of Dr. A. Fleming; for they prove that the palaeozoic rocks have a considerable range in the region of the Indus, a fact hitherto unknown to European geologists.

V/24. Vigne, G.T., 1842. *Travelers in Kashmir, Ladakh, Iskardo, etc.* 2nd edition. Colburn.

This is a 500+ pages book about the area. The first few paragraphs from the first chapter are reproduced here.

“At the village of Suru, not far from Bowun, is a well-sculptured figure of Sri, the Indian Ceres, or Lucksmi, as the goddess of plenty, in black marble, and about two feet in length, being the best specimen of the kind that I know of in Kashmir.

Proceeding along the northern side of the Karywah of Islamabad, we arrive at the place where the higher ranges begin to descend upon it; and at this spot alone, near the highest end of the valley, the most ungeological would be convinced of its having once contained a lake, as the remains of beaches formed of shingly conglomerate, are to be seen there deposited in horizontal layers, and resting upon distorted limestone strata. But I have before noticed this place, in my general remarks made upon entering the valley. Close at hand are some small ancient excavations in the limestone-rock, even with the ground, but not displaying any ornamental sculpture: They appear to be made for shelter rather than for any other purpose; at least I was not able to discover one.

Above them is a porch, elevated to the perpendicular face of the rock in which it is cut. The old pathway has been much injured, and I clambered up with some difficulty. Within is a small antechamber, from which a few steps lead into another excavation behind it; but I was deterred from going beyond the entrance, by the stench arising from the innumerable bats that I disturbed, which was rendered absolutely insupportable by the great heat of the weather. The Musalman, I may here remark, says that the bat was originally formed from a piece of clay, which Jesus Christ was accidentally moulding with his fingers, and that God gave it life afterwards, for the sake of its divine maker.

The excavation, is a dark and dismal-looking place, well suited to the purposes and trickery of priestcraft, which I have little doubt from its appearance were in full play within and near it. Perhaps this is the unfathomable cave which Abu Fuzl says is on one side of the springs of Bawun. On the ground, are the ruins of two Hindu temples, of the same shape as the interior building of Martund. The fine strath which I was ascending was the Pergunah of Kahawa, or Kaurah Parah. Kahawa signifies the left, and Parah is a corruption of Pergullah.

Duchin signifies the right, and Duchin Parah, is on the right side of the river Lidur, which flows downwards through the strath, to bear to junctioll with the Jylum, about three miles above Bij Beara. It is a very large river, inferior only to the Veshau, and when swollen with rain or melted snows its flood rushes down towards the plain with great impetuosity.

Harput Nag, or the Bears Spring, may be visited either from or on the way to Eysh Makam. It lies at the extremity of a strath that well deserves its name, being covered with the wildest jungul. I saw a wild cat, and my dogs unharboured a young bear, at which I got a snap shot; but he escaped to the mountains, by shuffling away at a pace I could not have given him credit for. The place is remarkable for its copper-mine, which formerly gave employment to numbers of workmen; but such is the arbitrary and oppressive nature of the Sikh rule that it is not now worked at all. Sher Singh, when governor of the valley, tried all he could to induce the people to resume their labours, but without effect. When compelled to work they will bring the demanded quantity of ore, but take particular care that it could produce little or no metal, and their masters know nothing about the matter. It is useless to attempt to punish them: the unfortunate Kashmirian is quite aware that his wages would probably not be paid, that the produce of his labour will nevertheless be taken, and that the display of a little will be the sure incentive to a demand for more; and these are reasons far more cogent than those that cause a strike amongst European operatives. I entered what I was informed was the principal mine. It extended into the quartzose rock, in a slanting direction, for not more than

twenty-five yards. The interior was much coloured by a nitrate of copper. I procured what purported to be specimens of the ore, but suspect that they were not of the best.”

V/25. Villa, I.M., 1997. High-grade amphibolites in Baltistan: t , T , p , Z , aH_2O , $^{40}Ar/^{39}Ar$, N_{ϕ} . Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 95.

Amphibolites from NW Ladakh Terrain and the Karakorum Metamorphic Complex in N Pakistan record $p \leq 1$ Gpa and $T \leq 700^\circ C$. In metabasites of the Ladakh-Kohistan island arc (Askore amphibolites, Shyok Suture Zone) and in gneisses of the adjoining Karakorum metamorphic complex (Chogo Lungma area, Remendok pluton) and High Himalayan Naga Parbat-Haramosh Massif, amphiboles and micas give Late Miocene-Pliocene ages {Villa et al., Tectonophysics 260 (1996) 201; Villa et al., Schw. Min. Pet. Mitt. 76 (1996) 245}. What is really controlling ages in this high-grade terrain? Temperature? Plotted in a conventional t - T diagram, samples do not define a meaningful family of “cooling paths”. Pressure? No. These amphibolites contain none of the excess Ar typical of eclogites {Tonarini et al., Terra Nova (1993) 13}. Only one gneiss of NPHM contains excess Ar (Ar/Ar biotite plateau=15 Ma, muscovite plateau=9.8 Ma, biotite Rb/Sr=5.7Ma).

Porosity? Dahl {GCA 60(1996) 3687} establishes crystal fields as controlling diffusion in crystals (surprise to so many!). The amphiboles in the metabasites have quite similar composition but ages scatter between 10 and 70 Ma. Resetting of Albian arc volcanics mainly depends on something faster than diffusion. Water? Of course it is known to enhance diffusivity by orders of magnitude. This is why virtually immobile elements such as Pb in zircon can be used as geothermometers. Regional fluid movement is the only way to homogenize Sr over the tens of km diffusion length scale implicitly required if WR Rb/Sr measurements are seen as metamorphic ages. The Rb/Sr data indicate open-system exchange with a fluid. Strain? If looked for, differences between deformed and undeformed muscovites a few meters apart are quite obvious, and correlate with ages. Phase mixtures? from Ar correlation diagrams, multiple generations of phases in the handpicked mineral separates can be diagnosed. Electron microprobe confirms $N(\phi) \geq 2$ where predicted by Ar. The key point is, where a texturally older amphibole or muscovite is still preserved, it also preserves an old age, reinforcing the notion that temperature alone won't reset all minerals. In summary, an age determination by no mean obviously translates into “ T_t point”. For this to happen, one must look at dry static rocks such as the Proterozoic Limpopo belt which exceeded the temperature necessary to erase any inheritance {Kamber et al., J Geol 103 (1995) 493}. In wet, hectic young orogens faster processes, such as recrystallization induced by deformation and fluids, overrun the very sluggish thermal diffusion in resetting mineral ages.

V/26. Villa, I.M., Lemennicier, Y. & Le Fort, P., 1996. Late Miocene to early Pliocene tectonometamorphism and cooling in south central Karakoram and Indus-Tsangpo Suture, Chomo Lungma areag(NE Pakistan). Tectonophysics 260, 201-214.

The Chogo Lungma glacier is located at the northeastern edge of the Nanga Parbat-Haramosh spur where the Ladakh-Kohistan arc formations are laminated between the Karakorum and High Himalaya units. In the Karakorum metamorphic complex, metamorphism of a pelitic and granitic protolith took place in two tectonometamorphic phases. Isoclinal folds ($\square 700^\circ C$, 1 GPa) were followed by doming ($\square 630$ – $700^\circ C$, 400–750 MPa) in a compressional climax (Lemennicier et al., 1996). One hornblende and two biotites associated to syntectonic magmatism with mantle affinities, contemporaneous of doming, give cooling ages between 3.0 and 7.7 Ma. A muscovite from an orthogneiss in the Karakorum gives an age of 5 Ma. Fast cooling (70–110 K/Ma) has prevailed ever since. Two muscovites from a foliated intrusion emplaced on the thrust of the Ladakh-Kohistan arc over the High Himalaya Crystallines have ages of 8.2 and >9 Ma (despite being collected in the same locality), dating the thrust at just before 9 Ma. All this points to a coeval tectonometamorphism and thrusting in that area during the Tortonian.

Key words: Miocene, Pliocene, metamorphism, tectonics, Karakoram, Indus-Tsangpo suture.

V/27. Villa, I.M., Ruffini, R., Rolfo, F. & Lombardo, B., 1996. Diachronous metamorphism of the Ladakh terrain at the Karakorum-Nanga Parbat-Haramosh junction (NW Baltistan, Pakistan). Schwitz. Mineral. Petrogrog. Mitt. 76, 245-264.

Metamorphic minerals from gneisses, amphibolites and schists of the Himalaya-Ladakh/Kohistan syntaxis in NW Baltistan were dated by $^{39}\text{Ar}/^{40}\text{Ar}$ stepwise heating.

The amphiboles from the Askore Amphibolite unit sampled in the Indus valley give discordant age spectra with step ages ranging from 35 to 70 Ma; we interpret the older step ages as mixtures between relict amphibole cores and new overgrowths. At least in the case of an amphibolite from the NW basal part of the Askore Amphibolite located just above the Main Mantle Thrust, a discordant age spectrum can be quantitatively interpreted using isotope correlations supplemented by petrographic observations and microprobe analyses. The cores retained their Ar during a 600-650°C amphibolite facies overprint. In the Shyok Suture Zone, amphibole ages are much younger, between 9 and 14 Ma. The young radiometric ages are thought to be associated with new amphibole formation along the foot-wall of the Main Karakorum Thrust.

Three biotite ages from the Shyok Suture Zone range between 6 and 8 Ma, similar to that from the NW part of the Askore Amphibolite, while two biotites from the Askore Amphibolite further SE give ages around 35 Ma, very close to the coexisting hornblendes. Biotites from the "Layered Sequence" of the Nanga Parbat-Haramosh Massif contain excess Ar, as shown by comparing $3\text{yAr}/4\text{Ar}$ biotite ages (15 and 27 Ma) with muscovite $3\text{Ar}/4\text{Ar}$ ages (10-12 Ma) and a two-point biotite-plagioclase Rb/Sr age of 5.6 Ma. The Rb/Sr age may point to open-system fluid circulation and/or to Sr inheritance in plagioclase. The muscovites probably date the initial stages of the still-continuing formation of the Nanga Parbat-Haramosh Massif antiform.

The Askore Amphibolite underwent amphibolite metamorphism before 35-40 Ma, followed by rapid exhumation. The Karakorum Metamorphic Complex was thrust over the Shyok Suture Zone between 10-15 Ma, thermally overprinting it. One Askore Amphibolite sample from the basal part of the Ladakh Terrain records a Late Miocene thermal overprint related to the young high-grade metamorphism and penetrative deformation affecting the "Layered Unit" of the Nanga Parbat-Haramosh Massif.

V/28. Villa, I.M., Tonarini, S., Oberli, F., Meier, M., Spencer, D.A., Pognante, U. & Ramsay, J.G., 1992. Eocene age of eclogite metamorphism in Pakistan Himalaya. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 94.

High-pressure rocks with an eclogitic assemblage (omphacite-garnet-quartz-rutile) from the Himalaya were first described by Spencer et al. and Pognante & Spencer. A geochronological investigation on two eclogites using the Sm/Nd, Rb/Sr, U/Pb and Ar/Ar methods is presented here. We obtained ages of 49 ± 6 (Sm/Nd on garnet-clinopyroxene pair), 43 ± 1 (Rb/Sr on phengite-clinopyroxene pair), 40 ± 1 (U/Pb on rutile), 91 ± 5 and 82 ± 1 Ma (Ar/Ar isochron on hornblende and plateau on phengite, respectively). The Sm/Nd isotopic system was fully equilibrated during eclogitization and not disturbed since; its mineral ages may date the peak metamorphic conditions ($650\pm 50^\circ\text{C}$ at 13-18 kbar). The Ar/Ar ages indicate that high-pressure minerals may give statistically acceptable but geologically meaningless numerical results. The other three mineral chronometres agree with the post-Cretaceous age proposed on paleomagnetic grounds by Klootwijk et al, for the collision between the Indian and Asian plates. The collision, subduction and the eclogitic metamorphic peak was already completed in the NW Himalaya by 50 Ma, although not in the Central and Eastern Himalaya before this time.

V/31. Vince, K.J. & Treloar, P.J., 1993. Late-stage extension along the Main Mantle Thrust (Pakistan, Himalaya): New field and microstructural evidence. Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, p.81.

Recent geochronological work on metamorphic rocks from the Besham area of North Pakistan has yielded evidence of re-activation of the Main Mantle Thrust as a zone of late-stage crustal extension. This has been accommodated in the footwall and hangingwall by displacement along a set of E-W striking normal faults. This trend is roughly parallel to that of the Main Mantle Thrust. Local variations in strike occur as a result of folding of the Main Mantle Thrust into a minor syntaxis around the Besham region. The E-W trending normal faults cut across all the earlier ductile and brittle structures produced by south-verging deformation and are therefore late-stage.

E-W trending south-dipping normal faults in the Indian Plate rocks of the Main Mantle Thrust footwall exhibit topside to the south movement. Extensional fabrics displace the northerly dipping ductile shear fabric of the footwall rocks that were formed as a result of the collision between the Indian plate and Kohistan Island arc although, on a smaller scale, some extension was accommodated by brittle re-activation along fabric surfaces. These can be interpreted either as Riedel shears associated with the earlier south-verging thrusts or, surfaces along which extensional collapse of the entire metamorphic pile occurred. Riedel shears are also associated with a few of the E-W trending faults.

The Kohistan Island arc forms the hangingwall of the Main Mantle Thrust. E-W trending normal faults occurring in the ultramafic rocks can be divided into two groups according to their movement: topside to the south, similar to the footwall and topside to the north. The latter are developed parallel or sub-parallel to the shear fabric of the hangingwall rocks. This is not as well developed as the fabric of the footwall sequence but implies clear north-verging extension. Many minor extensional faults are associated with the larger scale faults in the Kohistan ultramafics.

A second set of normal faults, striking N-S, are associated with the late deformation which folded the Main Mantle Thrust into a minor syntaxis producing an antiform in the Besham region. This east-west directed extension was more pronounced in the hangingwall of the Main Mantle Thrust than in the footwall and is attributed to outer-arc extension of the developing fold.

V/32. Vince, K.J. & Treloar, P.J., 1995. Early-Miocene-aged northward extension along The Main Mantle Thrust, Northwest Himalaya, Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

During the early stages of the Himalayan orogeny rocks of the Kohistan Island Arc were thrust southwards onto the Indian Plate along the Main Mantle Thrust (MMT), a northerly-dipping south-vergent crustal-scale fault zone. As a result, the cover sediments of the Indian Plate were decoupled from the lower-to middle-crustal basement and imbricated along large-scale thrusts. Crustal thickening of the decoupled Indian basement occurred beneath Kohistan by means of internal imbrication, ductile shearing and recumbent folding producing considerable thicknesses of blastomylonites (Treloar et al., 1989). Later thrusts re-imbricated cover and basement rocks and led to further thickening of the Indian Plate as the south-vergent thrusting of Kohistan over the Indian Plate continued. During the phase of thrusting the basement gneisses and granitic lithologies of the Indian Plate developed a strong south-vergent S-C fabric, and were mylonitised in zones of very high shear strains.

However, the presence of high-grade metamorphic rocks on the footwall and low-grade rocks on the hangingwall of the MMT suggests that the crustal-scale fault was later reactivated as a zone of extension. For instance, to the west of the Indus River kyanite-bearing rocks of the Swat Nappe in the footwall of the MMT are in structural contact with blueschist and greenschist facies rocks of the melange sequence (Treloar et al., 1991). To the east of the Indus chlorite-rich metasediments of the Banna Nappe structurally overlie sillimanite grade gneiss at the top of the Hazara Nappe.

Field investigations have illustrated that the mylonitic gneisses and granitic rocks of the Indian Plate immediately below the MMT contain abundant northerly-dipping C' shear surfaces (Platt & Vissers, 1980; Cobbold et al., 1971; Cosgrove, 1976). These ductile shear structures extensionally displace all the earlier south-vergent S-C fabrics in a top-to-the-north sense within the upper 30m of the MMT footwall. However, with increasing depth below the MMT the abundance of the extensional shears decreases rapidly over a relatively narrow zone.

At depths greater than 30m beneath the fault the late-stage deformation is accommodated along brittle transposed mylonitic fabric surfaces which carry N-S trending slicken fibres. Extension fractures and large E-W trending, north-dipping normal faults become progressively more dominant with increasing distance into the footwall of the MMT. However, no evidence for the extensional deformation is observed at depths > 400m beneath the MMT. This indicates either that the late-stage extension was partitioned into a very narrow zone immediately below the fault or, that the zone of ductile shearing was initially much thicker but has since been thinned or cut-out by the later brittle faulting. This is consistent with crustal extension during the transition from ductile to brittle deformation processes, as the ductile extension progressively thinned the crust it allowed cooling to take place which eventually led to brittle extension.

Metamorphic discontinuities also exist within the Indian Plate itself. The north-dipping Banna Shear juxtaposes the low-grade Banna Formation metasediments at the base of the Banna Nappe against the high-grade Mansehra Granite gneiss at the top of the Hazara Nappe. The topside-to-the-north extension has been accommodated along dominantly ductile C' shear surfaces within the gneissic footwall of the fault. As observed within the granitic rocks immediately below the MMT the majority of the northerly-dipping north-vergent ductile extensional shears are concentrated within the top 30-40m of the footwall but are sparse at greater depths.

The north-verging extensional displacements have been accommodated within the low-grade hangingwall of the Banna Shear along north-vergent fold and thrust structures and small-scale conjugate sets of north- and south-dipping normal faults. With increasing distance from the shear zone the extensional structures become progressively more brittle.

Field and laboratory evidence suggests that the Banna Shear either developed contemporaneously with the north-vergent deformation along the MMT or represents the extensional reactivation of a southerly-dipping backthrust which originally thrust low-grade metasediments northwards in association with a phase of brittle imbrication within the Indian Plate. However, there are no late-stage north-vergent structures within the low-grade metasediments which outcrop in the root zone of the proposed backthrust to support the former origin for the Banna Shear.

Microstructural and geochemical investigations have shown that the late-stage ductile C' shears within the footwall rocks of both metamorphic discontinuities developed in association with the retrograde shearing of muscovite and biotite mica during a phase of north-vergent normal displacements. As a result the extensional shears are defined by very fine-grained cataclastic biotites and the growth of new biotite and chlorite. Quartz has undergone dominantly ductile deformation within the granitic and gneissic lithologies. Mica 'fish' show ductile shearing into the C' surfaces at the onset of extension and water brittle fracturing as the deformation continued. Feldspar porphyroclasts underwent dominantly brittle deformation with the formation of sheared and rotated domino fault blocks, which dip to the south. Core and mantle textures around plagioclase porphyroclasts show a lower Anorthite (An) content within the recrystallized mantle, suggesting a retrograde metamorphic event.

On the basis of field criteria, reaction products and microstructural observation, it is likely that late-stage north-vergent extension along the MMT operated under conditions characteristic of greenschist facies metamorphism. Differences in fission track ages exist across the MMT between the footwall and hanging wall rocks. The zircon blocking temperature is recorded as 45Ma in Kohistan and only 20Ma in the Indian Plate. However, the lower temperature apatite ages of 19-16Ma (Zeitler, 1985) contour at the same structural level across the fault. This suggests that the phase of northward extension along the MMT was early Miocene in age, synchronous with north-vergent extension within the main Himalayan chain, where it is believed to have been driven by uplift along the Main Central Thrust (MCT). There is no obvious MCT analogue within the Pakistan Himalaya, The question thus arises as to whether late orogenic extension is a function solely of relatively shallow level thrusting or a result of isostatic adjustment following over thickening of the deep crust.

Key words: Orogeny, tectonics, Eocene, Kohistan island arc, MMT, Himalaya.

V/33. Vince, K.J. & Treloar, P.J., 1996. Miocene, north-vergent extensional displacements along the Main Mantle Thrust, NW Himalaya, Pakistan. *Journal of the Geological Society of London* 153, 677-680.

Structural data from N Pakistan show that early Tertiary, S-vergent structures within the upper part of the Indian Plate and the Himalayan suture zone were overprinted by regionally developed N-vergent extensional structures. Such extension has been suggested, but not previously described from the NW Himalaya. Cooling histories suggest extension was Miocene in age. Extension was most likely the result of isostatic rebound resultant from crustal, or lithospheric, thickening and/or delamination.

V/34. Viridi, N.S., 1981. Presence of parallel metamorphic belts in northwest Himalaya - Discussion. *Tectonophysics* 72, 141-146.

Kumar (1978) has recently described two belts of metamorphics from the northwestern Himalaya on the basis of the low pressure-high temperature and high pressure-low to high temperature mineral assemblages. Of the two belts, the southern corresponds to the Central Crystallines while the northern consists of Puga and Sumdo formations. Further it has been suggested (op. cit., p. 126) that the two belts together constitute a pair similar to those observed in California, Japan and Taiwan. Kumar also is not clear in his views on the nature of the Indus Suture Zone. Though firstly (op. cit., p. 122) he regards it as "nothing but a deep mantle-reaching fault" represented by a zone of ophiolites, later, however (p. 130), he describes it as marking the trench at the continental margin along which ocean bed was dragged down, in other words a subduction zone. This "suture" or "deep seated fault" is supposed to separate the Himalaya proper from Tibeto-Karakorum Range of "altogether different geological province". It may be pointed out here that Crawford (1974) was the first to have suggested the Indus Suture to be a deep mantle-reaching fault and not a subduction zone; Kumar, however, has not referred to this work. Geological investigations by the author and others both in Ladakh, Karakorum and the Central Crystallines have shown that the ideas presented in the paper are highly inconsistent with the actual geological set up in the region and the various models proposed to account for the geo-tectonic evolution of the Himalaya (Shankar et al., 1976; Gansser, 1977; Viridi et al., 1977; Viridi, 1980; and Frank et al., 1977). Also the Indus Suture does not separate the Karakorum from the Himalaya but, as will be discussed, it forms an important link between the two.

V/35. Viridi, N.S., 1979. On the geodynamic significance of mega lineaments in outer and lesser regions of western Himalaya. *Himalayan Geology* 9, 79-99.

Two types of mega-lineaments one trending NW-SE and conforming to the Himalayan strike and the other transverse to it are observed on the Landsat imagery of the Outer and Lesser regions of the western Himalaya. A majority of these lineaments coincide with known thrusts and faults while the others have exercised a profound control on the topographic features in the area through which they traverse. The NW-SE trending linear have also controlled the limits of sedimentary basins and exercised influence on intensity of deformation during and after the sedimentation. The transverse linears have rotated or dislocated the longitudinal linears and they can be traced southwards through the piedmont zone and probably coincide with deep-seated faults in the basement under the alluvial cover.

Key words: Geodynamics, lineaments, Himalaya.

V/36. Viridi, N.S., 1987. Metamorphic belts in the Indus-Kohistan suture zone and its surroundings: Evolution in space and time. In: Sychanthavong, S.P.H. (ed.), *Crustal Evolution and Orogeny*, 221-248.

The western segment of the Indus-Tsangpo suture zone in Kohistan and Ladakh and the southern margin of the Karakorum exhibits three important metamorphic belts which are more or less continuously traceable from west to east. The northernmost belt, the Pongong-Baltit metamorphic belt forms the basement of the Karakorum and contains older rocks metamorphosed and intruded by granitic batholiths. The regional metamorphism (M₁), probably Late Jurassic to Early Cretaceous, was superimposed by contact metamorphism (M₂) during the Late Cretaceous. Younger events related to the collision of the Indian and the Tibetan plate during the Eocene also affected these rocks, resulting in widespread thrusting and retrogression. The Gilgit-Shyok belt lying farther south consists of metamorphosed sediments, volcanics and tuffs formed in a magmatic arc and the back-arc basin north of the Kohistan-Ladakh magmatic arc. The metamorphism is of the low to medium pressure-medium to high temperature type and varies in intensity from greenschist to amphibolite in Ladakh and from greenschist through amphibolite to pyroxene granulite facies in Kohistan. The prevailing geothermal gradients are high, varying from 30" to 37"C/km and the grade increases due south towards the magmatic arc. South of the magmatic arc in Ladakh, a belt of fore- arc flysch occurs between the Gilgit-Shyok and the Indus-Kohistan belts. However, northwest of Dras in the Deosai and Nanga Parbat regions, the two belts occur in close juxtaposition. The high pressure belt consists of blueschists in Ladakh and blueschists and garnet-granulites in Kohistan. These have been derived from the ophiolitic

melange and the ultrabasic-rocks under high pressure-low temperature to high pressure-high temperature conditions with low geothermal gradients (15° - $18^{\circ}\text{C}/\text{km}$). The high-pressure and low-pressure belts constitute paired metamorphic belts that developed in a Pacific type subduction zone at the southern margin of Tibet during the Cretaceous. A two-stage model for the evolution of these metamorphic belts is proposed.

Several studies have related the cyclic aspect of the sandstone-mudstone repetition in the Siwaliks to complex stream systems. A genetic relationship has been demonstrated between these fluvial cycles and aggrading stream systems of varying sinuosity. The paper covers the flood plain stratigraphy in the Upper Siwaliks of the Potwar. The Markov chain analysis is applied to a portion of the stratigraphy at the Gauss/Maruyama polarity transition in a number of places in the area. From this they derived the principal deposition facies in a region of contemporaneous gluvial deposition. The rocks may have formed in a frequently flooded, sedimentation-dominant flood plain environment. Deep pedogenic overprinting may have occurred much later than the active migration of the stream course.

V/43. Visser, P.C., 1934. The Karakoram and Turkestan Expeditions of 1929-30. Geographical Journal 84, p821.

Difficult though it may be to give in a limited space an account of an expedition which took more than one and a half year and which not only had a geographical aim, but at the same time had in view the investigation of geological, glaciological, zoological, botanical, and meteorological problems, I will nevertheless try to give in a

narrow compass a synopsis of our third expedition to the mountains of central Asia. This time our object was first of all to explore the as yet unknown regions of the Karakoram and Salto-Karakoram (formerly known as Kailas-Karakoram) lying in the upper course of the Shyok and Nubra rivers. In this part of the Karakoram, which differs entirely from that which we visited in 1925 in Hunza, it looks as if Nature had tried not to compress the greatest possible number of mountain ranges into the smallest possible space, as is the case in Hunza, but just to model them on a wider base, thereby leaving space between the mountains and ranges, as if to show them better. Whoever has admired a Jungfrau or Bernina, a Mont Blanc or Breithorn, will be able to understand that Matterhorns are not always required to make a landscape charming and impressive. In the Salto-Karakoram we found however almost perpendicular granite walls among the highest in the world, and we found mountains which need yield to none as regards beauty and majesty.

Our programme further included the exploration of the tableland, at that time still unmapped, which is situated to the east of the Karakoram Pass and the regions of the Kunlun, which confine it on the north; also observations on the borderlands of the Taklamakan desert. Not only did we intend to map out as carefully as possible the mountains which we had chosen for exploration, but also to *try* to find out something more about the connection of the Karakoram and Aghil mountain ranges and their continuation eastwards.

V/54. Völk, H., 1999. Deep-seated mass rock creep along the Karakoram Highway in the middle Indus valley near Chilas, Northern Pakistan, with special focus on the interaction between erosion, valley fill and mass movements. Terra Nostra 99 (Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany), 164-165.

Unexpected sudden landslides along the Karakoram Highway (KKH) are a common and feared phenomenon, but the causes have scarcely been related to processes of persistent rock creep, which are to be presented here. Mass rock creep in motion cannot be experienced by direct observation because of being an extremely slow type of mass movement; the rate of velocity measures only app. < 1-10 mm/a. However the results of these extremely slow rock movements morphologically conspicuous and important from the point of view of engineering geology, especially along glacially eroded valley flanks. It is the change in geotechnical properties, which is linked with rock creep and impairs the stability of valley slopes (Selby 1985; Chigira, 1992; Cruden & Varnes, 1996). Geologically speaking the mountainous region of Chilas is made up of mafic-ultramafic plutonites of a former oceanic island arc, which have entered the geological literature as Chilas Complex of the Sub-Kohistan Arc in the Karakoram (Kazmi & Jan, 1997; Searle & Asif Khan, 1998). Although the Indus valley bottom at Chilas (Middle Indus) only lies at 1030 m asl this trunk valley course of the Indus was glaciated, too, as well as filled up by sediments and deeply eroded several times (Shroder et al., 1993).

Through the enormous incision of both glacier and river processes, which have to compensate for the amazing uplift of the high mountain chains of the Karakoram and the adjacent Nanga Parbat Massive, a deep trough valley with high and steep valley flanks came into being. Mass rock creep in the sense of deep-seated gravitational slope movement (down to 300 m) accompanied by opening of joints, fracturing and dilation, can be observed especially on those places where the Indus river has exposed or undercut the rock flank by recent or subrecent entrenchment. The fluvial disposal of Quaternary valley fill, such as till, gravel, lake deposits etc., deprives the valley slopes on the stoss sides of the river from their support at the footwall. As a consequence the rock walls are progressively failing and exhibiting various phenomena of collapse structures sometimes even reaching the mountain tops and ridges, adjacent to the valley. In the course of our study on mass rock creep in the region of Chilas, app. 8 km up- and downstream of this village, we can distinguish mainly two modes of slope failure:

Plane failures, consisting of several massive rock sheets (slabs) sliding into each other, indicating listric bending of shear planes in the distal part near the slope foot, representing a primary system, resulting in concave slopes.

Toppling failures, consisting of numerous plate-like rock segments near the distal margin of plane rock sheets, representing a secondary system superimposed on the plane failure system (1), resulting in convex slopes. Most geotechnically active joints along which plane failures occur, correspond in position with the regional "layering" of the meta-gabbros dipping towards NE, whereas joints of toppling type steeply dip in the opposite direction (SW) since they are frequently symmetric to the first ones and therefore show the same strike direction. Depending on the respective shear stress in the valley flanks other potentially active joints might also appear enabling the slope to attain general mobility.

Results

The geomorphological result of deep-seated rock creep is a prograding slope foot, thus a narrowing of the valley bottom. Conspicuous fracturing of rocks and opening of joints in outcrops along the KKH must be ascribed to mass rock creep rather than to tectonics. The conclusion must be that probably all events of rockfall are caused and controlled by mass rock creep on the valley flanks. This is particularly important for engineering work along the KKH.

Key words: Deep-seated rocks, geomorphology, Indus valley, KKH.

V/55. Volk, H.R., 2000. Deep-seated mass rock creep along the Karakoram Highway and its geomorphological consequences in the middle Indus valley near Chilas, Northern Pakistan. Geological Bulletin, University of Peshawar 33, 11-27.

Unexpected sudden landslides along the Karakoram Highway (KKH) are a common and feared phenomenon, but the causes have scarcely been related to processes of persistent rock creep, which are to be presented here. Mass rock creep in motion cannot be experienced by direct observation because of being an extremely slow type of mass movement; the rate of velocity measures only - 1-10 mm/a. However the results of these extremely slow rock movements are morphologically conspicuous and important from the point of view of engineering geology, especially along glacially eroded valley flanks as in the case of the Indus valley course in question. Mass rock creep in the sense of deep-seated gravitational slope movement produces irregular slope profiles with trenches accompanied by opening of joints, fracturing and dilation. As a consequence the rock walls are progressively failing and exhibiting various phenomena of collapse structures sometimes even reaching the mountain tops and ridges, adjacent to the valley. In the course of our study on mass rock creep in the region of Chilas, - 8 km up- and downstream of this village, we can distinguish mainly two modes of slope deformation.

1. Toppling movements, consisting of numerous book-like rock segments on the upper slope, rotating out of the slope, representing a primary system, resulting in convex slopes, sections through bulging.
2. Sliding movements, consisting of several massive rock (slabs) slowly gliding downwards upon each other, showing secondary listric bending of shear planes in the distal part near the slope foot, representing a secondary system, resulting in concave slopes. Geologically speaking the mountainous region of Chilas is made up of mafic ultramafic plutonites of a former oceanic island arc, which have entered the geological literature as Chilas Complex of the Kohistan Arc in the Karakoram.

V/64. Vyvyan, M., 1939. A Journey in the Western Karakorum. *Alpine Journal*, 51, 231-242.

The author has passed through the Himalaya and Karakorum. This is his findings during the journey. As this is a travelogue with no abstract. Thus the first few pages from the article are presented here.

The present conventions of Himalayan travel, which is now perhaps in its classic period, somewhat resemble those of Alpine travel in its corresponding stage nearly a century ago. In each case it is usual to explain, if not to justify, being among high mountains by some accomplishment in the way either of practical mountaineering or geographical or scientific investigation, but the subsequent development of Alpine mountaineering inclines one to the belief that these purposes and accomplishments are rather the mould or pattern of mountain experience than the essence of it. This belief is, at any rate, the excuse for the present paper describing a short journey in the western Karakoram last year which has no accomplishments to its credit. Indeed, to return to my comparison, this account will probably read to students of serious Himalayan undertakings much as some 'Narrative of an Excursion to the Aar Glacier' did three quarters of a century ago to those following in contemporary Alpine literature the progress of attempts on the Matterhorn and the triangulations of Adams Reilly.

The plan with which Campbell Secord and I started from England for Gilgit in the first days of June 1938 was to explore the upper basin of the Kunyang Glacier, the first large northern tributary met in ascending the Hispar, and

from it to make, if possible, a pass across the western end of the main Karakoram as the range at this point is sometimes regarded. The outskirts of the western Karakoram are perhaps more familiar to travelers than any other part of the Himalaya, for here roads and settled valleys probably reach nearer than elsewhere in the world to very great mountains. The main range is cut by the Hunza valley and the famous Gilgit road between Kashmir and Sinkiang which follows the river, while its southern fork terminates in the knot of Rakaposhi where the Hunza bends to the S. But although the approaches to these mountains have been frequently visited since Conway's great traverse of the Hispar and Baltoro in 1892, not only his work but that of later high-level explorers such as the W orkmans and the Vissers seems to have been continually hampered by bad weather. - For this reason, mainly, the Kunyang Glacier, dominated by Disteghil Sar (25,868 ft.) and Pumarikish (or Kunjut No. 2, 24,580 ft.) had not been penetrated far enough for the latter mountain to be seen, and the attraction of these recesses led Campbell Secord and myself to follow Colonel Mason's recommendation to visit it. If in exploring the upper basin we could find a col leading to the Malangutti or Yazghil Glaciers, this might be the route between the Hispar and Shimshal valleys which has been reputed to exist among local inhabitants on each side of the range. As it turned out, the party which did reach the northern end of the glacier was not adequate for summit ridge climbing nor equipped for proper surveying. This was the more unfortunate in that the weather was more continually flawless during my brief journeys than I have ever heard of it being among such great mountains; the benevolence of the skies seemed to be a contemptuous gift considering their treatment of our more competent predecessors.

Secord and I came up from Abbottabad in the N.W. Frontier Province via Chilas, a route which is more rapid but gives a longer stretch of the desert Indus valley than the more alpine Kashmir road. Neither of us had been to the Himalaya before and our first sight of great mountains was therefore one of our summer's more important happenings. It fell to us on entering the Indus valley; they were far away to the W. in unadministered tribal territory and looked like broken blue stones. Not till a few days later did 've see high mountains in full white panoply and then there was suddenly the stupendous mass of Nanga Parbat, complicated and alone to the S., and Haramosh and a slice of Rakaposhi (25,550 ft.) to the N. It was this very first revelation of Himalayan decolletes that distracted us from our serious purposes. Looking at them as we lay among long grass in one of the little carpet-like oases that are spread at intervals on the desert shelf above the Indus and its tributaries, we reflected that Kunyang was at least a week of sandy marches further away than the foot of Rakaposhi, and that our feet longed for the more familiar accidents of rock and snow, so 've resolved on a temporary defection. Shortly after we reached Gilgit, therefore, we left on a flying visit to the base of Rakaposhi in order to prospect its N.W. ridge which no one seemed to have approached before, but which looked promising from some R.A.F. photographs in our possession. Crossing the browri surf of the Hunza in a native ferry of inflated skins, whose rowers showed great skill and power, was the only sensational part of this preliminary journey, and then we had one of the most unusual pleasures of mountain travel that of gaining height unexpectedly at the end of the same day. After we had marched through sand which scorches even local porters' feet in the heat of the day, our path wound some 600 ft. up a precipitous gully in what we thought was merely a detour to avoid a cliff jutting out into the river, but reaching the top we found there was no descent. We were in a luscious green alp in the Jaglot valley which we had been making for, and whose main exit seems to be a fairly sheer drop over a cliff which only the Jaglot stream passes on its way to join the Hunza. We camped above Jaglot and the next day we reached the base of our ridge at some 12,500 ft.; we found it at least worth trying and were well on our way down the Hunza valley by nightfall. In fact we were back in Gilgit in 2-1/2 days after leaving it, having covered about 50 miles and, up and down, some 16,000 ft. in that time, travelling alone with packs and two walking ponies for some of the way.

Key words: Karakoram.

W/1. Waagen, W., 1872. Rough section showing the relations of the rocks near Murree (Mari), Punjab. Geological Survey of India, Records 5(1), 15-18.

This note gives a brief description of nummulitic limestone with some shales overlain by reddish sandstone and slates. Presence of main faults is also mentioned. Describe section from Khera Gali to Murree.

Key words: Limestone, shale, sandstone, Murree.

W/2. Waagen, W., 1879. Note on the Attock Slates and their probable geological position. Records of the Geological Survey of India 12(4), 183-185.

The first page of the article: In the "Records of the Geological Survey of India, Vol. XII, pt. 2, there is a paper by Mr. Wynne, entitled "Further notes on the geology of the Upper Punjab," which bears a special interest on account of the general views on the geology of that country. As many of the points treated of in the paper are yet to be considered as open questions, it seems not advisable to pronounce any opinion on them until further materials have been collected, but it may not be useless to notice some points which might be of value towards the elucidation of the questions discussed by Mr. Wynne.

There is before all the age of the "Attock slates." Mr. Wynne is quite right when he considers the evidence upon which the opinion of their being of Silurian age is founded very scanty indeed; and only the absence of any other clue towards the determination of the age of those slates could at the time justify the opinion expressed in our joint memoir on Mount Sirban, that the occurrence of lower Silurian fossils in gravels in the Kabul river, which lay approximately in the strike of the "Attock slates," would make a Silurian age probable also for the latter.

It is very much to be regretted that to the careful search of Mr. Wynne the slates have proved absolutely unfossiliferous up to the present. Yet this sterility in fossils seems not to prevail at all localities. Among the materials which have been most liberally sent to me by the Geological Society of London, there are about a dozen specimens of a *Spirifer*, which bear, however, only the label "Punjab." These specimens are preserved in a black slate, which, if the specimens came really from the Punjab, "and there is no reason why this should be doubted," must have belonged to the Attock slates, as there is no other rock known to me in that part of India which would bear similar petrographical characters, and from which the specimens could have come.

Though these fossils are more or less deformed by oblique pressure, yet the species can without difficulty be determined. All the specimens belong to one and the same species, and cannot be distinguished from *Spirifer keilhavi*, Buch., (8p. Bajah, Salt.). As this species is one of those most characteristic of the carboniferous formation in the Himalaya, and as thus the determination of the age of the rocks from which these fossils came considerably differs from the age hitherto attributed to the Attock slates, it is necessary to be doubly cautious in accepting the current opinion regarding these slates.

The rock in which the fossils are preserved is, as stated above, a black, not very hard slate, such as I have seen to occur at many places in the Attock slates; but there are also outside of the Punjab some localities where similar slates occur. I have myself seen similar slates from the Milam pass which seem also to belong to the carboniferous formation, and seem to be there inferior to white limestones, also full of carboniferous fossils, the latter, however, of a much more recent type. Similar slates have been described by Lydekker from Eishmakam. in Kashmir, whilst at other places in the same territory the carboniferous formation is composed nearly entirely of thick limestones. The slates of Eishmakam have been compared by Lydekker to the "Kiol group" and the limestones to the "Great limestone" of the outer Himalaya. Thus it might be very possible that in the Himalaya the carboniferous formation should present two sub-divisions, one older slaty, and one younger calcareous sub-division. This, however, does not prevent that at many localities the whole formation might be made up of massive limestones.

Key words: Limestone, petrography, palaeontology, stratigraphy, Attock slates.

W/14. Wadia, D.N., 1937a. The Cretaceous volcanic series of Astor-Deosai, Kashmir and its intrusions. Geological Survey of India, Records 72(2), 151-161.

Granitic rocks, a volcanic series, and sedimentary rocks from the south western part of the Deosai plateau and the adjacent Kishan Ganga valley were mapped and briefly described. The complexly folded and some 20 km broad volcanic belt, presumably occupying a synclinal flexure was shown to extend NW to SE toward Dras. Wadia noted that the volcanic series consist of a sequence of well stratified ash beds with some siliceous bands, gritty siliceous toughs, slates (some agglomeritic), agglomerates and flows. The ash beds and agglomerates are each several hundreds meters thick and the volcanic series contains intercalated sediments of Cretaceous age and scattered masses of ultramafic, mafic and granitic rocks.

W/17. Wadia, D.N., 1938b. Deposits of Ice Age in Kashmir. Geological, Mining, Metallurgical Society of India, Quaternary Journal, 10(4), 191-200.

The only accessible and legible records of the Pleistocene glacial epoch so far studied in India are those met with in the Kashmir Himalayas. A wide extent of the country above the latitude of 33°N and lying between the parallels of 73° and 78°E., especially the parts above an altitude of 6,000 ft. contain abundant proofs of ice-erosion and ice-borne debris covering hill slopes, valleys, cirques, glacial lakes and building terraces and mounds. At lower levels than 5,000 ft. ice-action is likewise indicated by copious occurrences of reassorted moraines, fluvio-glacial drift, lake-deposits and erratics. Many important details and even fundamental data, however, yet remain to be investigated about the Ice-Age in Kashmir and the problem may be said to have only just begun to receive the attention it deserves. Although of late years a large volume of evidence has been obtained proving the importance and extent of the post-Tertiary Ice-Age in Kashmir, precise data of its commencement in terms of the Siwalik sequence, its main fluctuations, or the date of its termination in reference to the Indo-Gangetic alluvial deposits, yet remain to be obtained by long and patient field work. Although, for many parts of Kashmir, the body of evidence is voluminous, no detailed investigation has been possible so far by the Geological Survey of India because of its preoccupation with the more vital stratigraphic and tectonic questions; and their classification and the determination of the sequence of even the major glacial and inter-glacial phases still remain for the future and will supply to the local geologists and naturalists of Kashmir a fascinating occupation. One unique circumstance which has supplied Kashmir Ice-Age with a recording chronometer of its principal episodes is the contemporaneous existence of a great lake, the Karewa lake, which filled the present valley basin of Kashmir, and which in the height of the Pleistocene glacial age must have been no less than 3,000 sq. miles in area. The vicissitudes through which this lake, a true tectonic synclinal basin, with only a single outlet, has passed, the alternations of freezing and non-deposition during the glacial phases and of basin-filling with active deposition during the inter-glacial phases, these alternations going on simultaneously with the intermittent uplift of the Western Himalayas, are registered in the alluvial strata of this lake, designated as the *Karewa Series*. The lake's existence must have been an intermittent one, attaining maximum extent during the warm inter-glacial pauses, succeeded by periods of minima, draining and refilling. Nearly half the area of the present Kashmir valley basin is covered by deposits of the Karewa Series which range in altitude to-day from the level of the Jhelum, 5,200 ft., to over 11,000 ft. on the slopes of the bordering mountains. Both in respect of their horizontal extent and the length of Pleistocene stratigraphic record they represent, the Karewas contain materials for a detailed systematic study of the Ice-Age in the Western Himalayas. Evidence is certain to come to light yielding results in Pleistocene orography, human paleontology and anthropology, besides purely glacial geology. Broadly speaking, four main oscillations of climate have been detected in the glacial cycle of Kashmir, by Dainelli (1913), De Terra (1938) and lately by myself, but it would be premature to try to correlate the Kashmir glacial and interglacial periods with the four main glaciations of the Alpine Ice-Age, nor have sufficient data been yet discovered to allow us to attempt anything more than a broad classification of the glacial formations of Kashmir. The glacial cycle of Kashmir proves to be a highly complex one, displaying varying interrelations of great mountain-building uplift movements, climatic and hydrographic changes, with at least three, or four, advances and retreats of the ice. The deposits formed under these various conditions during the whole glacial period in the Kashmir Himalayas, and which constitute our principal source of information of post-Pliocene geology, may be classified under the following five heads. These are of unequal applicability and reliability for different regions of the mountains, but each class of deposit is of value in throwing light on some particular aspect of the problem:- Moraines of different glaciations at various levels.

W/25. Wagner, R. & Wachten, A., 1971. Exploration and ascents in the Buni group. Himalayan Journal, 31.

We planned the Kolner Hindu Kush Expedition 1971 on the assumption that sensational discoveries and explorations in large areas of the Hindu Kush could hardly be a target for expeditions in the 'seventies' any more. Besides, for a group of nine climbers, all of amateur status, a too ambitious aim could spell disaster. For this reason we decided on a range which is somewhat away from the spectacular seven-thousanders of the Hindu Kush and had not been explored much; the Buni Zom group in Chitral, south of Buni and Awi, on the Mastuj river. From expedition results in the years 1957, 1965 and 1967, 6 Section Graz ', under the leadership of Dr. Gruber, had worked at sub-dividing the whole Buni Zom group. In 1970 a work was published in which Dr. Gruber differentiates between the North Buni Zom group, situated between Mastuj valley and the Phargam Gol, with the Khorabohrt, Gordoghan and Phargam glaciers and the South Buni Zom group, south and south-west of Phargam Gol, with the mountain areas around the Rizhun, Sohnyoan, Golen, Rinzhoo, Shiak, Shachiokuh, Isporili, etc., glaciers. C The Buni Zom Group in Chitral'—O.A.Z., Vol. 1370; reprinted in #./., Vol. XXX, 1970). Since our team of nine-eight men and one woman-constituted a rather large group, we decided on a double expedition, i.e. division into two groups ; George Holtmann, Herbert Hoven, Christoph Meizka and Albert Wachten were to attempt through a steep climb the difficult-to-reach Phargam glacier and into the untrodden basin to investigate and climb the virgin Awi Zom, the second highest summit of the whole of Buni Zom group; Heinz Dieter Bohme, Anno Diemar, Manfred Heintz, Erika and Robert Wagner had the task to get a clear picture of the Sohnyoan glacier which had been reached for the first time in 1970 by two Japanese groups. Thus we planned to investigate the glaciers which debauched into the

Phargam Gol and which had hardly been given any attention so far. Both groups started from the Phargam Gol with its ideal situation for a Base Camp which was established at 3,987 m. on high ground of the valley at Kulakmali. In order to investigate the approach routes to the Buni Zom group, as also to ease the problem of porters, we set out in separate groups for the Base Camp. The possibility that the Base Camp would be unreachable by one route was also eliminated, and besides the ever-changing composition of the groups helped to overcome and lessen the usual strain of the expedition members. In three mini buses we set out over the route which is to some extent also used by tourists ; through Istanbul, Ankara, Tehran, Kabul, Peshawar and on 4 August we reached Chakdara. Here we parted—one group went in its own conveyance over Saidu to Kalam in the Swat valley; the other group went to Dir and from there on to Chitral by jeeps. The difficulties which the 'Chitral group' expected with the authorities did not occur. After a 70 mile jeep ride through the Mastuj valley up to Miragram, they quickly reached the Base Camp at Kulakmali with the porters and pack animals through Mastuj, Rahman and Phargam. The approach route through Kalam took a few days longer. Besides the collapse of a bridge which hampered our provision of petrol and the difficulties with the authorities, the main problem was to find 40 porters for the loads. In the end the porter team consisted of inhabitants from Kalam and Matiltan in equal proportions. There emerged some unhappy strains of competition between these two teams but we were fortunate to commence the eight-day march through the richly vegetated Ushu Gol over the Kachhikhani An (4,766 m.). After a climb up to a height of 4,805 m., immediate east of the pass, the path leads down north through Sor Laspur and Harchin to Kulakmali. Due to worries and shrinkage in our expedition kitty we had to rearrange the porters in Sor Laspur and Rahman. During the month from mid-August to mid-September our exploration worked out as planned concerning the Sohnyoan and Phargam glacier basins. The settled condition of the glaciers permitted a quick erection of camps in both areas. Each group had the help of two high-altitude porters-Tschapir from Sor Laspur and Seraman from Rahman for the Phargam glacier; Mir Alam from Matiltan (Ushu Gol/ Swat) and Nigaban Shah from Phargam for the Sohnyoan glacier. While the group 'Sohnyoan' began from Kulakmali with the transport of the loads, the other group 'Phargam' erected a further Base with the material which had been already deposited there during the approach march. Besides the rapid glacier stream which descends from the Khorabohrt glacier and which had to be traversed west of the Kulakmali camps, the Sohnyoan group found no difficulties in reaching the Sohnyoan glacier. The glacier which entered the Phargam Gol without any step was reached effortlessly over the western moraine; a steep step between 4,500 m. and 4,650 m. at the foot of the ENE. ridge of the Shupel Zom E. was also easily traversed and thus after ten days all material had been moved from the Base Camp to Camp I (4,700 m.). On account of the huge stone falls along the flanks, the camp was erected in the middle moraine of the glacier. The aim of activities from Camp I for the next 2/3 weeks was the exploration of the routes to the neighbouring valleys, the Rizhun Gol, the Rinzhoh Gol and the Golen Gol as also the possibilities of climbing the boundary walls of the Sohnyoan glacier which showed a prominent salient to the west. For this reason we climbed Pt. 5,625 m. which the Japanese reached in 1970 and which they named 'Sohnyoan Zom'. Once we did this over the north flank and the SW. ridge and another time over the NE. ridge. The climb up the highly glaciated North wall was interesting and not too difficult. The descent though took up much time due to great amount of stone fall so that we were forced into a bivouac at 5,100 m. The descent over the NE. ridge is recommended. A wonderful view offered itself from the lower summit west of the 4 Sohnyoan Zom' which we named 6 Kolon Zom. This flat summit gives an uninterrupted view of the Sohnyoan glacier (9 km. long) beyond the place where it turns north—also an interesting view into the Khorabohrt glacier basin. The result of these climbs showed that the route from the Sohnyoan glacier into Rizhun Gol, either through the north-east pass or the south-west pass, was possible only with the greatest difficulty. The climb of the mighty massif south of the upper Sohnyoan basin seemed possible either over the heavily glaciated north flank or over the rocky ESE. ridge. The last possibility proved objectively too dangerous as we witnessed, after a climb of the pre-summit (Pt. 5,700 m.), the enormous crevasses and dangerous stone falls of the ridge. Investigations into the upper Sohnyoan basin showed that one could reach the Rinzhoh Gol without difficulty over a high saddle (Rinzhoh An, 5,343 m.). On the other hand, a climb of this chain from the west should hardly be considered. There remains the above-mentioned north flank which rises 1,100 m. high from the Sohnyoan glacier towards the eastern corner-stone of the massif which has been shown on the half-inch map of 1954 as Ft. 6,100 m. and which was measured by Gruber from the Khorabohrt glacier as 6,000 m. An attempt was made on this flank but time was against us i we gave up at the steep pure ice passages at the beginning of the second half of the wall. The route for the most favourable climb in this chain was found but it would require the climb of Pt. 6,100 m. and the traversing of the ridge for which we had, in September, no more time. Considerable additions could be made to the map of the northern boundary of the upper Sohnyoan glacier, i.e. to the southern slope of Shupel Zom massif. Contrary to the markings in the half-inch map, the glacier-arm goes direct southward between Shupel Zom West and East and only shortly before it enters the Sohnyoan glacier does it bend towards the east. Over this route we reached the 5,650 m. saddle which we named c Shupel An \ Here we discovered, south of the Shupel Zom E., a summit of 5,810 m. which one ascends by a prominent west ridge. After

climbing this we gave it the name 'Golen Zom' and noted that Shupel An from the Sohnyoan glacier as well as from Golen Gol offers an ideal starting point for the three summits of the Shupel Zom group. We did not attempt to climb the eastern boundary of the lower Sohnyoan glacier since the constant stone fall in the exceedingly broken chain made it appear rather unrewarding. An exception is probably the glacier-arm which descends from Pt. 5,909 m. to Pt. 5,824 m. The Base Camp of the 'Phargam' group is just above Phargam at a height of about 3,300 m. It stands sloping on the moraine in an awkward position. Towards the north one views from here direct into the steep icefalls of the Phargam glacier; the view and the route to Awi Zom (6,484 m.) are yet hidden. The main object of this group was to find a route into the glacier on which no one as yet had set foot; it would be for our own use or it could be of help to any future expeditions. After a march on foot for one and a half hours, at a height of about 3,700 m., a great gorge is formed by the mountains which frame the Phargam glacier. The glacier-tongue plunges over a large rock-fall into the depths; it is impassable as is also the orographic left boundary wall. The only possible ascent is offered by the orographic right rock wall (600 m. height) at the foot of which we erect a provisions depot. The climb now is not difficult; however, one has to be careful about stone falls and we reach the glacier floor at 4,300 m. One hour's advance on to the glacier and then we erect Camp I at 4,584 m. We now transport provisions and equipment from the Base Camp over the steep step to Camp I. From here we view Awi Zom for the first time. Two further crevasses present some difficulties (the first is traversed on the orographic right side and the second on the orographic left) and then we are able to erect Camp II at 5,265 m. in close proximity to the mighty SW. wall of Awi Zom hardly a fortnight after arrival at the Base Camp. Now we can start on its climb. To attempt to climb the deterring SW. wall does not seem advisable and we plan to reach the ridge connecting Awi Zom with Buni Zom so that from there we may attempt the climb over the West ridge. The only possibility to reach this connecting ridge is over a broad sloping rubble band which traverses at the lower end of the SW. wall and ends in a steep groove which leads on to the ridge. At the mercy of the stone falls we cross this strip—we name this crossing 'Crossing of the gods'—and we reach the ridge where we erect at 5,889 m. a high-altitude Camp I. This is the lowest point of the west ridge of Awi Zom. We name the ascending ridge to Buni Zom IV the 'Fairy Tale Ridge' Frightful descents on the Awi Zom west ridge towards our high camp frustrate a climb of the ice-giant. However, the 'Fairy Tale Ridge' with its average height of 6,000 m. offers a demanding and strenuous traverse. We surmount six humps on it which to date have not been mapped, and which no one has yet climbed; the most prominent ones quite close to Buni Zom IV we name: k P. Phargam I and P. Phargam II' (both about 6,000 m.). We return to Camp II. It appears that the only approach to Awi Zom is the above-mentioned SW. wall. A spur runs through the wall and we think it is possible to erect an intermediate camp on it. We keep towards the right (in the direction of the ascent) and in the late afternoon we start (on account of the lessened danger of stone falls) and with the darkness we reach a well-formed saddle on the spur on which we can erect our bivouac tents. But even this place is not absolutely safe of falling stones. From here ascends obliquely to the west ridge, a furrowed snow-field. Next day we cross this snow-field in the morning and also after sunset and now and then some stones fall from the summit wall but they fortunately do not hit us. At about 6,150 m. we at last reach the secure West ridge. Over snow and over rocks we proceed rather effortlessly and reach on 3 September 1971 at 12.45 p.m. the summit of Awi Zom which had not been climbed previously. We would not recommend our route of ascent. Our undertaking had extended up to the last days of summer. Already on the morning of our combined departure from Kulak-mali over Phargam and II to Chitral it was snowing up to the Base Camp.

We were quite aware that we had not returned with any sensational climbs and explorations. Yet, we knew that our stay and work in the Buni Zom area tallied with what we had set out to do. We do hope that the report of our expedition will be a useful addition to the knowledge of this area. [The authors are unduly modest of their achievement, both in climbing activity and exploration. All this is most valuable information and is complementary to the research of Dr. Gruber and other earlier visitors to the area.—Eds.]

Between 70 and 80% of the total annual run-off from the upper Indus Basin originates from heavy snowfall and glacierized basins at elevations greater than 3500 m a.s.l. However, very little is known concerning the mountainous headwaters of the Indus. This is especially true with respect to the amount of snowfall in the major source area, the high Karakoram. Recent studies of high-altitude alpine glaciers indicate that geochemical dating techniques can accurately and confidently identify seasonal and annual stratigraphy within snow pits and ice cores, and thus can be used to determine the seasonal and annual rate of snow accumulation. In addition, chemical records can usually be employed to determine sources of precipitation. Six snow pits, each 5- 0 m deep, were investigated in the accumulation zones of the Biafo and Khurdopin Glacier basins. Both accumulation zones are characterized by broad, open basins separated by steep, narrow ridges in which direct precipitation is the dominant form of nourishment. Seasonal stratigraphy is delineated through an analysis of the seasonal variation in the chemical and physical characteristics of the snow-pack. Annual snow accumulation in the Biafo Glacier basin ranges from 0.9 to 1.9 m water equivalent: maximum accumulation occurs in the elevation band 4900-5400 m asl. Roughly one-third of this snow accumulation occurs during the summer.

W/31. Wake, C.P. & Searle, M.P., 1993. Rapid advance of the Pumarikish Glacier, Hispar Glacier Basin, Karakoram Himalaya. *Journal of Glaciology*, 39, 204-206.

Pumarikish Glacier is approximately 7 km long and flows south from the main crest of the Karakoram. It is one of the main transverse tributaries feeding into the northern margin of Hispar Glacier, which is 62 km long and flows west from Hispar Pass (5150m) and eventually drains into the Hunza River (Fig.1). Hispar Glacier flows roughly parallel to the southern contact of the Karakoram granite batholith, which corresponds to a belt of mountains with the highest average elevation and the fastest uplift-erosion rates anywhere in Asia (Searle, 1991). Pumarikish Glacier is fed predominantly by avalanches, which originate from the north faces of Pumarikish (7429m) and Khinyang Chhish (7854m) on the northern and western edges of the basin, and from the lower unnamed peaks of the eastern margin. The granite headwall of Pumarikish Glacier is over 2500m from the summit icefields to the upper glacial cirque. The avalanches deposit snow, ice and debris in a small gently sloping basin at 4600-4700m. The lower 4km of Pumarikish Glacier descend gradually from this small accumulation basin to 4000m in a well-defined trough less than 500m wide.

Recorded observations of Pumarikish Glacier are few. Conway traversed and surveyed Hispar Glacier in 1892. From observations of tributaries on the north side of Hispar Glacier, Conway (1894) noted that:

"It is remarkable that whereas the Lak Glacier. has so greatly shrunk of later years, this Chur Glacier [Pumarikish Glacier on our map], its immediate neighbor, and which drains another flank of the selfsame mountains, should, on the contrary, have greatly swollen. It overflows all its moraines and pours in a broken spreading wave on to the surface of the Hispar."

Hayden (1907) made no mention of the north-bank tributaries of Hispar Glacier. Dr Kooncza and Dr Caliat, two surveyors who accompanied the 1908 Workman expedition to Hispar Glacier, found that Pumarikish Glacier was "connected by terraces" to the main body of Hispar Glacier (Workman and Workman, 1910). Their map shows a relatively direct crossing of Pumarikish Glacier at the snout. The map produced by Eric Shipton's Karakoram Expedition of 1939 (Mott, 1950) also shows an apparently straightforward crossing of the snout. No account was mentioned of difficulties encountered while crossing this glacier. No mention was made of Pumarikish Glacier in published reviews by Mason (1930), Hewitt (1969), Mercer (1975) or Mayewski and Jeslike (1979).

Our own observations of the glacier began on 19 August 1985 when it was crossed during a reconnaissance of the Hispar Glacier Basin as part of the Snow and Ice Hydrology Project. At that time, the glacier was easy to cross. There was a well-marked path on both lateral moraines and across the glacier used by shepherds to bring their yaks to summer pastures further up the margin of Hispar Glacier. The surface of the glacier showed only mild undulations and was covered in debris which ranged in size from large boulders to silt and mud. The surface was several tens of metres below the top of the lateral moraines. The appearance of the glacier had changed little when it was crossed on 8 August 1987 en route to Hispar Pass. However, by 29 June 1988, the snout of the glacier had thickened by at least 20m. The surface was still debris-covered but now also showed large debris-covered hillocks and deep valleys. There was no path or obvious route across the glacier. The eastern margin of the glacier was defined by a vertical ice cliff 1520 in high which descended to a narrow defile bordered on the far side by the lateral moraine. Steps had to be cut in the ice and the porters were belayed down this section. The upper surface of the glacier was approx. 10-20m below the top of the lateral moraine (Fig.2a).

Further observations were made during July and August 1989, when a base camp was established at Bitanmal, 3 km west of Pumarikish Glacier. The snout of Pumarikish Glacier had thickened so dramatically that the upper surface of the glacier was 16-22m above the top of the lateral moraine (Figs.2b and 3). The glacier had also advanced 1 km, reaching almost the middle of the 2-2.5km wide Hispar Glacier (Fig.4). The entire length of Pumarikish Glacier was now heavily crevassed and impossible to cross at any point (Fig.5). The regular path up to Hispar Pass was now cut off and to continue up-glacier it was necessary to circumnavigate the advancing snout by travelling out into the middle of Hispar Glacier and around the front of the Pumarikish Glacier ice. This diversion added about 4-6h on to the journey. The pastures along the ablation valley beside Hispar Glacier upstream of Pumarikish Glacier were cut off, and the Hispar yaks now grazed mostly at Bitanmal. A brief reconnaissance up Pumarikish Glacier failed to reveal any snow, ice and/or rock deposits which would have been indicative of a major avalanche or landslide.

It is clear from Conway's observations in 1892 that the upper level of the glacier surface was above the top of the lateral moraines so that ice flowed over them, and that Pumarikish ice flowed well out on to Hispar Glacier. Furthermore, Conway's observation that Khiang Glacier had thinned in the years prior to 1892 indicates that the advance and thickening of Pumarikish Glacier was an isolated event and not characteristic for the north-bank tributaries of Hispar Glacier. The swollen nature of Pumarikish Glacier described by Conway appears strikingly similar to our observations during the summer of 1989, suggesting that the glacier had experienced at least two periods of rapid advance separated by approximately 100 years.

Several glaciers in the Karakoram have been known to surge in the past (Hewitt, 1969; Gardner and Hewitt, 1990). The majority of documented surging glaciers in the Karakoram are concentrated along the main range. In the summer of 1989, Pumarikish Glacier exhibited features characteristic of a glacier in surge: rapid advance of the snout unrelated to activity of nearby glaciers, exceptional rates of advance and the formation of new surface features. In addition, Pumarikish Glacier displays basin-morphology features described by Hewitt (1969) as characteristic of surging glaciers in the Karakoram: medium size for the region, nourishment predominantly via avalanching, and steep tributary glaciers and snow avalanches which supply relatively small, low-angle accumulation zones. While the observational record of Pumarikish Glacier over time is limited, the morphological changes and repetitive nature of rapid advances over the past century, combined with basin morphology which is characteristic of surging glaciers in this region, suggest that Pumarikish Glacier can be added to the list of documented surging glaciers in the Karakoram.

W/32. Walton, J.L.W., 1984. Special techniques for surveying on mountain terrain. In: Miller, K.J., (ed.), *The International Karakoram Project*, 1, Cambridge University Press.

At some stage in almost all land surveying projects a network of fixed or "control" points has to be set up. When the area being studied involves moving terrain, such as a glacier, special survey techniques have to be used either to eliminate errors incurred by the moving control points, or to actually determine their velocity. This paper contains a review of a number of these special techniques ranging from simple "by eye" approximations to complex methods requiring extensive computer facilities. Some of these techniques may be applied to problems involving infinitesimal velocities such as the tectonic plate movement studies planned for the 1980 international Karakoram Project.

W/33. Wang, W., Huang, M. & Chen, J., 1984. A surging advance of Balt glacier, Karakoram mountains. In: Miller, K.J., (ed.), *The International Karakoram Project*, 1, 76-83. Cambridge University Press.

In November 1977, it was discovered that the Balt Bare Glacier's terminus had moved downwards 1.6-km since 1974. This movement took place mainly in 1976. During the investigation in October 1978, it was found that the terminus had further advanced a distance of 0.4-km but had begun to thin. The glacier terminus, 2.5-km in length, was surveyed and mapped at a scale of 1:5000 and a short-term measurement of surface velocity and temperature on the glacier was taken. We believe that the temperature in the surveyed section is high, and at melting point on its bottom. When the thickness and the basal sliding velocity of the glacier are estimated, one would consider that basal sliding was the dominant mechanism of the surge. It was predicted that the glacier would be thinner in the near future and that this surging advance would arrest.

W/35. WAPDA (Water And Power Development Authority, Pakistan), 1962. 1961 snow surveys. WAPDA, Lahore.

For more than 50 years, Water and Power Development Authority (WAPDA) has spearheaded investigations in Water Resources, Water Logging & Salinity, Engineering Geology, Reservoir Engineering, Dam-site Investigation, Hydropower, etc., in Pakistan. In several of the projects, WAPDA also involved technically skilled personnel and specialized organizations from abroad. A wealth of data in the form of reports is available in WAPDA Headquarters in Lahore and in its Regional Offices. These data are not freely available, but can be accessed through proper channel by those engaged in academic and applied research. In the following are given the titles and key words of a number of these reports under the name WAPDA. Others, having authorships, are given in appropriate places. We would like also to mention that there are many more unpublished reports of WAPDA that might be of interest to geoscientists.

Geology of the northwestern part of Abbottabad quadrangle, Abbottabad has been described. The area is occupied by, from bottom to top, Abbottabad formation (Early Cambrian) and Hazira formation unconformably overlain by the Samana Suk formation (Jurassic), and Cretaceous Chichali and Kawagarh formations. Brief descriptions of the rocks are given together with a colored geological map and seven colored field photographs. The Abbottabad formation is represented by Saraban Dolomite member which is divided into Lower, Middle and Upper units.

W/56. Wartho, J.A., Dodson, M.H., Rex, D.C. & Guise, P.G., 1991. Mechanisms of Ar release from Himalayan metamorphic amphiboles. *American Mineralogist* 76. 1446-1448.

Changes in hornblende samples that occur during stepwise $^{39}\text{Ar}/^{40}\text{Ar}$ analysis were studied experimentally and mineralogically. A complex succession of reactions was seen (hornblende - oxyhornblende - clinopyroxene-structured phase - fine-grained reaction products + glasses) in the temperature range 750-1300°C. The release of Ar from hornblende in the vacuum furnace appeared to occur by fundamentally different processes from those resulting in Ar loss during metamorphism. Simple diffusional interpretations of the release patterns are, therefore, not capable

of revealing the thermal history of samples. In principle, some useful information may be obtained if long-standing fractures and other defects control both natural Ar loss and mineral reactions within the laboratory.

Excess argon in amphiboles linked to greenschist facies alteration in the Kamila Amphibolite Belt, Kohistan Island Arc system, northern Pakistan: insights from $^{40}\text{Ar}/^{39}\text{Ar}$ step-heating and acid leaching experiments. *Geological Magazine*, 133, 595-609.

A mineralogical and $^{40}\text{Ar}/^{39}\text{Ar}$ study of 13 amphibole samples in the Kamila Amphibolite Belt and Kamila Shear Zone in northern Pakistan has found a correlation between the degree of greenschist facies alteration and quantity of excess ^{40}Ar . Additionally, there is a north-south divide with amphibole samples from the northern region showing larger degrees of green schist facies alteration, brittle deformation, and excess ^{40}Ar incorporation compared to the predominantly plastically deformed, less altered, amphibole samples from the Kamila Shear Zone in the south. Acid leaching of two amphiboles from the Kamila Amphibolite Belt indicates that a large proportion of the excess ^{40}Ar is correlated with later greenschist facies alteration phases, and can be easily removed by acid etching, thus revealing acceptable regional $^{40}\text{Ar}/^{39}\text{Ar}$ plateau ages.

W/60. Warwick, P.D. & Wardlaw, B.R., 1992. Paleocene-Eocene Stratigraphy in Northern Pakistan: Depositional and Structural Implications. 7th Himalaya-Karakoram-Tibet International Workshop.

The Paleocene-Eocene strata of northern Pakistan are found in a northeast-trending trough that is well preserved south of the Main Boundary Thrust (MBT) but is structurally disrupted to the north of the thrust (fig. 1). The depositional trough south of the MBT can be reconstructed along a northwest-southeast cross section from lithofacies of the upper Paleocene Lockhart Limestone and associated Hangu and Patala Formations, the upper part of the lower Eocene Panoba Shale, and the uppermost lower Eocene Kuldana Formation. The Lockhart Limestone was deposited throughout most of the trough and is predominately red algal nodules in skeletal mudstones to packstones in the northwest (Hangu area), foram muds in skeletal mudstones to wackestones (packstones rare) in a central area (Makarwal), and foram-dasyclad sands in skeletal wackestones and packstones (mudstones rare) in the southeast (Salt Range). The southeastern facies of the Lockhart Limestone shows a gradual facies change shoreward to clastics that are indistinguishable from the underlying Hangu Formation and the overlying Patala Formation. During the deposition of the upper part of the Panoba Shale and equivalents, deltaic sands and muds are in the northwest, marls and shales in a central area, and nodular-bedded carbonates in the southeast. The Kuldana Formation is represented by red beds in the northwest and northeast (northern Potwar) and by evaporites and various marine units in the central area (Karak, north of Makarwal). North of the MBT, but south of Khairabad Thrust, where only the foram mud facies is present in the Lockhart Limestone, three sequences are recognized: Hangu missing below, Lockhart, and a Patala marl and shale sequence above, Hangu missing below, Lockhart, and Patala red beds above, and Hangu below (mostly mudstones rather than sandstone as it is south of the MET), Lockhart, and Patala red beds above. The Patala red beds north of the MBT indicate probable terrestrial and marginal marine

deposition during the upper Paleocene-lowermost Eocene, well before the generally widespread, younger Kuldana was deposited south of the MBT.

It appears the "red" Patala is generally present in structurally higher thrust plates north of the MET, suggesting that sequences and are not on the same thrust plate as mapped. The structurally juxtaposed stratigraphies north of the MBT are significantly different than those south of the MBT and are composed of marginal marine to terrestrial. Study Area in sediments that probably represent northern Pakistan. A general shoaling area at the northern end of the Paleocene-Eocene trough that presaged the continental collision.

W/70. Weinberg, R.F., Dunlap, W.J. & Whitehouse, M., 2000. New field, structural and geochronological data from the Shyok and Nubra valleys, northern Ladakh: linking Kohistan to Tibet. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya. Geological Society, London, Special Publication 170, 253-275.

The Nubra-Shyok confluence in northern Ladakh is a key area for understanding the tectonic evolution of NW Himalaya and provides the basis for linking the geology of Pakistan to that of Tibet. The geology of the confluence area has been the subject of much speculation centered mainly on the existence of ophiolites and their regional significance. These ophiolites are thought to represent the eastward extension of the Shyok Suture Zone (SSZ), which separates the Dras island arc from the southern margin of Eurasia, and which was overprinted by movement along the Khalsar Thrust (often thought to represent the eastern continuation of the Main Karakoram Thrust). The geology of the area is relatively complex and the little information available has hampered regional geological correlations. The Khalsar Thrust (KT) and the dextral Karakoram Fault (KF), two regional tectonic features of NW Himalaya, merge at the confluence defining a triple point and three block; the Ladakh block to the south, the Saltoro block to the northwest, and the Karakoram block to the northeast. Close to the triple point, the KF changes strike and movement direction. Movement vector analysis of the triple point indicates that the KT and the two parts of the KF could have moved contemporaneously, and allows prediction of the movement vectors across the faults. The KT and KF shear preferentially volcano-sedimentary rocks of the Shyok and Nubra formations, respectively. Contrary to previous interpretations, these sheared rocks do not represent disrupted ophiolites. Regional tectonic reconstructions, however, require suturing between the Ladakh block and Eurasia and the strike of the SSZ in Baltistan suggest that the suture zone might crop out north of the KT, either along the southern slopes of the Saltoro Range or further north along the Saltoro valley. In the few outcrops of the Saltoro block we were able to visit, we found no evidence of ophiolitic rocks. Instead we found outcrops of the calc-alkaline Tirit batholith. Although our observations do not confirm the presence of the suture-related rocks in the southern Saltoro block, this possibility cannot be ruled out. Zircons from a sample of Tirit granite (U-Pb ion-microprobe age) yielded an age centered at 68 ± 1 Ma. The similar range of modal composition and age of the Tirit and Ladakh batholiths suggest that they are part of the same magmatic event. This result and a number of other observations indicate that the post-75 Ma geology of the Ladakh and Saltoro blocks is similar. Thus, if there is a suture zone in the southern Saltoro block, suturing must have occurred before 75 Ma, as concluded by others along the same tectonic boundary to the west in Pakistan. The KF represents a much younger terrane boundary, juxtaposing rocks of the Ladakh and Saltoro blocks to those of the Karakoram terrane. Rocks related to suturing of continents were not found along the KF. Karakoram leucogranites cropping out in the southern part of the Karakoram terrane yielded a U-Pb zircon age centered at 15.0 ± 0.4 Ma (2σ). Because these leucogranites were not found south of the KF, this fault must have initiated after leucogranite intrusion and must therefore be younger than 15 Ma old. At the confluence the KF cuts across the regional rocks sequence than can be followed from Kohistan into Baltistan and into the confluence area. Movement on the fault displaces the sequence by approximately 150 km to southern Tibet was the regional rock sequence could be regained.

W/72. Wells, N.A. & Gingerich, P.D., 1983. Review of Eocene Anthracobunidae (Mammalia, Proboscidea) with a new genus and species, *Jozaria Palustris* from the Kuldana Formation of Kohat (Pakistan). University of Michigan, contributions from the Museum of Paleontology, 26, 117-139.

Anthracobune and its primitive bunodont-bilophodont herbivorous allies from the Eocene of Indo-Pakistan are grouped together in a new family, Anthracobunidae. Anthracobunids are interpreted as basal "tethytheres" that are probably broadly ancestral to proboscideans, sirenians, and desmostylians. The family includes five genera and species: *Anthracobune pinfoldi* Pilgrim, 1940; *Lammidhania wardi* (Pilgrim, 1940); *Pilgrimella pilgrimi* Dehm and Oettingen-Spielberg, 1958; *Ishatherium subathuensis* Sahni and Kumar, 1980; and *Jozaria palustris* (new genus and species). Anthracobunidae may be ancestral to Moeritheriidae among primitive proboscideans and Prorastomidae/Protosirenidae among primitive sirenians; they resemble both groups in size and general cheek tooth morphology, and they appear earlier in the fossil record. Anthracobunids are primitive in having four premolars and in lacking the tusks and specialized rostra seen in moeritheriids and protosirenids. Desmostylia may also be derived from Anthracobunidae. *Jozaria* appears to have fed on soft aquatic vegetation in brackish to freshwater marshes. Some *Pilgrimella* and *Ishatherium* specimens have been found in marine deposits. These observations are consistent with the postulated amphibious habits of moeritheres and the shallow-water littoral-marine habitats of sirenians and desmostylians.

W/73. Wells, N.A. & Gingerich, P.D., 1987. Paleoenvironmental interpretation of Paleogene strata near Kotli, Azad Kashmir, Northeastern Pakistan. *Kashmir Journal of Geology* 5, 23-42.

In the Kotli area of east central Pakistan, the Subathu Formation was deposited by a single cycle of transgression and regression during the early Eocene. The marine Subathu section, which is developed on a pre-Eocene bauxite, records the successive passage of a coastal coal swamp; a very muddy shoreline; shallow and highly turbid but quiet offshore waters depositing unfossiliferous green mud and organic debris; clear and probably deeper but still occasionally turbid wear over fetid muds and marls beyond the coastal turbid zone; progressively shallower water depositing shales and higher energy limestone; an oyster bank; a delta-related submergent sand-bar complex; and a back-bar bay or lagoon that trapped river muds. Finally, progradation of a brackish coastal marsh across the bay is inferred from the succeeding slowly accumulated and completely pedogenized onshore clays. The topmost marine shale is inferred to correlate with a regional regression at the end of the early Eocene.

W/78. West, R.M., 1980. Middle Eocene large mammal assemblage with Tethyan affinities, Ganda Kas region, Pakistan. *Journal of Paleontology* 54, 508-533.

A new collection of fossil mammals from the vicinity of Ganda Kas, along the southern edge of the Kala Chitta hills, Pakistan, provides new insights into the Paleogene faunas of southern Asia. Nineteen genera are now known from Ganda Kas, one described here as new. In addition, several taxa are referred to the Cetacea, *Khirtharia* is returned to the Helohyidae and shown to be a senior synonym of *Bunodentus*, and *Pilgrimella pilgrimi* is a junior synonym of *Anthracobune pinfoldi* which is a tethythere closely allied to the Moeritheriidae. The excellent new material of *Khirtharia*, *Anthracobune* and *Lammidhania* allows more complete description of their dentitions and, in the case of *Khirtharia*, the skull, than was previously possible. The abundance and diversity of cetaceans and tethytheres at Ganda Kas suggests marked affinities of South Asian faunas with the other major Tethyan Eocene assemblage at Fayum, Egypt. Other affinities are with eastern Asia through the brontotheres and artiodactyls. *Lammidhania* is retained in the Anthracotheriidae, although it surely is atypical and may, when the upper dentition is known, belong elsewhere. The fossil mammals from Ganda Kas fit well with the coastal environment postulated for Kuldana and Kohat Formation rocks.

W/82. Whalley, W.B., 1984. High altitude rock weathering processes. In: Miller, K.J. (eds.), *The International Karakoram Project volume 1*, Cambridge University Press.

High altitude rock weathering is poorly understood both in terms of processes involved and rates of activity. As well as freeze-thaw activity which produces small blocks, larger scale rock falls appear to be common. In addition, chemical processes are probably more important at high altitude than has been generally realized. This chemical weathering can take place in either cracks or on the surface to give sand and silt-sized particles (grus). Rock surface rinds, as a form of desert varnish, appear to form where special conditions operate, although these environmental parameters are not yet elucidated. Other places show grain by grain disintegration due to weathering in micro-cracks. The varnish rinds are of complex chemical composition and show preferential enrichment of Mn and Fe over the parent rock. A variety of techniques have been used to investigate these crusts. Examples are shown

of scanning electron micrographs and Mossbauer spectroscopy which suggest formation of haematite and a gel form of $\text{Fe}(\text{OH})_3$. The form of Mn concentration is not yet known but appears to be in small nodules (1 – 2 μm diameter) on the varnish surface.

W/83. Whalley, W.B., McGreevy, J.P. & Ferguson, R.I., 1984. Rock temperature observations and chemical weathering in the Hunza region, Karakoram: Preliminary data. In: Miller, K.J. (eds.), *The International Karakoram Project 2*, 616-633. Cambridge University Press.

Air, rock surface, 5 cm deep and crack temperatures were recorded around a variety of rock types at various altitudes in the Hunza Valley in July/August 1980. Clear sky and cloudy conditions were compared. Under clear skies rock surfaces can exceed air temperatures by as much 24°C with actual rock temperatures around 40°C even at 4250m. Cloudy conditions showed smaller excess. Rock surface minima reached nearly 5°C below air temperatures under clear skies but were about the same under cloudy skies. Rock cooling rate vary considerably according to cloud cover and rock color. At 4400m the effects of chemical weathering are significant in rock breakdown. Desert varnish is rare above 3000m.

W/84. Wheeler, J., Murdie, R., Potte, G.J., Prior, D.J., Treloar, P., Butler, R.H.W.H., George, M., Harris, N.B.W. & Jones, C., 1991. Structure of northern Nanga Parbat syntaxis and its relation to the Kohistan arc. Abstract Volume, 6th Himalaya-Karakoram-Tibet workshop, Auris, France, 95-96.

The Nanga Parbat syntaxis of Pakistan is a region of basement gneiss belonging to the Indian continental plate, structurally overlain by amphibolites of the Kohistan Island Arc which were emplaced along a complex set of faults, the Main Mantle Thrust (MMT). In turn, these arc rocks are bounded to the north in the Hunza region by Asian plate metasediments, the contact being the Northern Suture. The relation between the MMT and the Northern Suture, where they approach each other in an area north of the Indus gorge, is critical to understanding the relation between the formation of the Nanga Parbat syntaxis and possible late movements on the two major sutures.

They are three lithotectonic units identified within the northern part of the syntaxis. The Iskere Unit, found on the west side, consists of migmatic orthogneiss yielding Proterozoic ages. The Shengus Unit occurs on the east side of the syntaxis in the Indus gorge and further south, and contains metapelites and calc-silicate rocks, again sometimes migmatic. In the north and northeast, immediately underlying the MMT, is the Layered Unit. This is strikingly banded on the scale of 100s of metres, consisting of biotite gneiss alternating with thick sheets of orthogneiss, sometimes garnetiferous. Sheets of marble, and boudinaged sheets of amphibolite, are common.

The Shengus and Iskere units contain sheets of amphibolite, sometimes discordant to the banding in the surrounding gneisses, and inferred to be original basic dykes. The age of these is not certain; though both dykes and gneisses share a dominant N-S trending stretching lineation, and the dykes are frequently foliated parallel to their margins. Dykes were encountered in two areas.

In the Indus gorge, field relation suggests that the dykes were less ductile than gneiss during the post-dyke deformation. The main shape fabric in dykes and gneiss, and the north-south lineation, are Himalayan in age and relate to initial emplacement of the Kohistan Arc over the Indian Plate. This main fabric is folded into a broad antiform trending NNE, slightly oblique to the lineation.

Further N near the village Iskere, dykes are arched into an antiform with a roughly N-S axis and intrude the magmatites of the Iskere Unit. The dykes are foliated, but foliation in the gneiss is poorly developed and usually N-S subvertical. The migmatites were thus relatively ridged during folding, with dykes as "easily slip" horizons accommodating flexure whilst the gneiss form a crude axial-planar fabric.

A contact interpreted as the MMT is well displayed in mountain side to the N and E of the Iskere, where it separates epidotitic banded greenschist and amphibolites from the gneiss of the layered unit. Banding in both units appears parallel to the contact. Where it is seen further S, bounding the E side of the syntaxis in the Indus gorge, the contact is vertical and the foliations on the both side is concordant. In contrast, on the W side of the syntaxis, at Sassi and further N, it is heavily modified by ductile and brittle dip-slip and oblique-slip movement.

At least 1-2 km of Kohistan amphibolites is seen above the MMT north of Iskere: these are upper-arc rock. However, glacial rubble includes abundant pale green phyllites with garbenschiefer amphiboles. This distinctive

lithology is characteristic of metasediments of the Asian Plate, and possibly the Kohistan amphibolites are roofed by these rocks. This would imply that the “Northern Suture” is not a strait subvertical join here, as it is further west in the Hunza area, but a N-dipping contact. Tourmaline pegmatites showing little deformation are present throughout the syntaxis. In addition larger granitic sheets are common and, NW of Iskere, an undeformed 2-mica leucogranite intrudes syntaxis rocks.

W/85. Wheeler, J., Potts, G.J. & Treloar, P., 1990. Asymmetric structure and uplift of the Nanga Parbat syntaxis, Pakistan Himalayas. In: Abstract volume, 5th Himalaya-Karakoram-Tibet Workshop, Milano, 64.

The syntaxis is an anomalous N-S trending structure in which the Main Mantle Thrust (MMT) in an internal part of the Himalayan belt has been warped up to expose Indian Plate continental gneisses in its footwall, rimmed by ophiolitic material of the Kohistan Island Arc in the hangingwall. We studied a transect across the syntaxis in the Indus gorge to constrain its structural evolution. On the East Side, the MMT is vertical but there are no penetrative fabrics of syntaxis age, the main fabric being interpreted as of MMT age. Crossing an antiformal core region, the steep West margin contains fabrics with steep stretching lineations and shear bands indicating down-to-West movement along this margin. This uplift was accompanied by passive rotation in the East, but active shearing on the West margin. We suggest that the syntaxis formed above a deep detachment propagating westwards, perhaps a consequence of gravity spreading in the main Himalayan chain. Sticking on this led to large-scale buckle folding in metasediments now found in the east half of the syntaxis. Subsequent shortening in orthogneisses in the west was accomplished along a shear zone steeping upwards, giving overall tilting of the existing structures. Thus we predict asymmetric uplift ages due both to a west-propagating locus of uplift and to large-scale tilting of the partly formed syntaxis along a curved shear zone.

W/87. Wheeler, J., Treloar, P.J. & Potts, G.J., 1995b. Structural and Metamorphic Evolution of the Nanga Parbat Syntaxis: The Importance of Pre-Himalayan Events. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

The Nanga Parbat syntaxis remains a focus of scientific attention in the Pakistan Himalaya due to the rapid exhumation rates inferred for its recent history. Young fission track ages (Zeitler, 1985), recent overthrusting of Indus gorge gravels by the syntaxis gneisses (Butler and Prior, 1988), and apparently very young migmatites (Zeitler et al, 1993) have all been linked to large uplift rates with accompanying rapid erosion and perhaps tectonic exhumation. However, these basement gneisses, in common with other basement complexes in young orogens, have certainly be subject to a prolonged history, not all of which relates to the Tertiary plate collision which created the present orogen. The nearest parts of the Indian foreland exposed south of the Himalayas consist of Proterozoic gneisses, and Proterozoic zircon ages (amongst others) have been reported from the Indus gorge. The task of distinguishing recent structures and metamorphic assemblages (related to the Tertiary Himalayan history) from much older features is not trivial. In this contribution we present a summary of a detailed structural and metamorphic study of the Nanga Parbat syntaxis along the Indus gorge transect. We show how the kyanite-bearing migmatites, common in the gneisses of the Indus gorge, are pre-Himalayan: their genesis does not, therefore, relate either to the Himalayan burial/exhumation cycle or to the genesis of Himalayan granites. In contrast, the gross structure and main fabric preserved in the syntaxis is Himalayan. The gneisses in the gorge form a diverse array of ortho- and paragneisses with many textural variations. A crude subdivision into “Iskere” granitoid orthogneiss in the west, and “Shengus” paragneiss in the east is, however, sufficient to illustrate the main features (c.f. Chamberlain et

al., 1989). Most of the gneisses carry strong mineral shape fabrics and also banding, sometimes clearly migmatitic. An additional key group of rocks are sheets of amphibolite on the m- to 10 m scale. We first describe structural features as investigated in the field, and then summarise the metamorphic history of the syntaxis gneisses.

Structural history

Usually, mineral shape fabrics and banding are parallel in the gneisses. The planar composite fabric appears to define a large, tight antiformal closure in the east half of the syntaxis, and a more open closure on the west side (Fig. 1). Where gneisses are adjacent to interleavings of Ladakh island arc amphibolites on the eastern margin, LS fabrics in the two units are parallel. Since the Ladakh fabrics relate to Himalayan events, we infer that the shape fabrics in the gneisses do also. Thus, the eastern margin is the Main Mantle Thrust, rotated but otherwise unmodified. Omitting much detailed complexity (Wheeler et al., submitted), lineations throughout the syntaxis are roughly N-S and inferred to be Himalayan. The large tight antiform postdates the lineations but, as the fold axis is subparallel to them, they were not severely steepened. It is likely that the antiform affected the whole nappe pile of syntaxis gneisses and Ladakh-Kohistan island arc amphibolites, as Fig. 1 suggests.

The amphibolite sheets within the gneisses commonly carry the same LS fabric, with N-S lineation, as the adjacent gneisses. However, in some places it can be seen that the margins of the sheets truncate migmatitic banding in the gneisses. Moreover, no evidence for migmatisation of the amphibolite sheets has been observed, even when they are within intensely strained and migmatised gneisses. These two key observations show that migmatisation predated the intrusion of discordant basic sheets which now form the amphibolite sheets. This relationship is commonly obscured by subsequent deformation at amphibolite facies, which formed LS fabrics in both gneisses and basic sheets and transposed earlier structures, giving the illusion that banding and mineral shape fabrics relate to the same deformation event. There is no record of Tertiary basic magmatism within the Indian plate gneisses in the Himalayan chain or in the foreland. We infer that the basic sheets are pre-Tertiary - they may be part of the Panjal Trap magmatic event, and therefore Permian. The migmatisation of the gneisses, being still earlier than this, is therefore unrelated to the Tertiary Himalayan collision. The main fabric, often transposing migmatitic banding into parallelism with other features, is Himalayan in age.

Metamorphic history

The Shengus paragneisses contain several assemblages, but a "typical" assemblage is as follows: garnet-kyanite-orthoclase-biotite-plagioclase-quartz-accessories. Garnet and orthoclase both form porphyroclasts with irregular outlines. Garnet is commonly rimmed by a corona of biotite and kyanite. The edges of such coronas are commonly streaked out into a strong shape fabric defined by quartz ribbons, aligned biotite and blades of kyanite, and streaks of polycrystalline orthoclase. The occurrence of kyanite + orthoclase shows that muscovite, which must have been present in this metapelite originally, broke down by dehydration or dehydration melting. The occurrence of garnet + orthoclase is diagnostic of more extreme conditions. Figure 2, the petrogenetic grid of Vielzeuf & Holloway (1988) shows that these two phases can only be produced on a prograde path by a biotite dehydration melting reaction above 800°C: specifically, $\text{biotite} + \text{Al-silicate} + \text{plagioclase} + \text{quartz} = \text{garnet} + \text{orthoclase} + \text{melt}$. PT estimates using the garnet-biotite geothermometer (Ferry and Spear, 1978) and the garnet-kyanite-plagioclase-quartz geobarometer (Kozior and Newton, 1988) also indicate these extreme temperatures, although substantial post-peak resetting has modified the relevant phase compositions. Inclusions of sillimanite in garnet show that this reaction happened in the sillimanite stability field on the prograde path. The kyanite-biotite coronas are best explained by partial back-reaction of melt with garnet and orthoclase: the reverse of the above reaction, but in the kyanite stability field. These reactions, involving melt, were part of the migmatisation event. Subsequent deformation involved the recrystallisation of the biotite-kyanite coronas and other phases, but no further reaction. As argued in the structural section, this was a Himalayan event, probably much later than the partial melting reactions and corona development which relate to the migmatisation. Sporadic late sillimanite and muscovite (due to ingress of small amounts of water in the sillimanite stability field) are the only new Himalayan phases to be developed in the gneisses. This metamorphic history is summarised in Fig. 2. The Iskere orthogneisses show differences to the Shengus gneisses which are not due merely to bulk chemical differences. A typical Iskere gneiss assemblage is orthoclase-biotite-muscovite-plagioclase-quartz-accessories. Assemblages including garnet and/or kyanite also occur, but never with orthoclase. Biotite and muscovite are typically strongly foliated. It would appear, then, that muscovite never broke down in these rocks, and they never experienced the same temperatures as the Shengus gneisses: yet, since in the field migmatitic textures are common, this poses a problem. Wet melting is one possibility, but we prefer a model in which the Iskere gneisses did undergo substantial melting, perhaps at conditions comparable to those in the Shengus gneisses during migmatisation. Then, melt segregated on a small scale, but remained in chemical "communication" with the restite, enabling melt to back-react thoroughly as the migmatite complex cooled. Such a process would recreate the subsolidus amphibolite facies assemblage: any grain-scale reaction textures could then have been destroyed by the later Himalayan deformation, which gave rise to the two-mica shape fabric. Thus, we suggest that

the Iskere gneisses followed the same PT path as the Shengus gneisses during migmatisation, but that large-scale melt loss from the Iskere migmatites was insignificant, leading to complete back-reaction. The Shengus gneisses lost substantial melt, so that back-reaction was incomplete and the granulite-facies restite assemblage was preserved.

In summary, a significant part of the Indus gorge syntaxis history relates to pre-Himalayan events, specifically a migmatisation episode. This produced the banding still seen in the gneisses, although any accompanying shape fabrics have been obliterated. The migmatisation caused partial melting in all rock types at temperatures above 800 °C. Melt loss was limited, so that back-reaction was important during cooling of the migmatite complex. Subsequently, a swarm of basic sheets intruded the complex. During the Himalayan collision, the gneisses and basic sheets were intensely deformed at amphibolite facies, but there is no evidence for any further partial melting. Thus, these kyanite migmatites differ not only in grade but also in age from the reputedly Himalayan cordierite migmatites found further south. The pre-Himalayan inheritance of the basement gneisses cannot be ignored in any model for the Himalayan evolution of the Nanga Parbat syntaxis.

W/88. White, M.G., 1966. Copper, lead, zinc, antimony and arsenic in West Pakistan. US Geological Survey/Geological Survey of Pakistan, (IR) PK-4, 39p.

Copper localities that merit geological investigation are found in the western Chagai district, in North Waziristan agency and in the Salt Range in Mianwali and Sarrgodha Districts. No high-grade deposits have been reported from these areas and if deposits are developed they will likely be low-grade, high-tonnage, disseminated deposits. Those localities reported from Chitral State are too remote and inaccessible to be of interest now. All lead localities found to date are of minor importance; there has been small production at one locality in Chagai District and in the southern part of the Hazara District. Zinc, antimony, and arsenic are sparse in Pakistan and no important localities of these metals are reported. No base metals are reported in East Pakistan.

W/89. Whittington, A., 1995. The Thermal Evolution of Nanga Parbat, Northern Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

The Nanga Parbat - Haramosh Massif (NPHM) is a tongue of underthrust Indian Plate Precambrian basement exposed for 100 km protruding northwards into the Asian Plate, at the western end of the Himalaya. Geochronological studies over the past decade have shown that the whole massif has been exhumed exceedingly rapidly (up to 7 mm/y) over the past 5 Ma. In addition, Ar-Ar dating linked with detailed structural studies has shown that the recent exhumation is most rapid on the western margin, due to a combination of thrust and transpressive strike-slip faulting. This study concentrates on the southern part of the massif, around Nanga Parbat (8125m). Here recent structures related to rapid Pliocene & Pleistocene exhumation can be observed overprinting older Main Mantle Thrust structures associated with collision and initial crustal thickening. The present study relates the various stages of metamorphism and magmatism to the structural history and tectonics of Nanga Parbat. Preliminary Ar-Ar analyses on pelitic gneisses have yielded ages of 1.8 to 2.0 Ma for muscovite, and 2.3 to 3.1 Ma for biotite. The older biotite ages imply the presence of excess argon, so that the closure ages recorded are absolute maxima. These maximum muscovite ages of 2.0 Ma imply a minimum average cooling rate of 165°C/m.y. over the past two million years. For an arbitrary geothermal gradient of 40°C/km this represents an average exhumation rate of >4 mm/y. Initial results of thermal modeling shows that rapid exhumation can lead to very high near-surface geothermal gradients, and that the pronounced topography around Nanga Parbat may produce non-horizontal isotherms. The assumptions of horizontal isotherms and modest geothermal gradients are made in calculating exhumation rates from fission track data, and there may be significant over-estimation of these rates in the literature. The aim of future work is to integrate the results of various other techniques into a more detailed thermal model for the evolution of this part of the massif.

W/90. Whittington, A. & Harris, N., 1995. Anatexis of the Nanga Parbat Massif, Northern Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

An unusual thermal history of the Nanga Parbat-Haramosh Massif (NPHM) is indicated both by anatectic leucogranites of unusually young age (< 10 Ma) and by the recognition of even younger cordierite-spinel anatectic melts hitherto unknown to the Himalayan orogen. The NPHM forms a northward kink in the suture (MMT) between the Indian Plate and Kohistan Island Arc at the western end of the Himalaya. A combination of thrust and transpressive strike-slip faulting has resulted in unusually rapid exhumation rates (~ 7 mm/yr) of the western margin of the massif over the past 5 Ma^{1,2}. Recent compressional structures related to this rapid exhumation can be observed overprinting older MMT structures associated with collision and initial crustal thickening. Basement lithologies from the NPHM have undergone a complex thermal history involving at least three phases of anatexis. Migmatitic pelitic gneisses with anatectic leucosomes are cross-cut by amphibolitic sheets, probably of pre-Himalayan age³. These migmatites are intruded by tourmaline-two mica leucogranite dykes and plutons which are syn-tectonic with respect to exhumation structures. The NPHM leucogranites are similar in major-element geochemistry to High Himalayan leucogranites (intruded at ~ 20 Ma) exposed along the length of the Himalaya⁴, even though much younger ages (2.3 - 7 Ma) are indicated by ionprobe studies of accessory phases from NPHM intrusives⁵. Trace element abundances differ from those of High Himalayan leucogranites in that Rb/Sr ratios are significantly higher as are concentrations of Y, U and Th. Ba abundances are lower in the NPHM intrusions. Such variations suggest low degree partial melts from a pelitic source of unusually radiogenic character. Melting could be induced by a combination of high internal heat production and by rapid exhumation under vapour-absent conditions. Leucogranite emplacement was post-dated by local anatexis forming granitic pods, rarely more than 50 cm in diameter, within kink bands and shear zones. Both peritectic cordierite and spinel have been observed suggesting that biotite breakdown has occurred under fluid-present conditions, presumably due to local fluid ingress along structurally favourable channels. Further studies of such melts may constrain the behaviour of crustal fluids following rapid exhumation of the massif.

W/91. Whittington, A., Harris, N.B.W., Ayres, M.W. & Foster, G., 2000. Tracing the origins of the western Himalay: an isotopic comparison of the Nanga Parbat massif and Zaskar Himalaya. In: Khan, M. A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 201-218.

New Sr and Nd isotope data for basement gneisses and leucogranites are presented from two contrasting areas of the western Himalaya; the Nanga Parbat-Haramosh massif (NPHM) and Zaskar. Sr-isotope systematics of metapelites and anatectic migmatites from the Zaskar Himalaya are characterized by ϵ_{Sr} of 515-930, typical of the High Himalayan Crystalline unit as exposed for more 2000 km along strike. Moreover, Zaskar leucogranites are typical of the belt of Early Miocene granites intruding the High Himalayan Crystalline across the orogen (mean $\epsilon_{\text{Sr}} = 834$). In contrast, the NPHM leucogranites show an elevated average ϵ_{Sr} of 2400, and basement samples show a wide range in ϵ_{Sr} from 1850 to 8150. Errochrons for the metasedimentary gneisses indicate isotopic homogenization of the basement at c. 500 Ma for the Zaskar samples compared with c. 1800 Ma from the NPHM, confirming that the two terrains have experienced contrasting pre-Himalayan histories. Nd isotopic data from the NPHM indicate model ages from 2300 to 2800 Ma, indicating the mean crustal formation ages of the protoliths from which the sediments were derived. A compilation of published Nd data from the Himalaya indicates average protolith formation ages of 2640 ± 220 Ma for the Lesser Himalaya lithologies, compared with 1940 ± 270 Ma for High Himalaya unit. Gneissic lithologies from Zaskar and the NPHM have previously been correlated with the High Himalayan Crystalline Series, since both display high-grade Himalayan metamorphism and are intruded by syn-to post-tectonic tourmaline-bearing leucogranites. Isotopic systematics in the Zaskar region confirms this correlation. In contrast, the NPHM basement rocks are better correlated with Lesser Himalayan lithologies, exposed south of the Main Central Thrust. We conclude that the NPHM represents either a lower structural level of the Lesser Himalaya Series, or its protolith.

W/92. Whittington, A., Harris, N. & Butler, R., 1996. Field and analytical constraints on thermal evolution of the Nanga Parbat Massif, Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona (USA), 168-169.

In this contribution, a multidisciplinary approach elucidates the thermal and magmatic history of a rapidly exhuming terrane in the Western Himalaya. Inverse modeling allows investigation of the P-T-t path for exposed rocks from collision to exhumation constrained by geochronologic and thermobarometric data. We specifically address the problem of melt formation by considering the interaction between transient geotherms and fluid infiltration during rapid exhumation. The Nanga Parbat Syntaxis, or Nanga Parbat-Haramosh Massif (NPHM), forms a northward kink in the suture between the Indian Plate and Kohistan Island Arc at the western end of the Himalaya. A combination of thrust and transpressive strike-slip faulting has resulted in unusually young cooling rates on the western margin of the massif over the past 5 Ma (1). Recent compressional structures related to this rapid exhumation can be observed overprinting older Main Mantle Thrust (MMT) structures associated with collision and initial crustal thickening (2). The Tato Valley which runs north from the peak of Nanga Parbat to the Indus Valley at Raikot Bridge is particularly problematic for geochronological and thermal modeling studies due to (i) its exceptionally high cooling rates, interpreted to indicate rapid and increasing exhumation rates of 7mm/year (1) and (ii) its unparalleled topography of 7 km vertical relief over a horizontal distance of 21 km. The basement Indian Plate lithologies exposed in the massif have a polymetamorphic history, as indicated by pre-Himalayan amphibolite dykes cross-cutting some migmatitic fabric. Small tourmaline leucogranite plutons and sheets show sharp cross-cutting relations and are undeformed except in shear zones related to recent exhumation. All fabrics and units are overprinted in the core of the massif by cordierite-bearing granitic pods, which form preferentially in small conjugate shears with kinematics consistent with vertical stretching. Thermobarometric data from equilibrium pelitic assemblages suggest peak metamorphic conditions of $700 \pm 60^\circ\text{C}$ and $4.4 \pm 0.6\text{ kbar}$ (3). Some assemblages record higher pressures of about 6kbar at similar temperatures, suggesting a near-isothermal decompression path during exhumation. Published U/Pb ages on accessory minerals suggest that this is latest episode of high-grade metamorphism is Pliocene in age, broadly coeval with formation of the leucogranites (4,5). In present day study, $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology has been used to determine the exhumation path of these rocks, and while excess argon renders biotite ages only useful as upper limits to the timing of closure, muscovite ages suggest that these rocks cooled through about 445°C as recently as 1.8 Ma. Geochemical constraints indicate an origin for the leucogranites by fluid-absent muscovite breakdown (decompression melting) during exhumation. Accessory phase thermometry calculations indicate that melting occurred at temperatures of $710 \pm 10^\circ\text{C}$, consistent with such a fluid-absent melting reaction. Sr-isotope systematics can be used to find the precise crustal source of the granites. Data from leucogranite plutons define a narrow range of $^{87}\text{Sr}/^{86}\text{Sr}$ ratios between 0.87 and 0.90. Samples of basement gneisses from the massif define a much broader field from 0.77 to 1.25. This wide range of isotopic ratios suggests that pervasive fluid infiltration through the basement has not occurred, and confirms that lithologies are available in the massif with sufficiently radiogenic Sr to source the granite plutons. The likely source was geochemically similar to metapelites within the outcropping gneisses but lay at greater depth than lithologies exposed at present erosional levels. The most recent melt-forming episode, associated with melting of metapelites and local formation of pneumatolytic cordierite-granite pods, resulted from biotite breakdown during infiltration of an aqueous fluid along small shear zones. The combination of geochronologic and thermobarometric results provides powerful constraints on thermal models of the evolution of the NPHM between 50 Ma and the present day. Further limits can be imposed by structural arguments which bracket total exhumation since 50 Ma as between about 30 and 35 km, and the absence of large melt volumes exposed at the surface which indicates that fertile levels of NPHM crust did not cross the vapour-absent biotite solidus for pelitic assemblages. One-dimensional thermal models indicate that the unusually young cooling ages from this area do not necessarily imply extreme or rapidly increasing exhumation rates, because the advection of heat resulting from rapid exhumation leads to a steepened near-surface geotherm. The most important control on the present-day thermal structure of the NPHM appears to be the thermal structure resulting from obduction of the Kohistan Arc some 50 million years age. Transient geotherms calculated for the past 10 Ma can only be reconciled with published geochronological and thermobarometric studies if exhumation rates lay in the range of 3 to 4 mm/year, still considerably greater than exhumation rates determined from the main Himalayan orogen. Exhumation paths fitted to the cooling age data and calculated P-T fields require leucogranite formation at realistic depths (sources 2 to 5 km below present levels of exposure) times (2 to 8 Ma). Multidisciplinary approaches on samples from a restricted spatial area allow a well-constrained thermal and metamorphic history to be inferred. At Nanga Parbat the complex magmatic history is controlled by both the evolving thermal structure, involving relaxation of transient geotherms and recent telescoping of isotherms due to rapid exhumation, and fluid infiltration at moderate depths (<10-15 km).

W/93. Whittington, A.G., 1996. Exhumation overrated at Nanga Parbat, northern Pakistan. *Tectonophysics* 260, 215-226.

New $^{40}\text{Ar}/^{39}\text{Ar}$ laserprobe and thermobarometric data from the Nanga Parbat-Haramosh Massif (NPHM) in northern Pakistan provide important constraints on thermal models of the evolving geotherm of the massif. Simple thermal models indicate that the unusually young cooling ages from this area do not necessarily imply extreme exhumation rates of about 7 mm/y, because the advection of heat resulting from rapid exhumation leads to a steepened near-surface geotherm. The most important control on the present-day thermal structure of the NPHM appears to be the thermal structure resulting from obduction of the Kohistan Arc some 50 m.y. ago. Transient geotherms calculated for the past 10 Ma can only be reconciled with published geochronological and thermobarometric studies if exhumation rates lay in the range of 3 to 4 mm/y, still considerably greater than exhumation rates determined from the main Himalayan orogen.

W/95. Whittington, A.G., Foster, G.L., Harris, N.B.W. & Ayres, M.W., 1999. Lithostratigraphic correlation in the western Himalaya-an isotopic approach. *Geology* 7, 585-588.

We present the results of a whole-rock Nd isotopic study of two contrasting regions of the western Himalaya, using the neodymium model age approach on the scale of a single orogen. High-grade metasedimentary rocks from Zaskar yield model ages (TDM) that are similar to those of the High Himalayan Crystalline Series (TDM = 1.2–2.0 Ga; ϵNd = –6 to –16) and distinct from values from the Lesser Himalaya (TDM = 2.3–3.4 Ga; ϵNd = –18 to –27). Hence these two lithological sequences can be recognized for 2000 km along the strike of the orogen. Data for the basement of the Nanga Parbat massif at the western extremity of the Himalaya (TDM = 2.3–2.8 Ga; ϵNd = –18 to –30) suggest that these rocks are not equivalent to the High Himalaya, as previously supposed, but have affinities with the Lesser Himalaya. A thin metasedimentary cover sequence on the margins of the Nanga Parbat massif is isotopically indistinguishable from the High Himalaya (TDM = 1.6–1.8 Ga; ϵNd = –10 to –14). The prior misidentification of the provenance of the massif stems from its high metamorphic grade, characteristic of the High Himalaya, but in this case related to the unique Neogene history of the Nanga Parbat massif, which has exhumed a higher-grade equivalent of the Lesser Himalaya that is not seen elsewhere.

W/96. Whittington, A.G., Harris, N.B.W., Ayres, M.W. & Foster, G.L., 1998. Where did Nanga Parbat come from? *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 211-212.

The Nanga Parbat-Haramosh Massif (NPHM) is the most northerly exposure of Indian Plate basement, and forms a syntaxial loop at the northwestern end of the Himalayan orogen. It is bounded to the north by the Main Mantle Thrust (MMT), locally overprinted by more recent strike-slip and reverse faults that separate the NPHM from the Kohistan-Ladakh island arc terrane. The NPHM has long been considered to be a westward extension of the Higher Himalayan Crystalline Unit (HHC), which outcrops further east in the main orogen, in part because of its similarly high metamorphic grade, and in part because both the HHC and NPHM host tourmaline-bearing leucogranite bodies of Eocene age or younger. The leucogranites from both regions have similar geochemistry, indicating generation from a pelitic source by vapour-absent "decompression" melting (Harris and Inger, 1992). However, several discrepancies have become apparent in recent years between the P-T-t path followed by the NPHM and HHC terranes. For example, leucogranites at Nanga Parbat have crystallisation ages as young as 1 Ma (Zeitler and Chamberlain, 1991), compared to typical ages of 18 to 22 Ma for Higher Himalayan leucogranites (Harrison et al., 1997). Geochronological studies have revealed that Nanga Parbat is currently being exhumed at a rate of at least 3

mm/y (Whittington, 1996), that has resulted in an elevated geothermal gradient and exceptional topography, thus promoting vigorous fluid flux throughout the massif. These factors have in turn led to a second melting episode, generating small cordierite-bearing restitic assemblages localised in shear zones that are not observed in the main orogen (Whittington et al., 1998). Thus the timing of both exhumation and anatexis at Nanga Parbat differs from that seen in the central Himalayan orogen. Isotopic systematics of rocks of the NPHM and the HHC in Zaskar, the nearest outcrop of HHC to the NPHM, suggest different histories for the two terranes. NPHM leucogranites are exceptionally radiogenic, with ($^{87}\text{Sr}/^{86}\text{Sr}$) ratios of about 0.877 and ϵNd of -23 (present day), compared with ($^{87}\text{Sr}/^{86}\text{Sr}$) ratios of 0.74 to 0.78 and ϵNd of -13 to -17 for High Himalayan leucogranites from Zaskar (Ayres, 1997). When plotted on an errorchron diagram, Nanga Parbat basement lithologies display a trend corresponding to between 2100 and 2400 Ma, while Zaskar rocks display a trend corresponding to about 500 Ma, for both Rb-Sr and Sm-Nd systems. Supporting evidence Proterozoic events from the NPHM terrane comes from amphibolite sheets which cross-cut the oldest gneissic fabrics are characterised by Nd model age of 2200-2400 Ma; (ii) previously published zircon core ages from the NPHM cluster around 1850 Ma for the Iskere gneiss, and 500 and 2500 Ma for the Shengus gneiss (Zeitler et al., 1989; Zeitler et al., 1993). Thus isotopic evidence suggests that the NPHM basement is much older than the HHC unit, and the two cannot be correlated. These results pose the question of whether the NPHM basement unit is unique to this area, exposed locally by the exceptional exhumation history of Nanga Parbat, or does it outcrop elsewhere in the Himalayan orogen? Lesser Himalayan lithologies, exposed in the footwall of the MCT in the main orogen, are comprised of a metasedimentary succession, but have attained a much lower metamorphic grade. Published zircon ages from the Lesser Himalaya (1870 to 2600 Ma, Parrish and Hodges, 1996) are quite distinct from those found in the HHC unit (800 to 1000 Ma, *ibid.*), but match ages from the NPHM. While Himalayan-age granite magmatism is unknown in the Lesser Himalaya, the abundance of pelitic lithologies makes this sequence a fertile source, and the Nanga Parbat leucogranites reproduce the isotope systematics that would be expected if these rocks were melted during decompression. Cambro-Ordovician granites do occur in the Lesser Himalaya, and the leucogneisses found in the southern NPHM may represent their metamorphosed equivalents. An orogenic event of this age may also explain the presence of 500 Ma ages in some zircon cores from the Shengus gneiss, but clearly did not result in isotopic homogenisation on a bulk-rock scale. Hence in answer to the question, where did Nanga Parbat come from, it is possible that the c. 30 km of erosion experienced by Nanga Parbat in the past 10 Ma has exposed Lesser Himalayan basement rocks through the Kohistan island arc terrane. This raises a further question, what happened to the HHC rocks overlying the Lesser Himalayan sequence? Work in progress on the margins of the NPHM that seeks to address this question (Foster et al., this volume) is further complicated by the lack of a well-defined MCT in northern Pakistan, in contrast to the relatively uniform stratigraphy seen in the main orogen.

Tourmaline-bearing two-mica granite plutons and sheets intruding the basement lithologies of the Nanga Parbat-Haramosh massif represent the youngest known occurrence of High Himalayan leucogranite magmatism. Trace-element modeling using Rb, Sr, and Ba indicates an origin by vapor-absent muscovite melting. Accessory phase modeling suggest that anatexis occurred at temperatures of $\sim 720^\circ\text{C}$, and therefore depths of 20-25 km. The source of one such intrusion (the Tato pluton) is considered to be metapelitic gneiss similar to that cropping out in the massif, and isotopically distinct from the source of the Miocene Himalayan leucogranites. Initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of ~ 0.88 for the Tato pluton compare with 0.74-0.78 for Miocene granites intruded into the central Himalayan orogen.

Subsequent to, or coeval with, leucogranite emplacement, small cordierite-bearing leucosomes have been generated in ductile shear zones within the interior of the massif. These are geochemically variable, but are consistently characterized by strong depletion in high field strength elements and other incompatible trace elements. Petrographic and geochemical constraints indicate that at least some seam may be restitic, following localized incongruent melting of biotite in the presence of a fluid yielding a high melt fraction ($F \sim 0.5$). Other seams may be wholly or partly subsolidus in nature. Thermo-barometric data from these seams indicate that channelled fluid migration within the massif occurred at pressures <400 Mpa and temperatures of about 630°C. Geochemical constraints on contrasting granitic rocks from the interior of the Nanga Parbat-Haramosh massif chart a changing regime from fluid-absent anatexis in the mid-crust (~20 km depth) to fluid infiltration during ductile deformation in the upper crust (~10 km depth). These findings are consistent with the rapid exhumation of the massif with more modest exhumation rate around the margins.

W/99. Whittington, A.G., Kelley, S.P. & Harris, N.B.W., 1998. Fluid flow in the Nanga Parbat-Haramosh Massif: the use and interpretation of argon isotopes. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 210-211.

An extensive dataset of 175 $^{40}\text{Ar}/^{39}\text{Ar}$ analyses of mica separates are presented from the Nanga Parbat-Haramosh Massif, an actively deforming syntaxial region that forms the western Himalaya. Three critical areas were selected for sampling in order to distinguish genuine spatial and temporal patterns of cooling from the spurious effects caused by inherited excess argon. The majority of ages are interpreted as recording regional cooling due to rapid exhumation within the last 10 Ma. Younger ages of less than 1 Ma from leucogranite sheets and plutons approximate to intrusion ages, and support field evidence for magma emplacement into relatively cool country rocks by fracture flow rather than by diapirism. The widespread occurrence of "excess" argon, i.e. gas of unknown composition trapped at the time of closure, results in anomalously old ages that require multiple total fusion analyses of single grains to determine the true ages of geological events. The use of isotope correlation diagrams for multiple analyses enables some confidence to be placed in the resulting age, and the composition of non-radiogenic argon trapped at the time of closure may be used as a tracer of fluid pathways. In the interior of the massif, incorporation of excess argon suggests the presence of magmatic and/or metamorphic fluids at depth, while in the Liachar Shear zone on the western margin of the massif, the incorporation of argon with an atmospheric composition suggests circulation of meteoric fluids at shallower levels.

W/101. Williams, M.P., 1989. The geology of the Besham area, north Pakistan: deformation and imbrication in the footwall of the Main Mantle Thrust. Geological Bulletin, University of Peshawar 22, 65-82.

The gneisses, granites and metasediments of the northern exposed margin of the Indian plate in the Besham antiform consist of a Precambrian crystalline basement with younger sedimentary cover. These were metamorphosed during the main fabric-forming event of the Himalayan orogeny, a ductile simple shear dominated deformation of the footwall of the MMT during southward overthrusting of the Kohistan Arc. Deformation intensity and ductility decrease southwards. Subsequent thrusting brought together internally imbricated blocks, which have different deformation/metamorphic histories. High-grade rocks thrust over low-grade rocks within each block define an inverted metamorphic gradient produced by post-metamorphic thrusting. Major cross folding producing the Besham antiform, plus brittle faults are expressions of the later N-W directed backthrusting and E-W compression and uplift of the Besham area.

W/104. Willis, B.J. 1993a. Ancient river systems in the Himalayan foredeep, Chinji village area, northern Pakistan. *Sedimentary Geology*, 88, 1-76.

The Miocene Chinji and Nagri Formations (Siwalik Group) of northern Pakistan record ancient fluvial environments in the Himalayan foredeep basin. Excellent exposures on the Potwar Plateau (Chinji Village area) allowed detailed documentation of the geometry and stacking of sediment bodies that comprise these strata, and of variation of large-scale bedding geometry, grain size, sedimentary structures and paleocurrent orientations within such bodies. Major sandstone bodies are tens of meters thick and are continuous along strike for many kilometers. They are composed internally of interconnected channel belt deposits, each of which contain several storeys (channel bar and fill deposits). Individual storeys, defined by inclined bedsets dipping down to a major basal erosion surface at up to 11°, are only 5 to 15 m thick within the Chinji Formation but can be up to 30 m thick within the Nagri Formation. Bedsets within storeys reflect sediment accreted during individual flood events. Along-strike variation of bedsets within storeys and the stacking patterns of storeys within channel belt deposits reflect changes in the channel bed through time due to the growth of bars, migration of channels, and channel cutoff. Generally, braided channel patterns are indicated by the relatively large number of storeys within individual channel belt deposits exposed perpendicular to paleoflow, abundant evidence for channel bar superposition due to channel switching, local evidence for mid-channel bars, dominance of coarse-grained channel fills, and low paleocurrent variations. Paleochannel reconstructions from storeys exposed within the Chinji Formation indicate that individual channel segments generally had widths of 80–200 m, maximum depths of 4–13 m, wavelengths of 1.6–2 km and discharges of 400–800 m³/s. Full channel belt widths (1–2 km) estimated from exposures perpendicular to paleoflow, and evidence for 2–3 coeval channels within channel belts, indicate full channel discharges of 1500–2000 m³/s. Larger channel segments reconstructed from the Nagri Formation had widths of 200–400 m, maximum depths of 15–30 m, wavelengths of 3–5 km, and discharges of 3000–5000 m³/s. As Nagri Formation channel systems were also clearly braided, full channel dimensions and discharge estimates are probably at least a factor of two greater than for individual channel segments (i.e. order of 10,000 m³/s).

Strata between major sandstone bodies are dominated by lobate and wedge-shaped bodies (crevasse splay and levee deposits), minor channel-form bodies (deposits of minor floodplain channels), laminated mudstone bodies (lake deposits) and paleosols. These strata are arranged into meters to 10 m thick stratified sequences that were rapidly deposited, bounded by well developed paleosols recording periods when deposition rates were low. The thickness and grain size of such paleosol bounded sequences are not directly related to the proximity of a major channel deposit along strike. Instead, such sequences within overbank deposits appear to reflect local progradation of splays and levees into low areas on the floodplain.

W/105. Willis, B.J., 1993b. Evolution of Miocene fluvial systems in the Himalayan foredeep through a two kilometer-thick succession in northern Pakistan. *Sedimentary Geology*, 88, 77-121.

Sedimentological variations through a kilometer-thick coarsening-upward succession in the Miocene Himalayan foredeep basin (fluvial Chinji and Nagri Formations of the Siwalik Group) are documented in the Chinji Village area on the Potwar Plateau of northern Pakistan. From the Chinji Formation upwards into the Nagri Formation: (1) the proportion of major sandstone bodies increase relative to mudstone-dominated beds; (2) average thickness and mean grainsize of channel deposits increase; (3) sediment aggradation rates increase; (4) there is a reported change in sediment provenience; (5) paleocurrents are generally to the southeast and vary little upsection; and (6) paleosols are more distinct lower in the section where there is also more evidence of ponding of water on the floodplain. Smaller-scale (100 m thick) cyclic variations in the proportion of major channel sandstone bodies also occur in both formations.

In the modern Himalayan Basin, sediment dispersal away from the mountain belt is associated with: (1) major rivers that flow along the basin axis; (2) large rivers that drain substantial areas of the mountain belt and deposit low relief sediment fans extending hundreds of kilometers into the basin; and (3) smaller rivers in fan and interfan areas that drain local areas and carry finer sediment loads. Sediment variations through the Chinji-Nagri Formation boundary can be related to a shifting of depositional environments within such fan and interfan areas. Major basin-axial rivers are not exposed in this area. It appears that kilometer-thick upsection variations in these deposits record the progradation of the sediment fan formed by a large river system (river discharge on the order of 104 m³/s) over the floodplain of a smaller river system (river discharge on the order of 103 m³/s).

Large-scale vertical sediment variations over hundreds of meters to kilometers appear to reflect changes in the basin subsidence and the rate of sediment input to the basin over time scales on the order of 105–106 years. Upsection variations can not easily be related to climatic change or eustatic variations in sea level. The most likely explanation for upsection changes is tectonism. Deposition rates and shifting positions of river systems within the basin responded more quickly to changes in basin subsidence rate, whereas increases in the proportion of sandstone bodies and increases in floodplain slopes lagged behind. Deposit variations in the Siwalik Group clearly record variations between different-scale river systems delivering sediment to the basin as well as the overall basin evolution.

W/106. Willis, B.J. & Behrensmeyer, A.K., 1995. Fluvial systems in Siwalik Miocene and Wyoming Paleogene. *Palaeogeography, Palaeoclimatology, Palaeoecology*, 115, 13-35.

The 3 km thick Miocene Siwalik Group (Himalayan foredeep in northern Pakistan) and the 2 km thick Paleogene Fort Union/Willwood formations (Bighorn Basin in Wyoming) both preserve long records of fluvial deposition adjacent to rising mountain belts. Depositional environments and associated habitats change across large basins along with changing physiography and with the location of different river systems that may have varied greatly in patterns of channel deposition and the drainage of adjacent floodplain areas. Deposits exposed in these two basins provide very different records of shifting paleoenvironments and patterns of basin filling. These differences reflect distinct patterns and scales of depositional environments. The nature of the exposures, and the types of sedimentologic studies that have been carried out in each basin.

The Siwalik Group fills a basin that extended at least 1000 km along its axis and 150–250 km away from the mountain front. Comparison of Siwalik deposits and modern drainages in the Himalayan foredeep suggests the ancient Siwalik basin was filled by large rivers that deposited low gradient sediment fans covering areas on the order of 1000 km², and by smaller intrafan rivers with more poorly drained floodplains. Despite the scale of these river systems relative to Siwalik exposures in Pakistan, transitions between different systems have been recognized. Deposits of coeval river systems in the Siwalik Basin show pronounced differences in alluvial architecture, the character of overbank deposits, and the abundance and taphonomy of organic remains.

In contrast, the Bighorn Basin in Wyoming is a relatively small intermontane foreland basin extending 200 km along its axis and about 80 km across. Bighorn Basin strata were deposited by a river that flowed south to north along the basin axis and by smaller rivers that flowed transverse to the basin axis. Much of this basin is exposed and thus it is possible to reconstruct changing patterns of deposition and environments through time in more detail than in the Siwalik Basin. These patterns indicate changes in basin-wide drainage conditions and environments through time, but there are also important differences among coeval strata.

Upsection shifts in environments and vertebrate faunas within both the Siwalik and Bighorn Basins may reflect tectonic or climatic forcing, but this comparison emphasizes the importance of recognizing deposits from different contemporaneous river systems before inferring such large-scale controls on paleoecological change through time.

W/107. Willis, B.J. & Behrensmeyer, A.K., 1996. Architecture of Miocene overbank deposits in northern Pakistan. *Journal of Sedimentary Research, Section B-Stratigraphy & Global Studies* 65, 403-407.

The paper presents a description and analysis of the architecture of ancient overbank deposits from the Miocene Chinji Formation of northern Pakistan (see also Behrensmeyer, 1987, Willis, 1993a). The authors described meters-thick paleosol bounded sequences that are defined by an alternation of relatively mature paleosols and stratified deposits with a lesser degree of pedogenesis. They asserted that the mature paleosols represent relatively long periods of very low deposition rate, whereas the stratified deposits represent relatively short periods of high deposition rate. They proposed and evaluated five end-member hypotheses for the origin of the paleosol-bounded sequences. It is concluded that the stratified deposits were formed by local rapid filling of low areas on the flood plain, independently of the position of major channels: such filling may have been a more or less continuous process, or may have been a short-lived event associated with river-channel avulsion. They specifically dismissed the possibility that the nature of the stratified deposits was related to the proximity of major channels and the growth of alluvial ridges. They also dismissed the possibility that paleosol-bounded sequences could have been related to regional variations in sediment supply and deposition rate, or to valley incision and filling.

W/109. Windley, B.F., 1981. Phanerozoic granulites. *Journal of the Geological Society, London*, 138, 745-751.

Granulites can form at every stage of the Wilson cycle: during plate accretion (Mid-Atlantic Ridge), in active plate margins of island-arc and Andean type (Ivrea Zone, main complex in Kohistan in the Karakorums), in the roots of Andean-type batholiths (Coast Range Complex, British Columbia; Santa Lucia Range of California), during the closure of a marginal basin (Aracena belt, Spain), during Himalayan-type collision (Jijal Complex in the Karakorums of N Pakistan and at l'Agly in the Pyrenees) and during post-tectonic intrusion at depth (São Paulo, Brazil). Himalayan-type orogenic belts may, in principle, contain any of such granulites. The majority of granulites form along active plate margins in the roots of magmatic arcs, which are the main sites of crustal growth in the Phanerozoic. Layered stratiform complexes, formed largely by cumulate processes, are common in Phanerozoic granulites (Kohistan, Ivrea, Calabria in Italy, Cabo Ortegal in NW Spain, Brittany and N Pyrenees). Their granulite-grade parageneses may have formed during cooling from an igneous temperature, or during superimposed metamorphism. Variations in the types of granulites may help in understanding how different types of lower continental crust are constructed.

W/110. Windley, B.F., 1983. Metamorphism and tectonics of the Himalaya. *Geological Society London Journal* 140, 849-865.

Metamorphism connected with the main growth and deformation stages of the Himalaya ranges from mid-Cretaceous to the Quaternary. Northward subduction gave rise in the early to mid-Cretaceous to an island arc complex with greenschists, amphibolites, granulites and blueschists in the W (Kohistan-Ladakh) and an Andean-type margin with greenschist-amphibolite grade metamorphism in the E (India and Tibet). Ophiolitic nappes were thrust southwards over the Indian continental margin in the Palaeogene during the final stages of closure of the southern arm of Tethys. The Indus-Zangbo Suture bifurcates westwards and between the two sutures lies the Kohistan-Ladakh island arc which was converted to an Andean-type arc in the Palaeocene-Eocene. The Karakorum Range underwent northward subduction at least during the late Cretaceous to give rise to a complex and prominent calc-alkaline batholith. Post-collisional southward thrusting of crustal slabs over the Indian continental margin took

place in the early Miocene with production of high-grade metamorphism, inverted isogrades and crustal melt granites. Later southward thrusting in the Pliocene to Quaternary gave rise to localized low-grade recrystallization against the thrusts.

W/112. Windley, B.F., 1985. Geochemical and time constraints on the evolution of the Kohistan arc-batholith, Pakistan. Abstract Volume, 1st Himalayan Workshop, Department of Geology, University of Leicester.

The Kohistan arc-batholith went through three stages of growth. New Rb-Sr isochron dates are by M.G. Petterson, an ³⁹Ar/⁴⁰Ar date is by D. Rex and geochemical data are by I. Luff and M.G. Petterson. We do not know when the island arc began to form. The Yasin Group Sediments which were deposited in intra-arc basins (C. Pudsey) contain Albian-Aptian faunas. The arc pluton consist of a bimodal suite of low-K tonalitic and high-K diorite gneisses, one of which has a Rb/Sr age of 102±12 Ma. The overlying Chalt Volcanics comprises pillowed primitive basaltic tholeiites succeeded by andesites, dacites and rhyolites, typical of many mature island arcs. The Chilas Complex consisting of norites and layered cumulates formed by deep-level fractionation (dominated by orthopyroxene precipitation) from the magma, which gave rise to the island arc. All these rocks were deformed by major fold structures, which are correlated with the formation of the Northern Suture, after which the island arc was intruded by an Andean-type calc-alkaline batholith on the northern active continental margin of Tethys. The first expression of the I-type batholith was the intrusion of a swarm of NE-SW trending hornblende diorite dykes, one of which has a ³⁹Ar/⁴⁰Ar hornblende age of 75 Ma. The main constituent of the batholith is a suite of medium-K intrusions emplaced throughout its evolution, which ranges from gabbro to granite, though the dominant rock type is granodiorite. In the Gilgit area this suite is intruded by high-K diorite plutons. Two plutons near Gilgit have Rb-Sr isochron ages of 54±4 Ma and 40±6 Ma. Limited Sr-isotope data indicate a dominantly mantle source for the batholith and trace element patterns are typical of subduction-related magmas. The Dir-Utror Group of calc-alkaline lavas (and sediments with Eocene fossils) are probably remnants of the volcanic cover of the batholith. Following formation of the Indus Suture in the Eocene, the batholith was intruded by an intense swarm of layered aplite-pegmatite, S-type granite, sheets at 34±14 Ma and 29±8Ma, as a results of partial melting of the island arc crust thickened tectonically and/or by magmatic accretion or of the underplated Indian below the arc.

W/113. Windley, B.F., 1988. Tectonic framework of the Himalaya, Karakoram and Tibet, and problems of their evolution. *Philosophical Transactions of the Royal Society, London*, A326, 3-16.

The Himalaya, the Karakoram and Tibet were assembled by the successive accretion to Asia of continental and arc terranes during the Mesozoic and early Tertiary. The Jinsha and Banggong Sutures in Tibet join continental terranes separated from Gondwana. Ophiolites were obducted onto the shelf of southern Tibet in the Jurassic before the formation of the Banggong Suture. The Kohistan--Ladakh Terrane contains an island arc that was accreted in the late Cretaceous on the Shyok Suture and consequently evolved into an Andean-type batholith. Further east this Trans-Himalayan batholith developed on the southern active margin of Tibet without the prior development of an island arc. Ophiolites were obducted onto the shelf of India in the late Cretaceous to Lower Palaeocene before the closing of Tethys and the formation of the Indus--Yarlung Zangbo Suture at about 50 Ma. Post-collisional northward indentation of India at ca. 5 cm per year since the Eocene has reformed this accreted terrane collage; palaeomagnetic evidence suggests this indentation has given rise to some 2000 km of intracontinental shortening. Expressions of this shortening are the uplift of mid-crustal gneisses in the Karakoram on a late-Tertiary breakback thrust, folding of Palaeogene redbeds in Tibet, south-directed thrust imbrication of the foreland and shelf of the Indian Plate, north-directed back-thrusts along the Indus Suture Zone, post-Miocene spreading and uplift of

thickened Tibet, giving rise to N-S extensional faults, and strike-slip faults, which allowed eastward escape of Tibetan fault blocks.

W/114. Windley, B.F., Coward, M.P. & Jan, M.Q., 1986. The geology and tectonic evolution of the Karakoram-Kohistan range of the Himalaya of N. Pakistan. In: Huang, J.Q. (ed.), *Proceedings of Symposium on Mesozoic and Cenozoic Geology. 60th Anniv. Volume Geological Society of China*, 455-467.

The Indus suture in northern Pakistan splits into two branches that bring rocks of diverse nature in contact. The exact position of the northern suture is uncertain. North of it pelitic and calcareous rocks show a rapid northward increase in grade of metamorphism; in the sillimanite zone they are intruded by the Tertiary calc-alkaline Karakoram batholith. Sedimentary rocks to the north of the batholith are mostly Palaeozoic in age and are dominated by pelites, calcareous and arenaceous rocks, and extend to the Chinese border. The southern suture, with associated high-pressure granulites, meta-ultramafics and blueschists, is bordered on the south by rocks of the Indian plate consisting of a basement of late Precambrian pelites intruded by Cambrian granites and overlain by a cover of Mesozoic carbonates and shales which, with its basement, was highly folded, thrust and metamorphosed up to sillimanite grade during the Tertiary.

Between the two sutures occur rocks of the Kohistan sequence belonging to a mid-Cretaceous island arc (formed during northward subduction) which is represented by (north to south): tightly folded pillow-bearing basic volcanics and sediments; foliated tonalites and diorites; the Chilas complex which is a stratiform cumulate body over 300 km long and 8 km thick; an amphibolitic belt of mixed lithologies; and the Jijal complex which is a 200 km² tectonic wedge of high-pressure mafic granulites and chromite-layered ultramafics. The Chilas complex was folded by an F1 isoclinal anticline (and metamorphosed in the granulite facies) and the upper part of the Kohistan arc by a major F2 syncline; both folds formed during collision of the arc with the Indian plate in the early Eocene. The arc was upthrust on a ramp during the collision so that it is now subvertical, providing a remarkable section through the crust. The Kohistan sequence became an Andean-type arc in the Eocene (during southward subduction) when calc-alkaline plutonics and volcanics were intruded and extruded. Several plate tectonic models are evaluated for the production of the Karakoram batholith and the northern suture. Factually, the Kohistan sequence (and its eastern extension in Ladakh) is a double arc with an intervening period of collision (Coward et al., 1984). From the Chinese border to the Karakoram batholith is a thick sequence of low-grade fossiliferous sediments, mostly slates, phyllites, dolomites, limestones and sandstones, ranging from Devonian to early Cretaceous (Desio and Martina, 1971; Tahirkheli, 1979). The structural history of this sequence of deformed sediments is unknown.

The Karakoram batholith (> 350 km long and 10 km wide) consists of a complex sequence of intrusions which can be broadly divided into two groups: early large plutons of foliated biotite or hornblende-granodiorite, adamellite and quartz diorite were intruded by small intrusions and sheets of undeformed leucogranite with rare garnet and tourmaline, adamellite, and pegmatite and aplite with tourmaline, garnet and beryl. Preliminary data suggest the granodiorites and granites have K/Ar ages in the range 65-5 Ma (Blasi et al., 1980; D. Rex, pers. comm.). Broughton (1981) found from a chemical (XRF and microprobe) study of these rocks that they represent two distinct petrogenetic groups. The more mafic granodiorites, tonalites and diorites have a calc-alkaline chemistry and are diopside normative and contain modal hornblende, sphene, more calcic plagioclase and magnetite $\pm$ ilmenite, in contrast to the more alkali-rich leuco-granites which are corundum normative and contain modal garnet and tourmaline and ilmenite as an opaque phase.

South of the Karakoram batholith there is a meta-pelitic sequence which shows a marked southward decrease in grade via closely spaced isograds. Sillimanite schists in the north pass via garnet-staurolite schists, garnet-chloritoid phyllites to chloritoid slates and chlorite-biotite slates at Chalt. Chloritoid schists occur in the same tectonic position in the Skardu area (Zanettin, 1964). Adjacent to the batholith there is a 4 km wide belt of corundum-bearing marbles with complex sulphide mineralisation which crystallised at 600-700 °C and 7 kb fluid pressure (Okrusch et al., 1976).

W/115. Winslow, D.M., Chamberlain, C.P. & Zeitler, P.K., 1995. Metamorphism and melting of the lithosphere due to rapid denudation, Pakistan Himalaya. *Journal of Geology* 103, 395-408.

The Nanga Parbat-Haramosh Massif of the western Himalaya has undergone a complex metamorphic and tectonometamorphic history over the past 1.8 Ga. metamorphism in the Tato region is characterized by a Barrovian type metamorphism by partial melting and recrystallization along shear zones during nearly isothermal decompression while the massif was still at temperature $>550^{\circ}\text{C}$. mineralogical and textural evidence for this path includes garnet zoning pattern, late-stage migmatization, abundant cordierite both in schists and leucogranite dikes, replacement of high-pressure assemblages by low-pressure assemblages, and abundant low-density inclusions. Thermobarometry on the nonmigmatized gneisses reveals conditions of $540\text{--}740^{\circ}\text{C}$ at $7.1\text{--}13.1\text{ Kbar}$. Thermobarometry in the migmatized rocks reveals final equilibration at $608\text{--}675^{\circ}\text{C}$ at $3.9\text{--}6.8\text{ Kbar}$. Early fluid inclusions occur in quartz inclusions within garnet porphyroblasts that grew during decompression. The last fluid inclusions to be trapped occur in microfractures that locally crosscut several grain boundaries and, hence, record conditions after quartz grain boundary migration ceased. Examination of all the petrologic and fluid inclusion data conclusively show a very rapid denudation event late in the collisional process. Rapid denudation resulted in the advection of isotherms to shallow crustal levels causing an elevated geotherm ($\sim 60^{\circ}\text{C/km}$) in the upper crust, metamorphism along zones, and partial melting of the crust at depths of ca. 22 km.

W/116. Winslow, D.W., Zeitler, P.K. & Chamberlain, C.P., 1993. Characterization of Neogene metamorphism in the polymetamorphic Nanga Parbat syntax, Pakistan, Himalaya. Abstracts with Program, Annual Meeting of the Geological Society of America, p. A-123.

Pelitic units metamorphosed under upper amphibolite-lower granulite facies conditions record the complex tectonometamorphic history of the Nanga Parbat Syntax (NPS) with peak metamorphic conditions of 145°C and 7.1 kbar . The NPS is an extension of Indian basement which has undergone rapid exhumation over the past 10 Ma resulting in its exhumation from beneath the Kohistan paleoisland arc terranes. Recent geochronologic work indicates that the massif has experienced extensive metamorphic and igneous activity coincident with rapid exhumation. Here we report petrologic and thermobarometric evidence for polymetamorphic history within the NPS.

The first example is from a shear zone found just south of Talo village along the Raikot valley. The shear zone which has been brought to the surface along the associated brittle fault, contains the assemblage $\text{met} + \text{biotite} + \text{sillimanite} + \text{plagioclase} + \text{cordierite} + \text{K-feldspar} + \text{rutile} + \text{ilm.}$ Ca X-ray maps of Ca-Mn-Mg-Fe in garnet reveal a complex porphyroblast growth history. Ca and to lesser degree Mg , Mn and Fe record an early zoned euhedral garnet with compositions mirroring presumed paleocrystal faces. This growth was followed by the growth of homogeneous garnet and later resorption of the garnet characterized by a Mn enriched rim as well as physical replacement of garnet by biotite. Thermobarometry including biotite, matrix biotite and biotite in contact with the rim of the garnet yields an increasing P-T path from 814 to $845 \pm 50^{\circ}\text{C}$ at P of 6.8 and $7.1 \pm 1\text{ kbar}$ respectively for the zoned euhedral core followed by new garnet growth at temperatures of $688 \pm 50^{\circ}\text{C}$ and P of 6.1 kbar .

The second example is a shear zone located in the Diamir traverse 3 km from the Raikot fault and may be a ductile shear associated with earlier movement along the Raikot fault. Within the mylonite are relict porphyroclasts of garnet. The garnets are almost completely replaced by cordierite, biotite and plagioclase. Garnet-biotite in contact yield final equilibration temperature of 555°C at 2.2 kbar . While garnet cores and biotite yield temperatures of 670°C at 2.2 kbar .

Cation zoning, petrography and thermobarometry suggests a complex tectonometamorphic history for the southern portion of the NPS. An early M1 metamorphism which overgrows a relict foliation is characterized by an increasing P-T path consistent with loading of the Indian plate by the Kohistan island arc terrane. Within the past 10 My , M1 was overprinted by a distinctively lower temperature lower pressure M2 metamorphism initiated as rocks recrystallized during decompression. Migmatization was probably coincident with this phase. This was followed by further decompression characterized by resorption of plagioclase and growth of $\text{Fe-rich cordierite}$ at the expense of garnet as rapid denudation perturbed isotherms.

Recent fluid-inclusion and $^{40}\text{Ar}/^{39}\text{Ar}$ cooling-age data show that currently exposed basement rocks in the Raikhot glacier valley of the Nanga Parbat-Haramosh massif, Pakistan Himalaya, were at temperatures of 350 ± 50 °C at depths of 6 ± 2 km (hydrostatic pressure correction). These data imply the presence of a steep thermal gradient in the upper crust at 1 Ma (29-100 °C/km) and denudation rates over the past 1.0 m.y. of 3-6 mm/yr, providing independent corroboration of previous estimates of rapid denudation at Nanga Parbat (4.5 mm/yr over 3.3 m.y.). Our data provide direct documentation of near-surface compaction of isotherms under conditions of rapid denudation, a result that has long been supported by thermal modeling.

W/121. Winslow, D.M., Zeitler, P.K., Chamberlain, C.P. & Williams, I.S., 1996. Geochronological constraints on syntaxial development in the Nanga Parbat region, Pakistan. Tectonics 15, 1292-1308.

$^{40}\text{Ar}/^{39}\text{Ar}$ data (hornblende, biotite, muscovite, and K-feldspar) and U/Pb data (zircons) were obtained from the Nanga Parbat-Haramosh Massif (NPHM), NW Pakistan, along three transects in the southern regions of the NPHM. We have based our interpretations on our new data as well as geochronologic dates from previous studies in the northern regions of the massif. Geochronologic data show that the NPHM has experienced exceptionally high denudation and cooling rates over the past 10 m.y. U/Pb ages determined through sensitive high-resolution ion microprobe (SHRIMP) "depth-profiling" experiments on metamorphic zircons and conventional U/Pb monazite dates suggest that the timing of metamorphism varied across the massif. In addition, we have documented that the massif has experienced postmetamorphic, differential cooling both along and across strike. Thermochronologic data on currently exposed surface rocks suggest that cooling occurred more recently and at greater rates in the south-central regions of the massif (representing deeper crustal levels) than along the margins and northern regions of the massif. Within the Tato region, cooling following peak metamorphic temperatures of 600°–700 °C was as high as 140 °C/m.y. following partial melting of pelitic units. Biotites from this area record plateau ages of 0.9 ± 0.1 Ma. Along the Astor and Indus gorges, cooling was less rapid (approximately 70°–80°C/m.y.) following peak metamorphism as indicated by U/Pb monazite ages of 6–8 Ma and $^{40}\text{Ar}/^{39}\text{Ar}$ muscovite cooling ages of 2.2–3.4 Ma. Cooling over the last 3 m.y. occurred at rates of 100°–140 °C/m.y. The overall cooling age pattern within the massif is interpreted syntaxial growth through the development of north plunging antiforms prior to 3 Ma, followed by reverse faulting along east dipping fault zones. Along the Raikot River transect the biotite cooling age pattern is consistent with the folding of isotherms during folding of the foliation surfaces. The age pattern was disrupted at 1 Ma due to faulting along the Raikot and Tato faults.

W/138. Workman, W.H., 1910. The tongue of the Hasanabad Glacier in 1908. *Geographical Journal*, 36, 194-196.

Here is a copy of the account from WH Workman: In the 'Records of the Geological Survey of India,' vol. 35, p. 135, Mr. H. H. Hayden calls attention to the story of the rapid advance of the Hasanabad glacier, which he obtained from the Mir and the Wazir of Hunza, according to which the glacier advanced several miles in the course of two and a half months, though it was said to be stationary when he observed its tongue in August, 1906. It was also said to have made a similar advance on a former occasion, of which the time was not specified, after which it retreated rapidly. In the course of the expedition of Mrs. Bullock Workman and myself to the Hispar region in the summer of 1908, before reaching Nagar we camped at Dadimal, about 6 miles distant from the Hasanabad nala. Being so near to it, I decided to devote a day to a visit to the tongue of the Hasanabad glacier, to see whether any change had occurred in its position or condition since Mr. Hayden had observed it two years previously. Accordingly, accompanied by a servant and a coolie to carry my instruments, I started early the next morning to walk the 6 miles that lay between our camp and it. On my arrival at the mouth of the nala about 10 a.m., I was met by the Wazir of Hunza, the medical officer of the Aliabad Dispensary, and a dozen attendants, dispatched by the Mir of Hunza to take me in charge and conduct me to Mr. Hayden's stations. They presented the Mir's compliments, together with a cordial invitation to our party to visit Hunza, of which, owing to other arrangements, we were unable to avail ourselves. After I had rested a short time, and quenched my thirst from a basket of delicious mulberries the Mir had thoughtfully sent over, the whole party went up the nala to the tongue of the glacier, first visiting Mr. Hayden's first station, just west of the extremity of the tongue. This was a huge granite boulder, with Mr. Hayden's inscription upon it in black letters as fresh and bright as if made the preceding day. We climbed to the top of the boulder, which was large enough to accommodate several persons. From here, station 2, marked on the

THE TONGUE OF THE HASANABAD GLACIER IN 1908. 195 rock-face of the mountain-wall opposite on the east side of the nala, could easily be seen, and the lettering on it read with the field-glass. A tripod was set up at the central point of the boulder-top, for use in sighting and photographing. A line sighted from this to station 2 passed directly over the extremity of the tongue, thus showing that, at the end of two years that had elapsed since Mr. Hayden's observation, the tongue remained in the exact position in which he found it. There was also no evidence, from the debris at the extremity, that it had moved either way during that time, one of my photographs of this portion being an almost exact reproduction of Mr. Hayden's, even the same boulders and debris-formations being seen in both. In other respects the tongue was not essentially altered in its appearance as shown in Mr. Hayden's admirable photographs. The steep, rough talus leading up to the Gamkin irrigation-canal, above which Mr. Hayden's station 3 was located, was next ascended, and the spot found where the boulder forming the station had rested, but the boulder itself was not there. It had slid down the slope to a point, below the canal, some 60 feet from its former position, where it was lying partially embedded in sand. Photographs were taken from here, as well as from station 1. The inspection being completed, the party returned to the mouth of the nala. The Wazir added nothing to the statements previously made about the glacial movement. We bade one another adieu about noon, after which I returned to Dadimal. The day was warm, the solar thermometer at 12.30 indicating 196°5' Fahr. I am not aware that the Hasanabad glacier has ever been explored by a European, or that its length is known. Its nala, as far as I could see into it, is narrow, and high snow-peaks tower above its upper portion. If, as seems probable, its length is not great, and its reservoir is large as compared with the size of the trunk, and the mountains enclosing its upper end descend sharply to it, a season or two of heavy snowfall would be likely to cause such an accumulation of snow in the reservoir as might easily induce a sudden augmentation of pressure, which would drive the trunk rapidly down the narrow nala. The last rapid advance would appear from the account to have taken place in the summer of 1903, after the stormy seasons of 1902 and 1903 in this region, when I also noticed a similar advance of a large branch of the Chogo Lungma descending sharply from the snowy Haramash mountains, which crowded the Chogo Lungma trunk bodily over for a considerable distance against its left lateral moraines, from which, in 1902, it stood well removed. The same cause might have been active on the former occasion, when the Hasanabad glacier advanced, and then retreated quickly. If the conditions I have mentioned as probable are the ones actually existing, an equilibrium of pressure having been established by the advance after stormy seasons, in succeeding seasons, without unusual or with less than the average snowfall, the tongue.

W/140. Workman, W.H., 1914. Physical characteristics of the Siachen Basin and Glacier system. *The Geographical Journal* 43, 273-292.

The first few paragraphs of the article: The term "glacier" is not sufficiently comprehensive to designate accurately the immense and, in arrangement, complicated bodies of snow, neve and ice collected in the great rock-basin extending north-west from the source of the Nubra River to Peak 23 (Hidden peak), 78.4 kilom. (49 miles), with an east and west average width for a considerable distance of 32 kilom. (20 miles), and having an area, approximately, of 2400 sq. kilom. (over 900 square miles).

The basin is crossed in various directions by many glaciers of the first order and innumerable lesser ones, fed by snow precipitated upon the mountains and slopes of its watershed, all converging on a great central trunk averaging 4 kilom. (2*5 miles) in width, that stretches the length of the basin in a north-west by south-east direction and discharges from its tongue water derived from the snow collected in all parts of this extensive region to give birth to the Nubra river. This central trunk with its multitude of affluents resembling a river-system is more fittingly styled the Siachen glacier-system. The four other great karakoram glaciers, as well as many smaller but by no means insignificant ones, are fashioned on the same plan. This type is peculiar to the Karakoram, being conditioned on the configuration of its valleys and the arrangement of its peaks. For this reason, as well as on account of certain structural features referable to existing conditions, all these glaciers merit the designation of glacier- systems or glaciers of the Karakoram type. The Siachen basin is separated by its enclosing walls, on the east, from an unexplored region containing the Remo basin, with which the Siachen probably communicates by an ice-covered pass, possibly two, leading from the head of the Tarim Shehr affluent, and further north a group of snow mountains discovered by us from the east Siachen head that give rise to a large glacier, apparently the Urdok, running north-west into Chinese Turkestan; at the north end, from a glacier-basin leading north-east from the Gasherbrum massif; and on the west from the Baltoro, Kabery (Kondus), Sher-pi-gang, Dong Dong, Bilaphond, and Chumik basins, with glacier-passes connecting with the Bilaphond and Kabery, the last first discovered and crossed by our expedition in 1912. The enclosing barriers of the Siachen consist of granite, gneiss, crystal- line schists, slates and shales, sandstones, amorphous and crystalline limestones, and conglomerates, with some igneous intrusions. These rocks alternate with one another at short intervals, and are in places intimately intermingled and interfolded. They are extensively foliated, friable, and easily disintegrated by frost and weathering. Even the granites, largely of the biotite variety, are divided into small sections by joints crossing one another, and intersected by bands of quartz, feldspar, s'chists, and shales, in consequence of which they split up easily into frag? ments. The physical condition of the gneiss and crystalline schists would suggest to the ordinary observer that they were formed largely by metamorphosis of sedimentary deposits. But whether this be the fact, or whether it be that they originated as primary granites and were afterwards metamorphosed by folding, they are brittle, and present in the one case an immature appearance as if incompletely developed, or in the other a decadent one, as if the original structure had been overwrought and dis- organized by strain and violence in the upheaval of the great ranges of which they form constituents. This fragile condition of the rocks accounts for the irregular, jagged outlines of the mountains of the region, especially of the granite peaks, many of which are greatly serrated, and for the vast detritus-deposits that load the glaciers and play an important role in the development of their structural features. Owing to the amount of snow covering the mountains and the staining and weathering of the visible rock-surfaces, it is often difficult, even from a short distance, to distinguish the character of the rocks composing a mountain, so that the observer, particularly if he is not a trained geologist, may well be in doubt as to what formation lies before him. The shales and slates, the latter largely of very dark color, are the most easily distinguished. The north-east wall of the Siachen trunk resembles in structure and extent that which, with an unbroken length of 63 kilom. (39 miles), forms the upper portions of the southern Hispar and western Biafo barriers.* Starting at the north-east head, it extends west 4*8 kilom. (3 miles), then turns south-east and continues on 22 kilom. (14 miles) to the Tarim Shehr affluent. Here it turns east and forms the north wall of the Tarim Shehr for 27 kilom. (17 miles) to its sources, making a continuous, unbroken wall 53 kilom. (33 miles) long. The upper 20 kilom. (12 miles) of this wall is, and the remainder appears to be, a part of the main watershed between Turkestan and the Indus, and as such it probably continues on from the head of Tarim Shehr tributary to the Karakoram pass. A second portion continuing around as the south wall of the Tarim Shehr glacier and extending west to the Tarim Shehr promontory there turns south-east and forms the remaining portion of the north-east wall of the trunk to its end, having a length of 53 Kilm. (33 miles). Stated in another way, the north-east Siachen wall stretches from the north head of the trunk south-east in a nearly straight line for some 72 kilom. (45 miles), being pierced only by one small and two large affluents. The south-west boundary of the upper half of the trunk can scarcely be called a wall. It consists of numerous mountains of irregular outlines, scattered about in an irregular manner, enclosing vast reservoirs of snow and ice that communicate with the

majba glacier by large secondary glaciers, the whole forming an ice-bound labyrinth that defies description. Still, the mountains and affluents stand in such relation to the main glacier that lines drawn from one headland to another suffice to mark the limits of its bed with sufficient accuracy. From the Peak 36 tributary to the tongue, a fairly continuous wall exists which is pierced by several large affluents. The structure of these walls may be stated in general terms as follows: The mountains enclosing the Indira Col and the north-east col, at the northern extremity, are composed of slates and shales, light and dark in colour with, possibly, some limestones. Thence down the north-east wall to within about 6 kilom. (4 miles) of the Tarim Shehr opening mostly of light coloured limestones and shales with some conglomerates and at least one igneous intrusion. The limestones are strongly in evidence in the moraines fed by this section. The rocks are soft and the peaks and ridges broken and jagged in outline. From a point shortly north-west of Teram Kangri, the wall and its peaks, including that summit, quite to their tops, forming the north barrier of Tarim Shehr glacier to its end, appear to be the same. The same is true of the visible rocks on the south side of Tarim Shehr glacier, though some of the ice-covered peaks at its upper end must contain granite and gneiss, as much debris of this character appears in the moraines of that side. On the extremity of Tarim Shehr promontory, most of which is composed of brown shale, granite crops out over a considerable area. Thence, beginning with Junction mountain, 6353 metres (20,840 feet), rising above the promontory, ascended by us in 1911, down to the great bend, some 25 kilom. (16 miles), the mountains are of dark brown and black slate with occasional sections of lighter colour broken into jagged points and cleft by deep, ragged ravines. The only granite noticed in situ in the whole length of this wall was at Tarim Shehr promontory. From our camps on moraines opposite this wall, the view toward it was most forbidding. The foreground was occupied by the huge black hillock-moraine coming from the Tarim Shehr affluent, the towering hillocks of which, resembling vast heaps of coal piled up at random in a Cyclopean coalyard, shut out from sight the white ice of the glacier beyond, while the background was formed by the succession of black peaks hard in outline and destitute of grace, rendered more desolate by contrast with the snow capping their tops, the whole constituting as sombre and depressing a landscape as could well be imagined, far eclipsing the most fantastic conceptions of Boecklin and casting an uncanny shadow over the soul. On the south-west side of the trunk a similar variety of formation occurs, but granite is more and limestone less in evidence. The last three peaks of the King George V. group ending the massive mountain-tongue, interposed between the heads of the Baltoro and Siachen glaciers, which form 11 kilom. (7 miles) of the upper south-west Siachen wall, appear to be mainly composed of granite and gneiss, though on an eastern spur and near its south-east extremity the granite passes over suddenly without discontinuity of outline into black slate. South of this tongue at the entrance of the upper western tributary into the Siachen, the Hawk, a graceful pointed spire of granite, soars from a circle of black slate peaks and ridges to an altitude of 6768 metres (22,200 feet). From this peak downward for 35 kilom. (22 miles) to the great bend, the south-west wall is largely, if not wholly, composed of sedimentary rocks, prominent among which are black slates. Just at the bend, two elevations, the ends of spurs descending from Peak 8, have the appearance of granite.

In 1974 and 1975, using terrestrial stereophotogrammetry, the Glacier Investigation Group of China made a survey of the Batura Glacier drainage area and drew a 1:60,000 map. A glacial inventory has been accomplished and much data on morphological measurements obtained. The Batura Glacier has some continental-type characteristics but there are number of maritime features; we call the Batura “a complex type glacier”. According to our forecast, the glacier will advance another 180-240 m but in the 1990’s it will once again be on the decline.

Key words: Glaciers, Batura, Karakoram.

Y/3. Yamin, F., 1981-83. Geology and petrology of Tangir valley (District Diamer) with special emphasis on the mineralogy/petrology of the intrusives. M.Sc. Thesis, Punjab University, Lahore, 143p.

Tangir covers 351 square kilometers area located between Kohistan in the South and Yasin in the North. According to plate tectonic concept it lies in between Indo-Pakistan and Eurasian plates comprising a part of Kohistan Island arc. The particular project area is mapped on a scale of 1:62500. In the thesis, an attempt is made to introduce the detailed Geology of the area. Bulk geological sequence of the area is consisted of Norite, Diorite, Amphibolite, Granodiorite and granite which is obducted on to the Paleozoic rocks of Indo-Pakistan plate in the South and subducted under the Eurasian plate towards the North. The Northern part of the area is in contact with Yasin Group which is volcanic. So Tangir area constitutes the lower sequence of Kohistan Complex.

Key words: Geology, petrology, igneous rocks, amphibolites, Tangir, Diamir.

Y/4. Yammoto, H., 1993. Contrasting metamorphic P-T-time paths of the Kohistan granulites and tectonics of the western Himalayas. *Geological Society London Journal* 150, 843-856.

In the Swat-Indus Kohistan area, lower crustal rocks of the Kohistan arc including amphibolites, granulites and ultramafic rocks are widely exposed. Detailed petrological-structural studies reveal that the Chilas-Jijal metamorphic complex comprises essentially intermediate- to high-pressure granulites with a granulite/amphibolite transition controlled by extensive retrograde metamorphism and ductile deformation. Contrasting patterns of compositional zoning in garnet and orthopyroxene suggest complicated P-T paths in the granulites. Geothermobarometry based on garnet-bearing granulites identify two distinct P-T-time paths: a high-pressure anticlockwise path of the Jijal complex and a low-pressure retrograde path of the Chilas complex. These P-T-time paths represent the evolution of middle to lower crustal rocks of the Kohistan arc. The anticlockwise P-T-time path combined with published isotopic ages reveals that: (i) the high pressure granulite facies metamorphism is related to the Kohistan-Asia collision and (ii) the crust of the Kohistan arc had been thickened at least 55 km before the India-Asia collision.

Y/5. Yamamoto, H. & Nakamura, E., 1996. Sm-Nd dating of garnet granulites from the Kohistan Complex, northern Pakistan. *Journal of the Geological Society, London*, 153, 965-969.

Sm-Nd mineral-isochron ages of garnet granulites in the southern part of the Kohistan complex are determined. The 91.0 ± 6.3 Ma age is obtained from a granulite body of the Jijal complex at Pattan and the 69.5 ± 9.3 Ma age is obtained from a granulite body of the Chilas complex at Zambil. These ages indicate that the granulite bodies at Pattan and at Zambil had cooled to below upper amphibolite facies by about 90 Ma and about 70 Ma respectively.

The time of cooling of the granulite of the Jijal complex is comparable to the time-lapse of the Asia–Kohistan collision (102–75 Ma), although that of the Chilas complex is probably younger than the Asia–Kohistan collision and certainly older than the Asia–India collision (c50 Ma).

Key words: Geochronology, Sm-Nd dating, granulites, Jijal, Kohistan.

Y/6. Yamamoto, H. & Nakamura, E., 1998. Sm-Nd dating of superposed replacements in mafic granulites of the Jijal Complex, Northern Pakistan. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 216–218.

The northern part of the Jijal complex (NJC) in the Kohistan arc is a rare example of the lower crust of an island arc. Two stages of replacement under the granulite facies conditions are observed in mafic to ultramafic rocks of the NJC. In the earlier stage, garnet clinopyroxene granulite (garnet+clinopyroxene+plagioclase+quartz) replaced two-pyroxene granulite (orthopyroxene +clinopyroxene ± hornblende + plagioclase ± quartz) and patches of relict, the two-pyroxene granulite, were left in the garnet-clinopyroxene granulite. In the later stage, many pod- and lens-shaped bodies of garnet hornblende (garnet+hornblende +clinopyroxene) replaced the garnet-clinopyroxene granulite. The two-pyroxene granulite and the garnet-clinopyroxene granulite are nearly equivalent in chemical composition and distinct from the garnet hornblende.

Sm-Nd isotopic systems have been studied in these three rock types. Samples for dating were collected from roadside sections along the Karakoram Highway around lat. 35°07' N and long. 73°00' E (near the Pattan village). Whole rock and mineral isochrons define the following ages: 118 ± 12 Ma for KU66A (two-pyroxene granulite), 94.0 ± 4.7 Ma for PD6B (garnet-clinopyroxene granulite), and 83 ± 10 Ma for PDI5B (garnet hornblende). Errors in ages are quoted as 2 σ . The age of KU66A shows that the protolith of two-pyroxene granulite had been formed before the Kohistan-Asia collision, which is dated between 102 and 85 Ma [1, 2]. The age of PD6B agrees with a 91.0 ± 6.3 Ma Sm-Nd age of KU66 (the garnet-clinopyroxene granulite from the same outcrop of KU66A in this study) in an earlier report [31]. All the above ages are consistent with relative order of the formation of the three rock types. The earlier replacement took place before c. 90 Ma (PD6B, KU66) and the later probably before c. 80 Ma (PDI5B). The result implies that these events in the NJC are related to the Kohistan-Asia collision.

Key words: Geochronology, Sm-Nd dating, granulites, Jijal, Kohistan.

Y/7. Yamamoto, H. & Nakamura, E., 2000. Timing of magmatic and metamorphic events in the Jijal complex of the Kohistan arc deduced from Sm-Nd dating of mafic granulites. In: Khan, M.A., Treloar, P.J., Searle, M.P. & Jan, M.Q. (Eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 313–319.

Mafic to ultramafic granulites in the northeastern part of the Jijal complex include two-pyroxene granulite, garnet-clinopyroxene granulite and garnet hornblende. Field and textural relations indicate that two-pyroxene granulite is a relict left after formation of the garnet-clinopyroxene granulite and garnet hornblende was an originally intrusive rock, which dissected the protoliths of mafic granulites. Sm-Nd mineral isochron ages of 118 ± 12 Ma, 94.0 ± 4.7 Ma and 83 ± 10 Ma were determined for two-pyroxene granulite, garnet-clinopyroxene granulite and garnet hornblende respectively. These ages, together with previously reported chronological data, led to the following tectonic implications: (1) crystallization of the granulite protoliths predates, or is coeval with, the tectonic accretion of the Kohistan arc to the Asian continent; (2) crustal thickening related to the accretion was probably responsible for the high-pressure granulite-facies metamorphism in the Jijal complex; (3) formation of the garnet hornblende assemblage was probably after crystallization of garnet-clinopyroxene granulite.

Geologically, the area under study is situated Lesser Himalayas Precambrian to recent rocks are exposed. Most of the area is covered by thick vegetation and rangelands. Samples were collected from springs, wells and streams for pollutants and bacterial study. The source of pollutants is faecal marked by the coliform organisms. Septic tanks, uncontrolled disposed off liquid and solid waste by the community, disposed off solid and liquid wastes from C.M.H and the fine sediments from Murree Formation contaminated the water as a whole. The rainwater flow through Murree Formation and the dissolution of carbonate and bicarbonate and other minerals from Murree Formation and the soils are also effected the water quality. The toxic metals like lead, zinc, copper and manganese coming into the water through aluminum pipes, or from the fitting used for the pipes. All the above sources arise the health based problems to the community in Rawlakot area. The diseases like enteric fever, typhoid, dysentery, diarrhea, cholera, abdominal pains and gastric enteric, brain hemorrhage and heart problems are water borne common infections in community. From the results it has been concluded that the drinking water from the springs, wells and streams are mostly at intermediate to high risk.

Y/12. Yaseen, C.M., 1995-96. Structure, stratigraphy, micropaleontology and petrography of Darthian, Narota & Karwal areas, Districts Haripur, Hazara (NWFP), Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 95p.

The Darthian, Narota and Karwali area are part of Attock-Hazara fold-and-thrust belt of the northwest Himalaya of Pakistan. The lithographic units exposed in the area are mainly sedimentary in nature and range in age from Mesozoic to Cenozoic. The area is deformed by folding and faulting during the Tertiary-Himalayan collision. The Early Cretaceous Lumshiwal Formation has conformable contact with the overlying Late Cretaceous Kawagarh Formation. The presence of glauconite in the Lumshiwal Formation reveals that the formation was deposited in marine condition during regressive as well as transgressive phases. The Late Cretaceous subduction of the Indian plate below the Kohistan Island arc caused the deepening of the Tethyan shelf in the subduction zone and initiated the deep marine deposition of the Kawagarh Formation. The contact between Kawagarh Formation and Early Paleocene Hangu Formation is marked by break in deposition which is evidenced by the presence of laterite/haematite and sandstone. The abrupt change in facies from deep water marine environment of Kawagarh Formation to terrestrial deposition of Hangu Formation indicates the initial Early Paleocene collision of the Indian Plate and Kohistan Island arc. The Lower Tertiary sequence exposed in the area is Early to Late Paleocene Lockhart limestone, Late Paleocene Patala Formation, Early Eocene Margalla Hill Limestone, Early Eocene Chorgali Formation and Early to Middle Eocene Kuldana Formation. The Lower Tertiary sequence marks the complete cycle of transgression and regression of the Tethyan Sea. The presence of early Paleocene to Late Eocene foraminiferal assemblage like globorotalia, globogorina, lockharia, assilina and nummulites in the limestones and shales of the Lower Tertiary sequence show the tropical sub-tropical open sea upper slope to outer shelf environments. The Kuldana Formation is composed of marine limestone, continental variegated clay, shales and evaporitic gypsiferous bands. These variegated lithologies show that the Early to Middle Eocene Kuldana.

Y/13. Yasin, A.R., 1982-84. Structural studies of Chinarkot-Galidada Area, District Mansehra. M.Sc. Thesis, Punjab University, Lahore, 87p.

The landforms bear a specific relationship with geological structures and the climate which can be worked out by qualitative as well as quantitative analysis of the topographic map. The most predominant lithologies of the project area are garnet mica schists, and Susalgali granite gneiss. The rocks of the project area have been classified into eight lithologic units for the sake of mapping purposes at a scale of 7 Cm. to a kilometer. Mesoscopic deformational structures are well exhibited in the project area including both planner and linear structures. The rocks have been folded isoclinally and later being refolded into open folds. The area is traversed by a shear zone, the Chalundri fault and is divisible into two structural domains. The area is deformed by different deformation phases, among which three are recognized on mesoscopic as well as microscopic scale and area is characterized by heterogeneous deformation. The rocks have been folded isoclinally and later being refolded into open folds. The area lies in the core zone of the regional synformal structure of the Mansehra Complex which has experienced metamorphism in Barrovian style. The project area has been metamorphosed up to garnet grade with local contact metamorphic effects along the contacts of granites.

Key words: Structure, granite gneiss, Metapelites, Mansehra.

Y/15. Yasir, A., 1988-90. The geology and petrology of Jijal and Pattan layered ultramafics-mafic complexes in the vicinity of Jijal & Duber with special emphasis on petrogenesis of these complexes. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 90p.

The project area covers about 368 sq. Km. located in the vicinity of Jijal & Duber, District Kohistan. The work has involved geological mapping of the area on a scale of 1:50,000 of toposheet No. 43 A/16 of Survey of Pakistan. This thesis deals with the geology, petrography and petrogenesis of the Jijal and Pattan complexes in particular and the relation of these complexes with other complexes of Kohistan Arc complex has also been discussed.

The geological sequence of Jijal complex consists of ultramafic and mafic cumulates. The ultramafic cumulates are divided into dunite, wehrlite, websterite, garnet-pyroxenite and garnet-hornblendite, whereas mafic cumulates are garnet gabbro. The geological sequence of Pattan complex also consist of ultramafic and mafic cumulates. The ultramafic cumulates are chromite, dunite and (meta) wehrlite, whereas mafic cumulates are divided into two pyroxene gabbro and two pyroxene-quartz-diorite. Field evidences suggest that Pattan complex was emplaced along pre-existing metamorphosed kayal cumulate complex. The top of the Pattan complex is marked by a spectacular, intrusive polymagmatic breccia. In Duber and NW of Duber Pattan complex is overthrust onto the Jijal complex, which is also a layered cumulate complex. While in Pattan area and SE of Pattan there is a faulted (strike slip) contact between Pattan complex and Jijal complex. The Jijal complex is southernmost, layered ultramafic-mafic cumulate complex of the Kohistan-Ladakh tectonic province. The Main Mantle Thrust (MMT) is the southern boundary of the Jijal complex, which interns is the southern boundary of Kohistan Arc complex. The Main Mantle Thrust (MMT) Duber Thrust Fault wedges out Jijal complex NW of Duber near Chert. On the other hand Main Mantle Thrust and Pattan Fault (strike slip fault) wedges out the Jijal complex on the eastern side near Pashto. The Jijal and Pattan complexes are generated by precipitation from subduction generated, hydrous, low K, picritic high Mg tholeiitic magmas and there is a strong possibility of finding economic metallic mineral deposits with in these layered cumulate complexes.

Y/18. Yeats, R.S., 1993. Earthquake Hazard of the Himalayan Front. Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, p.55.

Great earthquakes of $M > 8$ struck the Himalayan front of India and Nepal in 1897, 1905, 1934, and 1950, leaving seismic gaps between the 1934 and 1905 earthquakes and west of the 1905 shock that were only partially filled by earthquakes in 1803, 1833, 1869, and 1991. None of these great earthquakes has any documented surface rupture, although the 1905 event was accompanied by growth of folds at the Himalayan front.

However, there is abundant evidence of young folding and faulting, including back-thrusting, and these structures must be the surface expression of a décollement moving unmetamorphosed strata over the Indian shield. Beneath much of the Sub-Himalaya, the décollement is too shallow and thus too weak to generate $M > 8$ earthquakes, and the source must then be farther north, perhaps as far north as directly beneath the MCT, where the décollement may enter basement rocks. A major problem is the geological evidence for earthquake segment boundaries. These may follow Indian-shield discontinuities like the Hardwar Ridge and may be expressed at the surface by changes in tectonic style from imbricate thrusting to blind thrusting and development of duns. A second problem is the absence of evidence for great earthquakes prior to 1897. Civilized societies in the plains south of the Himalaya apparently did not record great events for the preceding 2000 years. On the other hand, the Taxila earthquake of A.D.25 in the northern Potwar Plateau of Pakistan may have been a great earthquake, and seismic risk to northern Pakistan may be as great as it is farther east despite the presence of Precambrian salt at the décollement farther south. The absence of Precambrian salt in Hazara and in ranges around the Peshawar basin suggests that the Precambrian salt basin terminates northward in the Himalayan foothills and therefore does not lessen seismic risk in Pakistan.

Y/19. Yeats, R.S. & Hussain, A., 1982. Zone of Late Quaternary deformation in the southern Peshawar Basin, Pakistan. In: Malinconico, L.L. & Lillee, R.J. (Eds.), Tectonics of Western Himalaya. Geological Society of America, Special Paper, 232, 265-274.

Four left-stepping pressure ridges extend for nearly 60 km parallel and close to the southern margin of the Peshawar basin, cutting diagonally across older imbricate thrust structures of the Attock-Cherat Range. Lacustrine, fluvial, and alluvial-fan deposits dated at 2.8 to 0.6 Ma are strongly folded, faulted, and eroded prior to deposition of alluvial-fan gravels, which are themselves cut by east-northeast-trending faults with their north sides up thrown. The pressure ridges postdate some of the fan drainage but deflect other drainage. The east-northeast-trending faults are high-angle and accompanied by Instrumental seismicity; there is no evidence for strike-slip except for the enechelon distribution of the ridges and low-angle slickensides on one of the faults.

Alluvial-fan and fluvial sediments are folded and faulted at Tarbela Dam, 40 km east-northeast of the easternmost pressure ridge, and the base of Indus River gravels is apparently displaced by a reverse fault with the northwest side up. Farther north, a fault adjacent to Tarbela Lake has left lateral displacement. Additional lineation and south facing scarps occur throughout the Attock-Cherat Range, and Jurassic limestone is faulted over gravels at the western end of the Nizampur basin. We interpret these features as part of a broad zone of deformation involving seismogenic crust; direction of slip is south-southwest. There is no evidence of surface rupture in this zone during Holocene time.

Key words: Peshawar basin, Late Quaternary, deformation.

Y/20. Yeats, R.S. & Hussain, A., 1987. Timing of structural events in the Himalayan foothills of north-western Pakistan. Geological Society of America Bulletin 99, 161-175.

The Attock-Cherat Range forms the southern boundary of the Peshawar basin and includes rocks transitional between metasediments of the Lesser Himalaya and foreland-basin strata to the south. The Attock-Cherat Range comprises three fault-bounded structural blocks which are, from north to south, (1) Precambrian metaclastic strata overlain by unfossiliferous limestone which is itself apparently overlain by Paleozoic strata with the contact not

exposed; (2) unfossiliferous flysch of Precambrian(?) age overlain by Cretaceous and Paleogene marine strata and Murree red beds at least in part of early Miocene age; and (3) unfossiliferous limestone, argillite, and quartzite correlated in part to Paleozoic strata in the Peshawar basin, overlain by a Tertiary sequence generally similar to that in block 2. Farther south, in the Kala Chitta Range, strata of Triassic to Eocene age occur in south-verging folds and thin thrust sheets. The similarity of the Tertiary sequences in the Kala Chitta Range and in blocks 2 and 3 demonstrates that the pre-Tertiary sequences were juxtaposed by faults prior to deposition of the Paleocene Lockhart Limestone. This may coincide with initial contact of the west-northwest-facing passive margin of India with Eurasia or nearby microplates. Major late Tertiary imbricate thrusting and folding took place prior to uplift of the Attock-Cherat Range and to deposition of Peshawar intermontane basin fill of Pliocene-Pleistocene age. The Peshawar basin formed as the Kala Chitta Range was faulted south on the Main Boundary thrust (MBT), forcing Siwalik foreland basins still farther south. Late Quaternary deformation in the southern Peshawar basin occurred along a seismically active zone of *en echelon*, stepped-left faulted pressure ridges that may reflect a subsurface ramp on the older MBT.

Key words: Structure, Himalayan foothills, Attock-Cherat Range.

Y/21. Yeats, R.S. & Hussain, A., 1989. Stratigraphy and structural events around the southern margin of Peshawar basin, Pakistan. Geological Bulletin, University of Peshawar 22, 45-54.

The Peshawar intermontane basin is superimposed on the fold-thrust belt at the southern margin of the 'Pakistan Himalayas. In the southern part of the basin the first Ordovician rocks were identified near Nowshera on the basis of discovery of trilobite trace fossils and consequently the Paleozoic stratigraphy of the area has been revised and modified. The Attock-Cherat Range forms the southern boundary of the Peshawar basin and includes rocks transitional between metasediments of Lesser Himalaya and foreland basin strata of Kala Chitta Range to the south. The range is dominated by slate, less metamorphosed argillaceous and arenaceous strata and subordinate limestone of Precambrian to Paleozoic age. These rocks are unconformably overlain by a thin cover of Jurassic, Cretaceous? Paleocene, Eocene and Miocene rocks. The structural events close to the Peshawar basin are recognized in pre-Paleocene, pre-Pliocene and late Quaternary times. The Peshawar basin formed as the Kala Chitta Range was faulted south on the Main Boundary Thrust (MBT) pushing the Siwalik foreland basin still further south. Evidence for active tectonics is found in four left-stepping *en-echelon* pressure ridges formed within Peshawar basin parallel to its southern margin.

Key words: Structure, stratigraphy, Peshawar basin.

Y/22. Yeats, R.S. & Hussain, A., 1993. Geology of the Himalayan foothills from the perspective of the Attock-Cherat Range. Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, p.56.

The Attock-Cherat Range contains boundaries between very different pre-Mesozoic terranes. South of the Hissartang thrust, the Kala Chitta Range and Potwar Plateau foreland fold-thrust belt comprises an unmetamorphosed Phanerozoic sequence with Ordovician to Carboniferous missing; Indian-shield rocks are overlain by Eocambrian evaporites. This correlates easily with subsurface cratonic rocks of the Punjab plains south of the Salt Range. North of the Khairabad (Panjal) thrust, late Precambrian continental-margin elastics (Manki Slate, Tanawal Quartzite) are overlain by a relatively complete Paleozoic and Mesozoic section which does not correlate well with the shield but is similar to sequences in Kashmir and Afghanistan. These strata are metamorphosed and intruded by granitic rocks, and they can be mapped northward across the Peshawar basin and Swat to the suture zone (MMT). Between the Khairabad and Hissartang thrusts are two problematical thrust plates. The northern plate is dominated by a late Precambrian flysch sequence (argillite, sandstone, and rare limestone, very weakly metamorphosed) named the Dakhner Formation; this is traced NE into the Hazara Formation. The Dakhner resembles the more highly metamorphosed Manki Slate farther north, but it lacks counterparts to the Tanawal Quartzite, Shahkotbala Limestone, Uch Khattak Limestone, and Shekhai Limestone characteristic of the Precambrian north of the Khairabad thrust. The fossiliferous Lower Paleozoic sequence overlying the Precambrian of the Peshawar basin is absent south of the Khairabad thrust, where the Dakhner is overlain directly by Paleocene strata and locally by Jurassic or Cretaceous rocks. Similar relationships are seen in the Kherimar Hills and Hazara. The southern thrust sheet consists of Darwaza Limestone, Hissartang Quartzite and associated redbeds, and Inzari Limestone overlain by Paleocene. The Darwaza to Inzari sequence lacks fossils and does not correlate easily with

the lower Paleozoic of the Peshawar basin or with any other sequence, including that of the Salt Range. The Mesozoic and Tertiary of these thrust sheets correlate with the fold-thrust belt to the south even though the older rocks do not, indicating that the Dakhner, Darwaza-Inzari, and Kala Chitta sequences were juxtaposed in pre-Paleocene and possibly pre-Jurassic time. The lack of evidence for Eocene collision suggests that the major encounter of the Attock-Cherat Range was between India and one or more microplates, and this encounter may have been largely strike slip on the western margin of the Indian plate.

Y/24. Yielding, G., Ahmad, S., Davison, I., Jackson, J.A., Khattak, R., Khurshid, A., King, G.C.P. & Zuo, L.B., 1984. A microearthquake survey in the Karakoram. In: Miller, K.J. (ed.), *The International Karakoram Project, Volume 2*, 150-169. Cambridge University Press.

A portable seismic network was operated in the Karakoram area of northern Pakistan for over two months during the summer of 1980. The principal objectives were to record possible subcrustal earthquakes beneath the Karakoram Range, and to monitor crustal activity throughout northernmost Pakistan. Of the 371 earthquake locations presented here, about two-third lie in the Hindu Kush intermediate-depth seismic zone. One intermediate-depth earthquake (at a depth of about 140-km) was recorded from beneath the Karakoram Mountains. Shallow crustal activity also occurs in the Karakoram Range, with events recorded from near the northwest end of the Karakoram Fault and near a number of smaller lineaments in Baltistan. Seismicity in Kohistan appears to be largely confined to the upper crust, though occasional earthquakes at 65-km depth (approximately the base of the crust) occur beneath areas of higher topography (Nanga Parbat, Rakaposhi). An area close to the Hamran (1972) and Darel (1981) earthquakes showed intense activity in depth range 0-20 km, similar to that involved in the main shocks themselves.

Y/25. Yin, J., 1992. Carboniferous sedimentary environment and tectonic setting in the western Kunlun and adjacent regions. In: Zheng, D., Zhang, Q. & Pan, Y. (eds.), *Proceedings of International Symposium on the Karakoram and Kunlun Mountains*, 130-142. China Meteorological Press, Beijing.

This is a sedimentological account of the Carboniferous lithofacies zones in the Kunlun and adjoining areas. The deposits can be classified into mobile, sub-stable and stable types. The Early Carboniferous deposits of the mobile-type located at central belt of sedimentary basin are characterized by thick volcanic-sedimentary rock assemblages (>6000 m). The Late Carboniferous of the same belt are composed of shelf platform type sediments (<200 m). Meanwhile, the lithofacies zones belonging to sub-stable and stable type deposits occurred on both sides of the mobile type deposits belt. Regionally, the contact between Upper and Lower Carboniferous strata is conformable or disconformable. It is reasonable to presume that the sedimentary environments and tectonics settings for Early and Late Carboniferous in the studied area may be referred to as a rift and post-rift basins, respectively.

While the paper deals with areas outside the geographic limits of Pakistan, it includes a regional geological map that extends up to Punjab foredeep and is reproduced here.

Key words: Carboniferous, environment, rift basin, Kunlun, northern Pakistan.

Y/26. Yin, J. & Bian Q., (Chief Compilers), 1996. Geological map of the Karakorum-Western Kunlun and adjacent regions. In: Pan Yusheng (ed.), Geological Evolution of the Karakorum and Kunlun Mountains. Seismological Press, Beijing, 288p.

This volume deals with stratigraphy and paleontology, characteristics of sedimentary rocks, ophiolites, geochemistry of granitic rocks, geophysics and regional geologic evolution and tectonics of the mountain region to the north of Pakistan border. The geological map, however, gives information on area as far to south as Nanga Parbat. There are brief descriptions in Chinese and English.

Key words: Mapping, stratigraphy, palaeontology, ophiolites, Karakoram.

Y/27. Yoshida, M., 1996a. Paleomagnetic synthesis of three phases collision in the Himalaya-Karakoram belt and surrounding terranes. Extended Abstracts, International Seminar on Paleomagnetic Studies in Himalaya-Karakoram Collision Belt and Surrounding Continents, November 20-21, 1996, Islamabad. Geoscience Lab, GSP, Islamabad, 23-26.

It has been widely accepted that the Himalaya-Karakoram ranges were shaped by a crustal deformation caused by the collision of the Indian subcontinent with the Eurasian continent. In the northwestern part of the Himalaya-Karakoram belt, this continent- continent collision is not simple because (1) the Kohistan-Ladakh arcs were captured between the two colliding continental blocks, Indian and Eurasia continents, and (2) on the west, the Himalaya-

Karakoram belt adjoins the Afghan block bordered by the Chaman strike-slip faults zone, which caused a complicated oblique-collisional tectonic setting of the region (Figure 1).

(1) Suturing around the Kohistan-Ladakh Arcs

The paleo-latitudinal changes for the Kohistan arc, northwestern part of Indian subcontinent (northern Pakistan), and Eurasian continent since mid-Cretaceous time are illustrated in the Figure 2.

MKT Suturing: The paleo-position of Kohistan arc in mid-Cretaceous time is estimated to be around the equatorial zone (Zaman and Torii, 1996). The paleomagnetic direction of mid-Cretaceous Kohistan rocks is quite similar to that of Cretaceous components maintained by the rocks in the immediate northern block belonging to the Eurasian continent (Klootwijk et al., 1994; Zaman and Torii, 1996), which indicates the paleo-position of the Kohistan arc at the mid-Cretaceous time was very close to the southern margin of the Eurasian continent. The Main Karakoram Thrust zone (Northern Suture or Shyok Suture zone) had been probably already sutured. The mid-Cretaceous landmass extended from the Kohistan arc to the Karakoram block (= southern marginal terrane of Eurasian continent) was, however, considerably distant from the Eurasian inland terranes, Tadjikistan and Tarim basins. Its latitudinal discrepancy is more than 20° (2,000 km+) despite only 2°-4° gap (several hundred kilometers) is given in present geographic frame, which suggests a remarkable crustal shortening (intra-continental subduction) along terrane-boundaries took place within the Eurasian continent. Figure 1: Geotectonic frame of the Himalaya-Karakoram collision belt and surrounding terranes (boundaries based on Jacob and Quittmeyer, 1979), and the triple collision zone.

MMT Suturing: In northern Pakistan, the India-Eurasia collision is represented by the suturing along the Main Mantle Thrust (MMT) between the Kohistan and subcontinent. According to the compilation of paleomagnetic data (paleo-latitudes), the northward movement of the subcontinent is very rapid up to around the Late Paleocene (ca.58Ma) but after that the rate of movement suddenly slowed (Figure 2). Then the discrepancy of paleo-latitudes between the northwestern margin of subcontinent and the Kohistan arc (Ahmad and Yoshida, this volume) exhibits very small in Middle Eocene time (ca.45Ma), which suggests a completion of MMT suturing. Similar evidence has been found in the paleomagnetic data of deep-sea sediments accumulated on the Indian oceanic crust (Klootwijk et al., 1992). These sudden slowdowns in the northward motion of subcontinent are probably caused by an 'initial collision' without complete suturing along the MMT. Continuous underthrusting ('subduction' within continental crust) might occurred along the MMT suture zone in Paleocene-Eocene time. This may provoke an immense deformation of the crust of Kohistan arc including tectonic rotations and formed a structural frame of the Himalaya-Karakoram collision belt in northern Pakistan. (2) Oblique Collision between India and the Afghan Block Paleomagnetic data is sparsely known in the Afghan block which is of fused micro-continent terranes such as Helmand, Lut and Kabul blocks. Paleomagnetic data obtained from the Chagai and Raskoh volcanic arcs, southern part of the Afghan block mark its paleo-position in Paleogene time. The India-Afghan suturing is considered to be an oblique collision in Pliocene (Treloar and Izatt, 1993). The collision corresponds to a reorganization of arc-subduction system around the Afghan block which is represented by the calc-alkaline volcanism in the Sultan arc since the Gilbert Chron (Akram and Yoshida, 1996). The tectonic rotation within the block after the India-Afghan collision is also unveiled by the paleomagnetic data.

(3) Triple Collision Zone

The Himalaya-Karakoram collision belt is therefore characterized as a triple collision zone. Three phases of collision (Treloar and Izatt, 1993) can be, at least, recognized in and around the Himalaya-Karakoram collision belt, northwestern Pakistan since Cretaceous time. The first collision is represented by the MKT (or Shyok) suturing occurred in the Early (?) Cretaceous. The second collision is India-Eurasia collision which occurred along MMT (Indus-Tsangpo) suture at Late Paleocene-Middle Eocene time. The third one is the oblique collision between the collage of India-Kohistan terranes and the Afghan block. On the basis of currently-available paleomagnetic data, terrane-scale displacement and tectonics of this triple collision zone will be synthesized.

(eds.), Rock Magnetism and Paleomagnetism. Recent Progress in Pakistan, Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad, 13, 59-79.

Chamosite-hematite type oolitic ironstone, the Langrial iron ore, is distributed in Hazara District, northwestern margin of Indo-Pakistan Subcontinent which is situated in the northwestern part of the Lesser Himalayan Belt. The ironstone bed is assumed to be a palm-laterite formed during Cretaceous -Tertiary (K-T) time. The oolitic ironstone bed induces a geomagnetic anomaly with a maximum anomalous intensity of c.500nT; and no meaningful anomaly pattern was observed by VLF-EM survey. The oolitic ironstone shows rather small magnetic susceptibility and relative weak NRM intensity but very hard coercivity. Ferromagnetic properties of the rock are mainly derived from hematite grains which possess two remanence component: the overprint component (Declination=83.6°, Inclination=27.7°) and the characteristic remanence component (DecWon=298.5°, Inclination=19.8°). The directions of these remanence components suggest two-phase clockwise tectonic rotation of the terrain after the acquisition of each remanent magnetization. The characteristic component probably indicates paleomagnetic direction during the formation of oolitic ironstone which is inferred to be a lateritization and erosion processes at Cretaceous-Tertiary (K-T) boundary time in the southern hemisphere. The overprint component which passed a reversal test was possibly a thermo-viscous remanent magnetization (TVRM) acquired by long-term burial heating due to a subsidence of the terrain in the northern hemisphere.

Y/35. Yoshida, M., Karim, T. & Zafar, M., 1996. Thorium–232 decay series anomaly in natural Gamma–ray spectra of Haro river Loess–Paleosol deposits, Attock district, Punjab. Geological Survey of Pakistan, Proceedings Geoscience Colloquium, 14, 129–138.

Late Quaternary loess-paleosol sequence of Ham river sections, Attock, Punjab, exhibits a spectral gamma-ray anomaly in the energy window t (2.45-2.79MeV) which represents the thorium-232 (^{232}Th) decay series. The horizons showing high Th anomaly are probably enriched in Th-bearing minerals such as monazite. The anomalous horizons also coincide with the beds of Au concentration which is of placer origin. It suggests that the spectral gamma-ray method can be applicable to explore placer gold in the area.

Y/38. Yoshida, M., Zaman, H. & Ahmad, M.N., 1996. Paleoposition of Kohistan arc and surrounding terrane since Cretaceous time: the paleomagnetic constraints. In: Kausar, A.B. & Yajima, J. (eds.), Geology, Geochemistry, Economic Geology and Rock Magnetism of the Kohistan Arc. Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad 15, 83-101.

Paleomagnetic data recently obtained from the rock units in Kohistan arc show considerably low paleo-latitude at early Tertiary and mid-Cretaceous times. Paleomagnetic data of the Indo-Pakistan subcontinent, paleo-latitude data of Indian deep-sea sediments, and sea-floor spreading data of the Indian Ocean have detailed the southern limit of the Kohistan arc for the past 80 m.y. Paleomagnetic data from the Tadzhikistan and Tarim basins of Eurasian continent blocks, also reveal the northern limit of the arc and lateral displacement of southern continental margin.

Analysis of the combined paleolatitude-age profiles for these terranes (Figure 6) indicates paleomagnetic constraints on paleoposition of the Kohistan arc and its collision timing.

Key words: Paleomagnetism, Cretaceous, Kohistan arc.

Y/39. Yoshida, M., Zaman, H., Khadim, I.M., Ahmad, M.N. & Akram, H., 1997. Paleoposition of the Himalaya-Karakoram belt and surrounding terranes since Cretaceous: Paleomagnetic reconstruction of three phases collision history. In: Khadim, I.M., Zaman, H. & Yoshida, M. (Eds.), *Paleomagnetism of Collision Belts*. Geoscience Laboratory, GSP, Islamabad, 49-72.

Paleomagnetic data recently obtained from Pakistan have made conceivable a history of three phases collision of the Himalaya-Karakoram collision belt and surrounding terranes since Cretaceous time. The early Cretaceous was the time of suturing between the Kohistan arc and the Asian continent. At that time Indo-Pakistan subcontinent was located far in the southern hemisphere and the southern margin of the Asian continent spread out around equatorial region. The southern margin of Asian continental block was continuously shifting northward during the Cretaceous period after the Asia-Kohistan collision. The Paleocene was the main collisional stage between the Indo-Pakistan subcontinent and Kohistan-Asia blocks. The collision caused gigantic deformation and crustal shortening in and around the Himalaya-Karakoram collision belt. Most of ophiolite blocks around the subcontinent (peri-Indian suture) were obducted during this stage of time. Suturing between Indian subcontinent and Asia-Kohistan block was followed by the oblique collision between Indian subcontinent and Afghan block to the west, which provoked large-scale counterclockwise rotation by the late Eocene to early Oligocene. Thus, analysis of the combined paleolatitude-age profiles and paleomagnetic investigation of the tectonic deformation for these terranes document the geohistory of three phases collisions of the Himalaya-Karakoram collision belt: the first phase Asia-Kohistan collision (along the Shyok Suture) in the early Cretaceous, the second phase Kohistan-India collision (along the Indus-Tsangpo Suture) in the Paleocene, and the third phase India-Afghan block (along the Chaman Strike-Slip Fault) collision in the late Eocene-early Oligocene.

Y/40. Yoshino, T., 1998. Magmatic underplating of the lower crust of the Kohistan arc (N. Pakistan) deduced from Al-zoning in clinopyroxene and plagioclase. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 220-221.

The Kohistan complex, lying in the north-western part of the Himalaya, has been considered as a Cretaceous magmatic island arc, namely the Kohistan arc. The complex displays a widely exposed lower crustal section composed of metabasic rocks (amphibolites, pyroxene granulites and garnet granulites) with gabbroic origin. Because the lower crust of the Kohistan arc commonly has a mafic composition derived from gabbroic magma, magmatic underplating should be considered as a crustal generation mechanism. During the period of subduction-related magmatism, the underplated materials at middle to deep crustal level could subsequently undergo metamorphism under high-T conditions corresponding to upper amphibolite to granulite facies. Hence metabasites derived from a gabbroic protolith of the lower crust might preserve information of the metamorphism after cooling from magmatic temperature. Metamorphic P-T paths of the rocks would provide a constraint on the overall history of crustal evolution.

The lower crustal part of the Kohistan arc is divided into three geological units: the Jijal complex, the Kamila amphibolite belt and the Chilas complex, from south to north. Yamamoto. proposed a tectonic thickening model on the basis of two contrasting P-T paths of garnet-bearing granulites in the Chilas and Jijal complexes. The P-T path of the Chilas complex involved approximately isobaric cooling at relatively low-pressure conditions, whereas that of the Jijal complex showed anti-clockwise path at higher-pressure conditions. Such anti-clockwise P-T paths may reflect crustal thickening due to magmatic underplating or accretion in the crust. It is insufficient, however, to consider models for these P-T paths, because the P-T path for rocks of the Kamila amphibolite belt, which is sandwiched by the Chilas and Jijal complexes, has not documented well. To understand the evolutionary process of the lower crust of the Kohistan arc, determination of P-T paths of the Kamila amphibolite belt is needed.

The lower crustal rocks of the Kohistan complex (northern Pakistan) are mostly composed of metabasic rocks such as pyroxene granulites, garnet granulites and amphibolites that were originally gabbros. P-T trajectories of the relic

two-pyroxene granulites, which are the protolith of the amphibolites within the Kamila amphibolite belt have been investigated. Aluminous pyroxene retains igneous texture such as exsolution lamellae developed at core. The significant amount of Al in clinopyroxene is buffered by breakdown reactions of plagioclase accompanied by film-like quartz as a product at grain boundaries between plagioclase and clinopyroxene. Distinct Al-zoning profiles are preserved in pyroxene with exsolution lamellae at core and plagioclase adjacent to clinopyroxene in pyroxene granulites. In the northern part of the Kamila amphibolite belt, Al-contents in clinopyroxene increase toward the rim and abruptly decrease at the outer rim, and anorthite contents in plagioclase decrease toward the rim and abruptly increase near the grain boundary between plagioclase and clinopyroxene. In the southern part of the Kamila amphibolite belt, Al-contents in clinopyroxene and anorthite contents in plagioclase simply increase toward margin of the grain. The anorthite zoning in plagioclase is in agreement with the zoning profiles of Ca-tschermaks and jadeite components inferred from variations of Al, Na, Ti and Fe³⁺ in clinopyroxene. Assuming that the growth surface between them was in equilibrium, geothermobarometry based on Al-zoning in clinopyroxene coexisting with plagioclase indicates that metamorphic pressures significantly increase with increasing temperature under granulite facies metamorphism. The peak of granulite facies metamorphism occurred at conditions of about 800 °C and 800-1100 MPa. These prograde P-T paths represent a crustal thickening process of the Kohistan arc during the Early to Middle Cretaceous. The crustal thickening of the Kohistan arc was caused by accretion of basaltic magma at mid-crustal depth.

Y/41. Yoshino, T., Yamamoto, H., Okudaira, T. & Toriumi, M., 1998. Crustal thickening of the lower crust of the Kohistan arc (N.Pakistan) deduced from Al zoning in clinopyroxene and plagioclase. *Metamorphic Geology* 16, 729-748.

The lower-crustal rocks of the Kohistan complex (northern Pakistan) are mostly composed of metabasic rocks such as pyroxene granulites, garnet granulites and amphibolites. We have investigated P-T trajectories of the relic two-pyroxene granulites, which are the protolith of the amphibolites within the Kamila amphibolite belt. Aluminous pyroxene retains igneous textures such as exsolution lamellae developed in the core. The significant amount of Al in clinopyroxene is buffered by breakdown reactions of plagioclase accompanied by film-like quartz as a product at grain boundaries between plagioclase and clinopyroxene. Distinct Al zoning profiles are preserved in pyroxene with exsolution lamellae in the Kamila amphibolite belt, Al in clinopyroxene increases towards the rim and abruptly decreases at the outer rim, and anorthite in plagioclase decreases toward the rim and abruptly increases near the grain boundary between plagioclase and clinopyroxene. In the southern part of the Kamila amphibolite belt, Al in clinopyroxene and anorthite in plagioclase simply increase towards the margins of the grains. The anorthite zoning in anorthite in plagioclase simply increase towards the margins of the grains. The anorthite zoning plagioclase is in agreement with zoning profiles of Ca-Tschermaks and jadeite components inferred from variations of Al, Na, Ti and Fe³⁺ in clinopyroxene. Assuming that the growth surface between them was in equilibrium, geothermobarometry based on Al zoning in clinopyroxene coexisting with plagioclase indicates that metamorphic pressures significantly increased with increasing temperature under granulite facies metamorphism. The peak of granulite facies metamorphism occurred at conditions of about 800 °C and 800-1100 Mpa. These prograde P-T paths represent a crustal thickening of the process of the Kohistan arc during the Early to Middle Cretaceous. The crustal thickening of the Kohistan arc was caused by accretion of basaltic magma at mid-crustal depths.

Y/44. Young, G.J. & Schmok, J., 1989. Ice loss in the ablation area of a Himalayan Glacier: studies on Miar Glacier, Karakoram Mountains, Pakistan. *Annals of Glaciology* 13, 289-293.

One of the main aims of the Snow and Ice Hydrology Project, a joint Canada-Pakistan endeavor, is to estimate ice loss in the ablation areas of glaciers in order to predict with greater confidence stream flow in the headwaters of the Indus River. To this end, Miar Glacier, located in the central Karakoram Range, north of Gilgit, was intensively studied during the summers of 1986 and 1987. Measurements of glacier mass balance by the monitoring of accumulation and ablation at stake locations is very difficult in the Himalayan environment. It is usually almost impossible to reach elevations above the equilibrium line without major effort, and always very difficult once there to make meaningful measurements; the ablation areas are often heavily crevassed and/or debris-covered, and this poses difficult sampling problems. The method used in this study was to monitor annual surface movement on a cross-profile as near as possible to the equilibrium line. The measurements, obtained in conjunction with depth soundings made on the same profile, allow the annual ice flux through the cross-profile to be calculated. If an approximately steady-state glacier is assumed, it would be expected that this flux would be roughly equivalent to the rate of ice loss below the profile. The movements of wooden stakes drilled into the glacier were monitored throughout each of the summers and, since two of the stakes survived the intervening winter, this allowed calculation of annual movement. Distances between the crests of ogives were also surveyed, providing an independent assessment of glacier movement. Depth measurements by radio-echo sounder were successfully made in the summer of 1987, showing maximum ice depths of 550 m. The annual ice flux through the transverse profile was estimated as $5.67 \times 10^7 \text{ m}^3$, which corresponds to a mean annual ice loss from the glacier surface below the profile of 8.10 m of ice.

Y/47. Younghusband, F.E., 1895. Chitral, Hunza and the Hindu Kush. *Geographical Journal*, London. 5(5), 409 – 422

As this article does not have an abstract, the first few paragraphs are reproduced here: It is with a good deal of compunction that I address you on these states of the Hindu Kush which are to form the subject of my lecture to-night, for I feel that the honour of doing so should have fallen on others than myself. I was not the first, by many, to explore and open up these states. Many had gone before me, and all that I could do was to follow in the steps of these first pioneers, and carry on the work which they had commenced. Poor Hayward, the first intrepid Englishman who pushed his way into these mountain recesses, never returned to tell the tale of what he saws for he was cruelly murdered in Yasin in 1870. But Biddulph, the first to visit Chitral and the first to visit Hunza, might well have borne the privilege which is now falling to me. And Macnair, Sir William Lockhart and the members of his mission Mr. Ney Elias, Colonel Durand, Dr. Robertson, Captain Tyler, E.E., were all my predecessors, and could have told a more interesting tale than mine of how they found these primitive, picturesque hill-men at their very first touch with the outside world. But while I cannot lay claim to your attention as the first to visit this interesting region, I can, at least, ask it as the last to do so. It has been my privilege to represent the British Government in both Hunza and Chitral, and it is only a few months ago that I returned from the latter place, after a stay of more than two years

among these little states of the Hindu Kush. Before, however, proceeding to any description of these it is necessary for me to put clearly before you the reasons why these regions should especially interest you. These are many. There are, first, the political and military reasons. Here is the point where, as the title of Mr. Linight's remarkably interesting book runs, 'Three Empires Meet.' The Indian, the Russian, and the Chinese empires all meet here, and where three such empires meet the eyes of the people who inhabit them must naturally be turned. To the members of a scientific society, however, such considerations may possibly not have much weight. These would require some deeper attraction than the mere political boundaries of different races. To such the Hindu Kush affords the highest interest; for we have here mountain ranges of colossal height and only of recent years explored, and races of people of a very primitive type, who, shut up for centuries in their mountain fastnesses, have preserved intact much of their original type of manners and customs. I was brought up a soldier, and became a "political," as we are called in India, my interests were therefore more purely military and political rather than scientific; but as it was a part - the main part, I may say - of my duties to study the character and nature both of the people and the country, I shall hope that some of the impressions I formed of them may prove interesting to you. The country I am to describe to you, then, is that lying immediately north of Kashmir and south of the Pamirs, which is drained by water flowing into the Indus, and comprises the states of Hunza, Nagar, and Chitral. It is an entirely mountainous country, with never a stretch of plain more than 3 or 4 miles in length. The valleys are all deeply cut, and even the longest mountains are 13,000 or 14,000 feet in height, while some rise to 25,000. The nature of the mountains will best be gathered from the lantern slides I propose to show you. Except in the lower part of Chitral and in occasional secluded side valleys, they are perfectly bare. In some parts one may travel for March after March without seeing a sign of a tree outside the valley bottoms, and the barren character of these hills has much to do with their forms and with that of the valleys. What we see here are great masses of rocky mountains, their summits in the loftier regions clothed in snow and ice, but in most parts bare, and their bases always so. On these rocks the sun in summer beats down with a force which makes them so hot it is impossible to keep one's hand on them without burning it; and in winter come frosts reaching below zero Fahrenheit, which freezes the draining of the snow and rain in the crevices of the rocks, and breaks them off by the same process as water swollen into ice bursts up our water pipes. Owing to the extremes of temperature, the rocks in all this region are very loose, so when the snow melts off them at the close of winter and still more so when a storm of rain or a cloud-burst falls upon these mountains, the whole of their sides is washed of their loose debris, which comes pouring down a liquid stream of mud and stones and boulders into the gorges, and there piles itself up till, by the pressure of weight from behind it is forced out into the more open main valley and then spreads itself out in one of those alluvial fans, or cones of deposition which occur in all mountainous countries, but which are seen in these dry lofty regions of the Hindu Kush in their fullest development. These are one of the most characteristic features of this country, and it is for this reason that I direct your attention to them. The traveller here sees in the distance some big snowy peak, but the greater part of the scene around him is of bare hillside, and the valley bottoms, which to traverse are simply a succession of these alluvial fans separated here and there by some huge rocky bluff, but often running one into the other in a continuous stretch. The climate of these regions is one of extreme. At Chitral (5000 feet) the maximum I registered was 100°, and at Gilgit (4800 feet) Dr. Roberts recorded a maximum of 110°. These temperatures were in the cultivated parts, where the vegetation makes it cooler. In the bare open valley, where the sun comes with full force on the rocks, it must be certainly greater. As to the minimum, in Chitral in February (I have no January records) the lowest reading was 15°, and in Mastuj (7800 feet) 5° below zero. In Gilgit it is not so cold; the thermometer there does not appear to fall below 20°. The air over most of the region is extremely dry and the rainfall very small. Nearly all the moisture from the monsoons, which break over the plains of India, is precipitated on the outer ranges of mountains before reaching these remote valleys; and, though not so dry as the countries east and north for a certain amount of moisture seems to come up the funnel of the Indus valley to Gilgit and Hunza, and over the Bajaur hills to Lower Chitral - the rainfall on the whole is very slight, and the climate dry and healthy.

Key words: Books, Continents.

Y/49. Yousaf, M., 1970. Gravity survey of Kohat Area. M.Sc. Thesis Institute of Geology, Punjab University, Lahore, 87p.

The gravity survey of Kohat area has been conducted in Collaboration with Gravity Party III of Oil and Gas Development Corporation, for the purpose of oil prospecting. A network of 562 ordinary gravity stations and 15 gravity base stations covering an area of about 5000 sq. Km was accomplished. The survey consisted of geodetic work and gravity observations carried out with a Russian transit theodolite and Wordon gravimeter respectively. The results of the survey are shown on a Bouguer anomaly map on the scale of 1: 250,000 which show a number of positive and negative anomalies both qualitative and quantitative analysis of this map has been done.

Y/51. Yousaf, M., 1987-89. The geology and petrology of Jijal and Patan complexes southeast of Indus River in southern Kohistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 80p.

The project area lies in some parts of Kohistan and Mansehra districts, covering about 150 sq. kms area, including south easterly sides of Jijal and Patan complexes, starting from Karakoram highway spreading up to Pashto village. The work has evolved geological mapping of the area on a scale of 1:50,000. This thesis deals with the geological, petrographical and petrogenetical studies of the Jijal and Patan complexes and their relation with Kayal complex. The project area lies in the frontal part of the Kohistan island arc which covers about 36,000 sq Km area, structurally bounded by sutures named as Main Mantle thrust (MMT) and Main Karakoram thrust (MKT) on its southern and northern sides respectively. The Kohistan arc is intruded by a large number of basic complexes starting from a very primitive Dasu complex up to Jijal complex along with a Kohistan batholith which was intruded at last. Previously, the metamorphosed mafic complexes have been lumped together as an undifferentiated mass called Kamila amphibolite. Now we under the guidance of our supervisors have divided the Kamila amphibolite into three complexes starting from very older Dasu complex down to Kayal complex and last emplaced Patan complex. Dasu complex is the oldest pluton which is highly metamorphosed, intruded in the island arc. Dasu complex is underplated by another pluton the Kayal complex which is metamorphosed upto amphibolite facies grade, but less metamorphosed as compared to Dasu complex. Again Kayal complex is being underplated by another pluton which least metamorphosed last emplaced Patan complex. Patan complex is in turn underplated by a highly metamorphosed Jijal complex which is being obducted into the Indian plate. The geological rock sequences of the area consist of ultramafic and mafic associations. The ultramafic association of the Patan complex is overlain by a thick mafic unit which grades into two pyroxene diorite at top and gabbro-norite at base. The ultramafic portion of the Patan complex is discovered by us for the first time which is well exposed in north western side of Indus River (in Duber stream) and is sliced off in south eastern side due to strike slip Patan fault. The ultramafic association of the Jijal complex consists of cyclic units of dunite/wehrlite-websterite-hornblende clinopyroxenite –garnet clinopyroxenite. The mafic association of Jijal complex consists of a massive garnet gabbroic unit of about 7 Km. Both Jijal and Patan complexes are interlinked by a strike-slip fault named as Patan fault. The field evidences reveal that both Patan and Jijal complexes are well layered intrusions emplaced in the frontal part of the island arc by underplating, phenomenon, among which Jijal complex is least metamorphosed. Both complexes were formed from two different cycles of magma which was hydrous, low K, picritic-high Mg tholeiitic in nature (Loucks, 1990).

The variation of chemical composition of the loess-paleosol deposits reveals that Fe, K, Al, and Mg contents are relatively high in the paleosol horizons than rest of the loess sequence, whereas Ca content is relatively low. Elemental ratios of $\text{SiO}_2/\text{Al}_2\text{O}_3$, and $\text{SiO}_2/\text{Fe}_2\text{O}_3$ generally decrease at paleosol horizons. These characteristics of chemical composition resemble to loess-paleosol deposits in Kashmir and China, it is applicable to identify paleosol horizon as well as paleoenvironmental condition in the area

Z/2. Zafar, M., Murata, M., Khan, T., Ozawa, H. & Nishimura, H., 1998. Major and trace element composition of post-collisional, peraluminous Garam Chashma granite in Trans-Himalaya, northwestern Pakistan. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 221-222.

Garam Chashma granite belongs to a suit of granitoids of the Asian continental plate in the Hindu Kush Range (Trans Himalaya), northwestern Pakistan. It is located about 30-km northwest of Chitral and northern suture covering an area of about 300-km². The Garam Chashma granite is a discordant and leucocratic rock, which intruded into pelitic metasediments and amphibolites formed during Barrovian type metamorphism that took place between 40-25 Ma ago. A comparative age of 28-12 Ma has been suggested for the Garam Chashma granite which is same as for some of the Higher Himalaya leucogranites. Petrographically, the major rock forming minerals include quartz, plagioclase, K-feldspar, muscovite and biotite with subordinate garnet and tourmaline. Ratio of muscovite to biotite is not constant. All accessory mineral cordierite has also been reported in the area. Grain size ranges from fine to coarse grained. Texturally the rocks are massive, however, slight to moderate foliation marked usually by muscovite and biotite, especially near the contact of intrusion can be observed. Aplitic and pegmatitic veins/dikes localising minerals such as garnet and tourmaline are widely spread through out the pluton. A total of about 72 rock samples were collected from the Garam Chashma area. Major and trace components (Ce, Cr, Nb, Ni, Pb, Rb, Sr, Th, Y, Zr, and Ba) were analyzed using X-ray fluorescence spectrometer. On the ternary discrimination diagram, for S and I-type granites, oxide mole values of Al-Na-K, Ca and Fe+Mg predominantly plots on the S-type field suggesting sedimentary source for the Garam Chashma pluton. The silica concentration variation range is very small (71.91-76.08 wt %). A/CNK ratio is greater than 1 thereby conforming the peraluminous nature of the pluton. Almost all the major elements when plotted against silica, show some sort of depletion trend with increasing silica, whereas Na shows an enrichment trend. Minor depletion trend of K may represent an early formation of K-feldspar along with ferromagnesian minerals during crystallization history of the pluton. Depleting patterns of Ba, Nb, Sr, Ti, and P, commonly found in subduction related magmatism, are observed. Decreasing K/Rb ratios in K/Rb versus Rb plot may be attributed to the fractionation of feldspars.

Furthermore, a chemical compositional comparison based on major and trace elements with two pre-collisional granitoid bodies named Tirichmir and Kafiristan in Trans Himalaya, located NE and SE of the Garam Chashma respectively, is also performed. Silica concentration ranges for Tirichmir (65.96-72.02 wt %) and Kafiristan (64.26-75.72) are higher than that of the Garam Chashma pluton, because of their predominant granodioritic nature. A/CNK plots reveal peraluminous and meta-peraluminous characteristics of Tirichmir and Kafiristan plutons respectively. In Si versus K plot, potassium shows an enrichment trend in Tirichmir and Kafiristan plutons when compared to Garam Chashma. Ca and Fe concentrations are higher than those for the Garam Chashma pluton because of the presence of more mafic minerals. However, higher Ca and Fe concentrations and lower Mg concentration in the Kafiristan pluton than the Tirichmir pluton, are probably due to the higher concentrations of hornblende in the former. Pb, Rb, Y, Th and Zr concentrations show enrichment in mafic fractions of both the granitoids. A positive correlation of Ba and Sr represents fractionation of mineral phases such as plagioclase and K-feldspar of the Garam Chashma pluton and hornblende, feldspars and biotite of the Tirichmir and Kafiristan pluton.

Z/5. Zaheer, B., 1990-91. Structure, stratigraphy and petrography of the western limb of the Hazara-Kashmir Syntaxis, Garhi Habibullah-Shinkari area, Northern Pakistan. M.Sc. Thesis, University of Azad Jammu & Kashmir, Muzaffarabad, Pakistan, 105p.

The Garhi Habibullah-Shinkari area lies along the western limb of the major northwest plunging antiformal structure known as the Hazara-Kashmir syntaxis. The 293 km² area has been mapped in this study. The western limb of the Hazara-Kashmir syntaxis has been divided into four fault-bounded tectonostratigraphic zones. These are named as the Muzaffarabad-Balakot zone, the Garhi Habibullah-Abbottabad zone, the Panjal zone and the Mansehra zone. These zones belong to different tectonic and stratigraphic provinces which have been juxtaposed during the Himalayan thrusting. The Muzaffarabad-Balakot zone lies to the east of Main boundary fault. This zone constitutes late Proterozoic to Cenozoic sequence. This sequence is involved in the Muzaffarabad-Balakot southwestward overturned anticline. The late Proterozoic Dogra formation forms the core of the Muzaffarabad-Balakot anticline. The Dogra formation is unconformably overlain by the early Cambrian Muzaffarabad formation. The Ordovician (?) Yadgar formation disconformably overlies the Muzaffarabad formation. The Yadgar formation is unconformably overlain by the Paleocene-Eocene sequence which includes the Hangu Formation, Lockhart Formation, Patala Formation and Margala Hill Limestone. This was followed by the late Eocene Kuldana and Miocene Murree molasses. The most of the Paleocene to Miocene sequence along the overturned limb of the Muzaffarabad-Balakot anticline is faulted.

The Garhi Habibullah-Abbottabad zone lies between the Main boundary fault and Garhi Habibullah fault. This zone is involved in the Garhi Habibullah syncline. The Cambrian Abbottabad group lies in the core and Hazara formation along the limbs of the anticline. In the Garhi Habibullah syncline, the late Proterozoic Hazara formation is unconformably overlain by the Cambrian Abbottabad group of rocks. The Jurassic sequence has been eroded from the core of the syncline due to later Himalayan uplift.

The Panjal zone lies between the Garhi Habibullah fault and Panjal fault. The Panjal zone includes the late Proterozoic to Triassic rocks which are involved in the Tarkot anticline and Doga syncline. In this zone the Carboniferous Chushal formation unconformably overlies the late Proterozoic Hazara formation and grades into the Permo-Triassic panjal formation. These rocks are metamorphosed up to lower green schist facies metamorphism. The Mansehra zone lies west of Panjal fault. It includes the late Proterozoic Hazara and Tanol formations and intrusive Cambrian Mansehra granite. The grade of metamorphism varies from chlorite-grade in the south to staurolite-grade in the north.

The Panjal and Mansehra zones are intruded by Permian mafic dikes and sills of basalts and dolerites. These basalts and dolerites are fresh but at places show weak Himalayan metamorphic effects. The sedimentary, metamorphic and igneous rocks of these zones are classified by petrographic studies.

The rocks of these zones have been affected by multiple pre-Himalayan and Himalayan deformational events. Four deformational events have been recognized as D₁, D₂, D₃ and D₄ deformations. D₁ Hazran deformation is restricted to the late Proterozoic sequence. D₂ deformation produced a barrovian type metamorphism which produced lower-greenschist to amphibolite facies metamorphism in the Panjal and Mansehra zones. The effect of D₂ deformation is weak or absent in Garhi Habibullah and Muzaffarabad-Balakot zones. D₃ deformational event produced southeast-directed folds and thrusts in Mansehra, Panjal and Garhi Habibullah zones. Whereas D₃ deformational event in the Muzaffarabad-Balakot zone produced southeast-directed folds and thrusts. The backsteepening and late extensional folding in all of the four zones occurred in the later phase of D₃ deformation. However, the D₄ deformational event is related to the northwest plunging antiformal and synformal structures which are related to the formation of the Hazara-Kashmir syntaxis.

Z/8. Zahid, M. & Moon, C.J., 1998. Genesis of stratabound scheelite mineralisation Chitral, Northern Pakistan. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 222-223.

Tungsten mineralisation lies within the Asian plate approximately 50-km to the north-west of Main Karakoram Thrust, which marks the suture zone between the Kohistan complex (Northern Pakistan) and Asian plate. Arkari Formation hosts the stratabound tungsten mineralisation at Miniki Gol, Chitral. This Formation is dominantly composed of garnet mica schist, phyllite, calc-silicate quartzite, marble and tourmalinite. Tungsten mineralisation is mainly represented by scheelite in the study area. Scheelite has been found in various rock types but is mainly concentrated in calc-silicate quartzite and subordinate tourmalinite. It occurs as discontinuous patches, stringers and conformable small veins within calc-silicate quartzite and thus can be classed as stratabound type.

Miniki Gol area has undergone at least two phases of deformation and metamorphism which are related to continent-arc collisions during the Cretaceous and Eocene respectively. The Miniki Gol metasediments are intruded by leucogranites emplaced after the culmination of amphibolite facies metamorphism. This felsic intrusion seems to be contemporaneous with the second phase of deformation.

Both the continuity and distribution of scheelite mineralisation appear to be influenced by the internal structure in the calc-silicate quartzite and tourmalinite. Scheelite in these rocks has partitioned along both overprint penetrative foliation and crenulation foliation. The concentration of some scheelite grains in hinges of the kink folds suggests that these foliation planes probably have acted as loci for the epigenetic mineralising fluids. The presence of scheelite grains within the cross-cutting quartz veins also suggests a post-granitic enrichment of the tungsten mineralisation.

The occurrence of calcic-amphibole (hornblende-actinolite), clinozoisite, titanite, calcite, anorthite, grossular garnet, diopside and scheelite fairly coordinates with the skarn mineral assemblage. Except for diopside and grossular garnet, these mineral compositions appear to show a consistent and common trend through out the deposits. This also establishes a genetic relationship between scheelite mineralisation and Miniki Gol leucogranite.

The high concentration of Zr, Hf, Be, Th, U, Ga, Nb, Y, Sn and W in scheelite-bearing calc-silicate quartzite compared to the unmineralised calc-silicate quartzite, psammite and schist implies a hydrothermal activity at the Miniki Gol area. Moreover, the consistency of the fluid inclusions both within leucogranite and calc-silicate rock also signify a genetic link between the scheelite mineralisation and the possible post-magmatic hydrothermal fluids.

Key words: Scheelite mineralization, economic geology, stratabound deposits, metapelites, Chitral.

Z/9. Zahid, M. & Moon, C.J., 1999a. P-T estimates of the calc-silicate rocks and the associated scheelite mineralization from the Miniki Gol, Chitral, N. Pakistan. Geological Bulletin, University of Peshawar, 32, 1-11.

Co-existing calcic-amphibole and plagioclase have been used to obtain pressure-temperature estimates from the calc-silicate rocks at Miniki Gol, Chitral, N. Pakistan. The Miniki Gol calc-silicate rocks are located within the Hindu Kush range, approximately 50 km to the northwest of the Northern suture zone. Jurassic Arkari Formation hosts the calc-silicate rock, composed of clinozoisite, quartz, calcic amphibole, plagioclase, chlorite, biotite, calcite, sphene, garnet and scheelite.

A pair of coexisting ferro-tschermakitic hornblende and anorthite from scheelite bearing calc-silicate quartzite and a pair of andesine and magnesio-hornblende from barren calc-silicate quartzite were selected for P-T estimates. These pairs have apparently formed under equilibrium conditions. The tschermakitic hornblende anorthite pair yields a temperature range of 600-650°C whereas the andesine and magnesio-hornblende pair

gives a temperature range between $530 \pm 20^{\circ}\text{C}$ and $490 \pm 20^{\circ}\text{C}$. These temperatures are compatible with those of the upper amphibolite facies and greenschist facies metamorphism, respectively.

A general agreement was also observed when these estimates were checked with the criteria described for the correlation of temperature with increase in TiO , Na_2O and Al_2O_3 , from actinolite to tschermakite. The chemistry of the tschermakitic amphibole indicates that the calc-silicate rock has formed at a pressure below 5 kbar. Keeping in view the variation of chemical composition (Al_2O_3 , content) in calcic-amphibole associated with scheelite grains, it can be suggested that scheelite crystallised in a temperature range of 550°C - 400°C .

Key words: Geothermobarometry, calc-silicates, scheelite mineralization, Chitral, Hindukush.

Z/10. Zahid, M. & Moon, C.J., 1999b. Genesis of tourmalinite from Chitral, Northern Pakistan. Geological Bulletin, University of Peshawar 32, 77-87.

Miniki Gol scheelite-bearing tourmalinite occurs within the Jurassic Arkari Formation. The Arkari Formation is located near the Pak-Afghan border within the Eastern Hindu Kush and is composed of garnet mica schist, phyllite, marble, mica quartzite, calc-silicate quartzite and subordinate tourmalinite. The extension of tourmalinite is very limited and has been identified at three locations within the mica schist. Tourmalinite is dominantly composed of tourmaline, spessartine-rich garnet, quartz and scheelite. Tourmaline reaches up to 80% by volume in some tourmalinites. The chemical composition of tourmaline and garnet of the tourmalinite fairly corresponds with those of the nearby exposed leucogranite. The values of K₂O, MnO, Zn, Rb and Ba of Miniki Go1 tourmalinite, are not markedly different from the associated schist and thus cannot be considered as siliceous chemical precipitates (exhalites). The limited extension of the tourmalinite is also inconsistent with the occurrence of exhalites. The lack of Sb, Hg, Ag, F and P in the tourmalinite also rules out the possibility of the exhalative activity in the study area. A linear relationship between LREE and elements of obvious igneous origin such as Zr, Hf and Be in the tourmalinite indicates a post-magmatic metasomatic activity. The Miniki Go1 leucogranite can be considered as potential source for the extreme enrichment of boron in the tourmalinite.

Key words: Tourmaline, scheelite, metasomatism, Chitral, Hindukush.

Z/11. Zaka, K.J., Bajwa, N.A. & Pervaiz, K., 1998. Landslide hazard zonation in the Hindukush Mountains at Golen Gol hydropower project, Chitral-A terrain evaluation approach. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, p.224.

Mitigation of disasters can be successful only when detailed knowledge is obtained about the expected frequency, character and magnitude of natural phenomena which may cause disaster in an area. The zonation of hazard must be the basis for any hazard mitigation project. To map such zones, a terrain classification map (TCM) has been prepared assuming slope as basic element. A land use map (LUM) was prepared using aerial photographs. A combination of TCM and LUM provides fair assessment of slope, vegetation, geology /structure and land use. Five hazard prone zones have been identified i.e. old stable landslides, old active landslides, recently active landslides and potential land slide zones. The interpretation of TCM, lineament map and engineering geological map leads to the conclusion that the area of thrusts and ridges are more prone to land sliding.

Key words: Landslide, hazard, hydropower, Hindukush.

Z/12. Zaka, K.J., Baloch, I.H. & Chaudhry, M.N., 1997. Provenance, alkali, aggregate reaction (A.A.R) and inservice behaviour of NW Himalayan gravels and sands in cement concrete at Terbala and Warsak Dams Pakistan. Geological Bulletin, Punjab University 31 & 32, 53-68.

Key words: Alkali aggregate, gravels, sands, cement concrete, Indus.

Z/13. Zaka, K.J. & Chaudhry, M.N., 1995. Provenance, alkali, aggregate reaction (A.A.R) and inservice behaviour of NW Himalayan gravels and sands in cement concrete at Terbala and Warsak Dams Pakistan. Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

The NW Himalaya in Pakistan from which the gravel and sand of Indus River and its major tributaries are derived is geologically very complex. The mountain chains comprising this area have been formed by India Eurasia collision initiating at ca 65 m.y. with the Kohistan-Ladakh Island Arc trapped in between. The Indian plate at the leading edge is composed of Higher Himalayan S-type granitoids, migmatites and a sequence of high grade calc-pelites, marbles, pelites and psammites with layers of amphibolites. Granitoid, migmatite, carbonate, amphibolite and hard schists derived from these blocks are innocuous. Extensive mylonites have developed along Main Central Thrust, Indus Suture Zone and Thakot Fault and rarely within the Higher Himalayan crystallines (HHC). Quartz rich clasts of mylonites derived from these zones contain highly strained quartz with anomalous optics and are potentially deleterious.

The Lesser Himalaya to the south of the Higher Himalayan Block is composed of a northern metamorphic-igneous zone comprised predominantly of porphyritic S-type cordierite granitoids, pelites and psammites. The southern sedimentary zone is comprised of pelites and psammites and a sequence of unmetamorphosed shelf carbonates with minor sandstone and shale horizons. The granitoid, hard schist and medium to high-grade psammites of metamorphic zone are innocuous. Slates, phyllites and graywackes in lower greenschist facies are potentially deleterious. Carbonate and sandstone clasts from the sedimentary part are innocuous. However chert clasts from this zone are potentially deleterious. The Balakot Mylonite Zone (B.M.Z) and Oghi Shear Zone (O.S.Z) yield deleterious strained quartz rich clasts. Microfractured quartz clasts derived from Hazara slate and Tanawal Formation of pelite psammite character from Lesser Himalaya are also potentially deleterious since they contain cryptocrystalline quartz along fracture cleavage developed during the second major deformation phase. The Kohistan Island Arc is composed of high grade amphibolites, acid to intermediate volcanics and I-type granitoids ranging in composition from granite to diorite and minor chert, volcanogenic arenites, carbonates, pelites and marl. The Kohistan terrain yields slightly reconstituted acid to intermediate ferro to cryptocrystalline volcanics, pyroclasts and volcanogenic chert/chalcedony and arenites metamorphosed to a very low grade. These are again potentially deleterious. I-type granitoids and amphibolites are innocuous.

A gabbro-norite batholith also occurs in this terrain. The huge batholith variously interpreted as having been formed under a spreading center (Ghazanfar et.al. 1991), as a core batholith to the Kohistan Island Arc (Jan, 1980) or formed due to rifting of a mature arc or under a back arc spreading center (Khan et.al. 1992) is composed of about 95% gabbro-norite, 1% ultramafics and 3% diorites and tonalites. The clasts derived from this source are innocuous.

The Kohistan Arc is bounded by two suture zones the northern of which is known as the Main Karakoram Thrust (MKT) while the southern branch is known as the Indus suture zone or the Main Mantle Thrust (MMT). The suture is composed of pillow lavas, peridotite and dunite cumulates, harzburgite tectonites, bedded cherts, volcanogenic chalcedonic cherts and flysch. The two suture zones contribute only small quantities of deleterious clasts derived from bedded/ribbon chert and other flyschoid sediments. The Karakoram Plate to the north of MKT is composed of a basement S-type granitoid complex overlain by high grade pelite, psammites, marbles and calc-pelites. This in turn is overlain by a sequence of slates and low grade carbonates. Only small quantities of potentially deleterious volcanics and low grade meta-argillites are contributed by this terrain.

The sand and gravel derived from this complex terrain has so far exhibited excellent physical characteristics. But these have shown alarming petrographic and chemical behaviour in concrete. A controversy has therefore continued over the past one decade as to the actual causes of deleterious deterioration in parts of already placed concrete.

In Tarbela and Warsak Dams natural sand and gravel from the river bed of Indus and Kabul were used respectively. In case of Tarbela the coarse aggregates is composed on the average of amphibolitic/foliated diorite 27.6%, granodiorite/granite 16.1%, greywacke group 13.7%, quartzite/micaceous quartzite 13.0%, schist/subschist 7.4%, acid to intermediate volcanics 6.8%, phyllite 5.5%, carbonates 4.2%, garnet amphibolite 2.4%, basic volcanics 2.2%, diabase 0.9% and chert 0.2%. The fine aggregates are composed of quartz/quartzite/micaceous quartzite 30.5%, granite/granodiorite 20.2%, amphibolite/foliated diorite 10.7%, feldspar 10.0%, micas 5.8%, greywacke group 5.3%, amphibole 4.6%, schist 4.0%, phyllite/slate 3.3%, iron ore 1.3%, epidote 1.3%, carbonates 1.2%, volcanics 0.6%, garnet 0.3%, sphene 0.3%, chert 0.2%, tourmaline 0.2%, apatite 0.1%, zircon 0.1%. These were considered non-deleterious and were used with ordinary portland cement having ~ alkali level ranging from 0.9% to 1.03%. Although the exact composition of cement used for construction of Warsak Dam is not known yet the record of analysis available show that the total alkalis level ranged from 0.9% to 1.20%.

The aggregates used in construction of Tarbela Dam contain large amounts of slightly metamorphosed acid to intermediate volcanics, argillites, microfractured quartzites, greywacke and a little chert. Although these aggregates contain large quantities of potentially deleterious rock types yet they were presumably regarded safe either because their parent rocks had undergone metamorphism or on the grounds that they had large quantities of mildly reactive rock types and therefore, would not develop deleterious reaction. It was only after twelve years of completion that A.A.R was confirmed in concrete structures of the dam (Chaudhry and Zaka 1994).

Similar type of aggregates were used for the construction of Warsak Dam. The coarse aggregates are composed of schist 11.6%, phyllite/slate 8.8%, amphibolite/amphibole gneiss 23.0%, quartzite 20.9%, granite/granite gneiss 21.5%, microfractured and strained quartzite 7.8%, acid to intermediate volcanics with microcrystalline matter 2.6%, limestone 3.0%, chert 0.8%. The fine aggregates are composed of quartz 35.2%, amphibole 12.3%, plagioclase/albite 7.9%, amphibolite/amphibole gneiss 7.0%, orthoclase/microcline 6.4%, quartzite 5.2%, schist 3.5%, granite/granite gneiss 4.1%, phyllite/slate 2.0%, magnetite 1.3%, biotite 2.6%, strained quartz 3.5%, microfractured and strained quartz 2.7%, muscovite 1.0%, chlorite 0.6%, limonite 0.8%, garnet 0.5%, acid to intermediate volcanic with microcrystalline matter 1.1%, limestone 1.6%, sphene 0.2%, chert + microcrystalline quartz 0.5%, tourmaline Tr. Warsak Dam civil structures have undergone deterioration due to A.A.R especially the Power House installations. The rock types, which are directly responsible for deleterious reactions, are microfractured quartzite, phyllite/slate, and partially reconstituted merrocryalline acid to intermediate metavolcanics and a little chert.

The aggregates were considered safe by earlier works on the grounds that the deleterious rock types like argillites, greywackes, quartzite and acid to intermediate volcanics had undergone metamorphism. We suggest that these rocks have been reconstituted in very low-grade metamorphic zone (Winkler, 1976) or prehnite-pumpellyite to lower greenschist facies. As such the reactive silica phases and phyllosilicates have not been reconstituted completely to innocuous mineral phases. We further suggest that such rocks are rendered innocuous only when metamorphosed to biotite grade on an equivalent reaction in greenschist facies. In phyllosilicate bearing rocks it is characterized by the transformation of illite to structurally well ordered micas or equivalent transformations.

The presumption that a large quantity of reactive rock types in Indus aggregate may render it innocuous is not proved. While Pessimism can be applied to gravel composed predominantly of one rock type (flint gravel of U.K. or France from London or Paris Basins) the same is difficult to extrapolate for polymit gravels with a variety of reactive rock types unless prolonged experimentation furnishes a justification. alkali, aggregate reaction (A.A.R) and inservice behaviour of NW Himalayan gravels and sands in cement concrete.

Key words: Alkali aggregate, gravels, sands, cement concrete, Indus.

Z/14. Zakir, S. & Shaheen, F., 2001. Monitoring of groundwater quality in Gadoon Amazai Industrial Estate, NWFP, Pakistan. Abstracts, 4th Pakistan Geological Congress, Islamabad, p.48.

Industrial effluents are potential source of water pollution. The lack of in-plant control measures, discharge of untreated wastewater through open drainage system and the lack of implementation of existing regulation remain serious threats to the quality of surface and ground waters. The present study was carried out to evaluate the pollution load of ground water contamination in the Gadoon Amazai Industrial Estate (GAIE). A total of 21 samples were collected from GAIE during three months from five tube wells, one hand pump and one dug well and analysed for biological oxygen demand, chloride, electrical conductivity, nitrate-nitrogen, sulphate and sulphide. The overall result showed that the concentrations of all the parameters were within the permissible limits as recommended by World Health Organization (WHO). These industries are however, the potential sources of ground water pollution. Immediate implementation of on site control measures, treatment plants and awareness of the industrialists are suggested as futuristic measures for saving the ground water from the expected industrial pollution.

Z/15. Zaleha, M.J., 1997a. Fluvial and lacustrine palaeoenvironments of the Miocene Siwalik Group, Khaur area, northern Pakistan. *Sedimentology* 44, 349-368.

The Miocene Siwalik Group (upsection, the Chinji, Nagri, and Dhok Pathan Formations) in northern Pakistan records fluvial and lacustrine environments within the Himalayan foreland basin. Thick (5 m to tens of metres) sandstones are composed of channel bar and fill deposits of low-sinuosity (1.08–1.19), single-channel meandering and braided rivers which formed large, low-gradient sediment fans (or 'megafans'). River flow was dominantly toward the south-east and likely perennial. Palaeohydraulic reconstructions indicate that Chinji and Dhok Pathan rivers were small relative to Nagri rivers. Bankfull channel depths of Chinji and Dhok Pathan rivers were generally ≤ 15 m, and up to 33 m for Nagri rivers. Widths of channel segments (including single channels of meandering rivers and individual channels around braid bars) were 320–710 m for Chinji rivers, 320–1050 m for Nagri rivers, and 270–340 m for Dhok Pathan rivers. Mean channel bed slopes were on the order of 0.000056–0.00011. Bankfull discharges of channel segments for Chinji and Dhok Pathan rivers were generally 700–800 m³s⁻¹, with full river discharges possibly up to 2400 m³s⁻¹. Bankfull discharges of channel

segments for Nagri rivers were generally 1800–3500 m³s⁻¹, with discharges of some larger channel segments possibly on the order of 9000–32 000 m³s⁻¹. Full river discharges of some of the largest Nagri braided rivers may have been twice these values.

Thin (decimetres to a few metres) sandstones represent deposits of levees, crevasse channels and splays, floodplain channels, and large sheet floods. Laminated mudstones represent floodplain and lacustrine deposits. Lakes were both perennial and short-lived, and likely less than 10 m deep with maximum fetches on the order of a few tens of kilometres. Trace fossils and body fossils within all facies indicate the former existence of terrestrial vertebrates, molluscs (bivalves and gastropods), arthropods (including insects), worms, aquatic fauna (e.g. fish, turtles, crocodiles), trees, bushes, grasses, and aquatic flora. Palaeoenvironmental reconstructions are consistent with previous palaeoclimatic interpretations of monsoonal conditions.

Z/17. Zaman, H., 1993. Geology, tectonics and paleomagnetism in northern Pakistan and the field program in Chitral. *Proceedings of Geoscience Colloquium, Geoscience Lab, GSP, Islamabad* 7, 34-43.

Geology and tectonics of northern Pakistan are briefly described together with an overview of paleomagnetism in Ladakh and Chitral. Preliminary paleomagnetic results from the Cretaceous-Paleogene Red Beds of Chitral (collected by Zaman et al) are given in an appendix. The data suggest low latitude for Chitral area in Cretaceous – Paleogene time. It is also inferred that Chitral area was not originally a part of Eurasia.

Paleomagnetic study of the Cretaceous red beds from the eastern Hindu Kush Range, northern Pakistan: Paleoreconstruction of the Kohistan–Karakoram composite unit before India–Asia collision. *International Seminar on Paleomagnetic Studies in Himalaya–Karakoram collision belt. Geological Survey of Pakistan. Geoscience Labs. Extended Abstracts,* 1-4

In order to study the tectonic displacement of the Kohistan–Karakoram region, we collected more than 350 paleomagnetic samples in two field trips from the Chitral district of northwestern Pakistan (35° 28' to 36° 16' N, 71° 44' to 72° 20' E). In the first phase of sampling Devonian to Cretaceous sedimentary, volcanic and plutonic rocks were sampled from the Kohistan and Karakoram terranes. In the second phase of samplings, mid-Cretaceous red beds were exclusively sampled from Drosh-Shishi area of Kohistan terrane. Here we report paleomagnetic results obtained from the mid-Cretaceous red beds of Drosh-Shishi and Buni areas.

On the basis of paleomagnetic results, thermal rather than alternating field demagnetization allowed the separation of multi-components magnetization. As shown in the Figure 1 (a, b, c), most of the samples (except

that of Northern Suture zone in Figure 1d) revealed three components of magnetization. The most unstable A component was broken down between 200° and 500°C. In the geographic coordinates the site mean direction for the A component ($D = 15.0^\circ$, $I = 54.2^\circ$) is close to the present field direction of the sampling area, indicating a recent origin for this component. An intermediate component (B) was separated from 300° to 660°C. Tilt-corrected mean direction for the B component from all three formations gave a mean direction ($D = 284.2^\circ$, $I = 1.0^\circ$) with northwestward declination and very shallow positive inclination. The omnipresence of this partially overprinted remanence across the Northern Suture zone is probably related to the time of temperature enhancement after the India-Asia collision, indicating that thermochemical remanent magnetization is responsible for the acquisition of B component. The direction obtained from the B component is nearly consistent with the previously reported characteristic direction (interpreted as a remagnetization) from the adjacent area (Klootwijk et al., 1994). The equatorial to low northern paleolatitude (-0.5° to 0.5°) from the B component is in good support to the Klootwijk et al. (1994) interpretation, that initial India-Asia contact was established at, or before the Cretaceous-Tertiary (KT) boundary at equatorial to low northern paleolatitudes.

Figure 1: Orthogonal projections and intensity plots of thermal demagnetization in the stratigraphic coordinates. Solid (open) symbols indicate projection onto the horizontal (vertical) plane. (a) Reshun Formation (b) Punt Formation (c) Drosh Formation (d) Northern Suture zone. The temperature range for the most stable characteristic remanent magnetization (0 is found to be variable from one locality to another, and is generally unblocked between 600° and 685°C. The mid-Cretaceous ChRM direction obtained from the C component is clearly divided into two separate groups. Group of sites from the Purit Formation gave a characteristic direction ($D = 311.2^\circ$, $I = -4.4^\circ$, $k = 12.4$, $\alpha_{95} = 17.8^\circ$) with northwestward declination and very shallow negative inclination. Dual polarity, very high coercivity and unblocking temperatures, positive fold and conglomerate tests all satisfies the condition that the ChRM of the Purit Formation was acquired before folding, and most likely as a depositional remanent magnetization. Comparison of mean declination from the Purit Formation group with the Cretaceous apparent polar wander paths (Besse and Courtillot, 1991) indicate a counterclockwise rotation of about 66° and 15° relative to Eurasia and India, respectively. The counterclockwise rotation is consistent with the regional structure of the Hindukush-Pamir-Karakoram syntaxial bend. The mean ChRM direction obtained from the Reshun and Drosh formations is, $D = 79.1^\circ$, $I = -4.7^\circ$, $k = 28.3$, $\alpha_{95} = 12.8^\circ$. Positive fold test, high unblocking temperature and relatively low coercivity suggests that the ChRM of Drosh Formation was acquired before folding, and most likely as a chemical remanent magnetization. In contrast to the Purit Formation, the northeastward mean declination from the Reshun and Drosh formations indicates that the sampling area experienced a clockwise rotation of about 62° and 113° with respect to Eurasia and India, respectively. This unusual clockwise rotation is not consistent with the regional superstructure, and is probably related to the local tectonic movement caused by the rotation of thrust sheets along the Northern Suture zone.

The paleolatitudes obtained from mean inclinations are 2.2° and 2.3° for the Purit and Reshun+Drosh formations, respectively. By comparing these paleoposition of the Kohistan-Karakoram area with the present day latitude (-35° N), implying that over 3500 km of crustal shortening was taken place since mid-Cretaceous time, of which more than 90% postdated the India-Asia collision (Figure 2). The shortened crust was most likely consumed by continental underthrusting, intercontinental thrusting with internal deformation and lateral extrusion along major and minor faults (Molnar and Tapponier, 1975). About 3° paleolatitudinal difference between B and C components indicates that the study area was pushed northward about 300 km from the time of red bed deposition to that of India-Asia collision (Figure 2). The displacement of the sampling area between two acquisition points is acceptable in the sense, that during the said period oceanic part of the subducting Indian Plate was pushing forward the Kohistan-Karakoram terranes towards north. The ChRM directions from the Reshun and Drosh formations are nearly consistent, which probably indicate that these two formations could be placed on the same platform, at the north side of the suture zone. In this case a faulted boundary between the Purit and Drosh formations cannot be ruled out, most likely under the cover of Shishi River. The mid-Cretaceous inclination values (Figure 2: Comparison of the paleolatitudes obtained from the intermediate B and C components with the Cretaceous paleogeographic reconstruction of Asia (redrawn from Chen et al., 1993)). It is indicated that more than 3500 km of crustal shortening was taken place after the ChRM acquisition at equatorial paleolatitude, and more than 90% of 11 postdated the acquisition of B component (probably related to India-Asia collision). obtained across the Northern Suture zone are almost identical, which indicates that suturing has been completed at the time of ChRM acquisition. This is in good agreement with the geochronological results from North Pakistan, which date the age of suturing at 102-85 Ma (Treloar et al., 1989).

Z/21. Zaman, H. & Torii, M., 1996b. Paleoposition of the Kohistan-Karakoram composite unit: A paleomagnetic study of the Cretaceous red beds from the eastern Hindukush Range of Northern Pakistan. Abstract volume, 11th Himalaya-Karakoram-Tibet Workshop, Flagstaff, Arizona, 175-176.

In order to study the tectonic deformation of the Eastern Hindukush region, we collected paleomagnetic samples within Chitral district of northwestern Pakistan ($35^{\circ} 28'$ to $36^{\circ} 16'$, $71^{\circ} 44'$ to $72^{\circ} 20'$). During two field trips, more than 350 hand samples of Devonian to Cretaceous sedimentary, volcanic and plutonic rocks were collected at 20 localities. Here we report paleomagnetic results obtained from the Mid-Cretaceous red beds of Drosh-Shishi and Buni areas (Purit and Drosh Formations from Drosh-Shishi area and Reshun Formation from Buni area; by Pudsey et al., 1985).

The rock magnetic parameters indicate that magnetic minerals are variable from one formation to another. The dominant magnetic carrier identified in the samples of the Purit Formation is a high temperature hematite. In the samples of the Drosh Formation two kinds of magnetic minerals are present, that is a dominant hematite and subordinate magnetite. The ratios of magnetic minerals are changing in the sample of Reshun Formation, where hematite and goethite are dominant in the red mudstone and pebble conglomerates respectively. On the basis of paleomagnetic results, thermal demagnetization allowed the separation of multi-components magnetization. Most of the samples revealed three components of magnetization (except two sites from the Northern Suture). A recent field component (A) was removed between 200° and 500°C . An intermediate thermal stability component (B) was separated from 300° to 660°C . The temperature range for the characteristic remnant magnetization (ChRM) component (C) is found to be variable from one locality to another, and is generally unblocked between 600° and 685°C . In the geographic coordinates the site mean direction for component A ($D=15.0^{\circ}$, $I=54.2^{\circ}$) is nearly similar to the present field direction of the sampling area, indicating a recent origin for this component. Tilt corrected intermediate component (B) from all three formation gave a mean direction ($D=284.2^{\circ}$, $I=1.0^{\circ}$, $k=7.9$, $a95=18.3^{\circ}$) with northwestward declination and very shallow positive inclination. A uniform presence of this secondary magnetization across Northern Suture indicates that it was probably acquired at the time of India-Asia collision. The direction obtained from component B is nearly consistent with the previously reported characteristic direction (interpreted as a secondary remagnetization) from the adjacent area (Klootwijk et al., 1994). The Mid-Cretaceous ChRM direction obtained from C component (thirteen sites) is clearly divided into two separate groups. Group of sites from the Purit Formation gave a characteristic direction ($D=311.2^{\circ}$, $I=4.4^{\circ}$, $k=12.4$, $a95=17.8^{\circ}$) with northwestward declination and very shallow negative inclination. The corresponding pole for the Purit Formation is located at 31°S , 133°E . The mean ChRM direction obtained from the Reshun and Drosh Formations is, $D=79.1^{\circ}$, $I=4.7^{\circ}$, $k=28.3$, $a95=2.8^{\circ}$, with corresponding pole position at 7°N , 169°E . In both cases the positive fold test indicates that the ChRM component was acquired before folding, and is most likely the primary magnetization.

Comparison of mean declination from the Purit Formation group with the Cretaceous apparent polar wander paths (Besse and Courtillot, 1991) indicate a counterclockwise rotation (Kohistan block) of about 66° and 15° relative to Eurasia and India, respectively. The counterclockwise rotation is consistent with the regional structure of the Hindukush-Pamir-Karakoram syntaxial bend. In contrast the northeastward mean declination from the Reshun and Drosh Formations indicate that the sampling area experienced a clockwise rotation of about 62° and 113° with respect to Eurasia and India, respectively. This unusual clockwise rotation is probably related to the local tectonic movement caused by the rotation of thrust sheets along the Northern Suture Zone. The paleolatitudes obtained from mean inclinations are 2.2 and 2.3°S for the Purit Formation and Reshun + Drosh Formations, respectively. By comparing this paleoposition of the Kohistan-Karakoram composite unit with the present day latitude ($\sim 35^{\circ}\text{N}$), implying that over 3500 km of crustal shortening was taken place since Mid-Cretaceous time, of which more than 90% postdate the India-Asia collision. The ChRM directions from the Reshun and Drosh Formations are nearly consistent, which probably indicate that these two formations could be placed on the same platform, at the north side of the suture zone. In this case a faulted boundary between the Purit and Drosh Formations cannot be ruled out, most likely under the cover of Shishi River. The Mid-Cretaceous inclination values obtained across the Northern Suture are almost identical, which indicates that suturing has been completed (or near to completion) at the time of ChRM acquisition. This is good agreement with the geochronological results from North Pakistan, which date the age of suturing at 102-85 Ma (Treloar et al., 1989).

Z/22. Zaman, H. & Torii, M., 1996c. Rock magnetism of the mid-Cretaceous red beds from the Kohistan and Karakoram terranes, northern Pakistan. Extended Abstracts, International Seminar on Paleomagnetic Studies in Himalaya-Karakoram Collision Belt and Surrounding Continents, November 20-21, 1996, Islamabad. Geosciences Lab, GSP, Islamabad, 102-105.

We report rock magnetic results obtained from the mid-Cretaceous red beds samples, collected from the eastern Hindukush ranges of northern Pakistan. Most of the rock magnetic samples were collected from the Purit, Drosh and Reshun formations, while two localities were sampled from the Northern Suture Zone. The Reshun

Formation of the Karakoram Plate side is a group of rocks including polymict pebble and cobble conglomerates, red calcareous shale and pale gray micritic limestone lies below the Reshun Fault and above Chitral slate or Darkot Group of sediments. On the basis petrographic work (Pudsey, 1986), it is suggested that fluvial sediments of the Reshun Formation was largely derived from the volcanic arc. The red beds of Drosh-Shishi area is lying just south of the Northern Suture zone within the Kohistan terrane, and is divided into three different rock units. In case of Purit Formation, red calcareous shale with abundant calcite veins is the most dominant rock type, while conglomerates and sandstone constitutes about one third of the formation in the lower half overlying the Purit Formation is the Drosh Formation, which is a sequence of thickly-bedded andesitic volcanics. Some thin red calcareous shales are interbedded with the lava flows. The overlying unit of Northern Suture zone consists mainly of dark-gray limestone interbedded with black phyllite and black calcareous shale (Pudsey, 1986).

Rock magnetic properties indicate that magnetic minerals are variable from one formation to another. From thermomagnetic analysis and low temperature measurements it is determined that hematite is the dominant magnetic carrier in the samples of Purit Formation (Figure 1c, d). Furthermore very high coercivity and unblocking temperature indicates that the hematite grains are probably detrital in origin, which in turn is the carrier of characteristic remanent magnetization (ChRM) in the red beds of Purit Formation. From the paleomagnetic components studies it is further indicated that some low thermal stability hematite is also present as a secondary magnetic mineral by comparing with the paleomagnetic results, it is suggested that low temperature hematite is responsible for the acquisition of B component (secondary remagnetization), and is probably related to the time of temperature enhancement after the India-Asia collision, indicating that thennochemical processes are responsible for the production of secondary magnetic minerals. This idea can fairly be compared with the temperature increase above 300°C deduced from zircon resetting at 55-68 Ma from the adjacent area (Zeitler, 1985). The ratio of magnetic minerals are changing in the samples of Reshun Formation, where hematite and goethite are dominant in the red mudstones and pebble conglomerates, respectively (Figure 1a, b). This probably indicates that the source and depositional environment of the existing magnetic minerals were different for the red mudstones and conglomerate beds.

(d) SIRM of 1 Tesla was imparted at 5 K and then heated up to 300 k

Figure 2: Results of the rock magnetic study for the samples of Drosh Formation (PU1-G2.3 and PU0 I-A1),an Northern Suture Zone (SRS1-G1.1 and SRS1-F1.2) (a and c) Strong field thermomagnetic analysis in air an argon. respxtnclly (band d) SIRM of 1 Tesla was imparted at 5 K and then heated up to 300 K.

In the samples of the Drosh Formation two kinds of magnetic minerals are present, that is a dominant hematite and subordinate magnetite (Figure 2a, b). As evident from the field observation, the red beds of Drosh Formation is thinly interbedded with the andesitic volcanics Here the source of red beds deposition is probably shared by the volcanic ashes and other fine sediments from the surrounding volcanic rocks, which could result in the possible presence of very fine grained magnetic minerals (Superparamagnetic and Single Domain magnetite grains). As described by Turner (1981) that in some cases the original sediments may have been rich in magnetite, but after progressive diagenesis (including oxidation of magnetite) very fine magnetite could be replaced by hematite. It is therefore predicted that the hematite of Drosh Formation was formed by martitization or hydrothermal alterations of the preexisting detrital magnetite, while the subordinate magnetite was probably recrystallized as a result of temperature enhancement after the India-Asia collision. By comparing with the palaeomagnetic results of the same samples it is suggested that hematite is the carrier of ChRM, and secondary remagnetization component (B) is carried by magnetite. The magnetic mineralogy in the samples of Northern Suture Zone is shared by hematite, magnetite and probably iron sulfides. On the basis of rock magnetic characteristics the dominant magnetic carrier is the low coercivity and low temperature hematite (Figure 2c). From low temperature measurements the verway transition of magnetite is very clearly determined, while the presence of hematite is very poorly shown (Figure 2d). This behaviour around the Morin transition zone of hematite (the decreasing change in the remanence with increasing temperature) may reflects the presence of the superparamagnetic grains, which unblocked near the room temperature (Hunt et al., 1995). Unstability of the magnetic minerals in the samples of Northern Suture zone is also indicated from the paleomagnetic results, where the direction of the ChRM is identical with the present Earth's field direction in the sampling area

Z/23. Zaman, H. & Torii, M., 1996d. Rock magnetism of the mid-Cretaceous red beds from the northwestern margin of Kohistan island arc, northern Pakistan. In: Kausar, A.B. & Yajima, J. (eds.), *Geology, Geochemistry, Economic Geology and Rock Magnetism of the Kohistan Arc*. Proceedings of Geoscience Colloquium (Geoscience Lab, GSP, Islamabad) 15, 207-232.

We report rock magnetic results obtained from the mid-Cretaceous red beds samples, collected from the northern margin of Kohistan island arc, northern Pakistan. Rock magnetic parameters indicates that magnetic minerals are variable from one formation to another. Detrital hematite is the dominant magnetic carrier in the samples of the Purit Formation, while low stability hematite is probably the carrier of secondary magnetization. In the samples of the bosh Formation two kinds of magnetic minerals are present, that is a dominant hematite and subordinate magnetite. Hematite here is probably formed by the in-situ oxidation of pre-existing detrital magnetite, suggesting the magnetization origin as a chemical. The magnetic mineralogy in the samples of

Northern Suture Zone is shared by hematite, magnetite and probably iron sulfides. Unstability of the remanence in the samples of Northern Suture Zone is probably due to the presence of superparamagnetic hematite grains.

Z/24. Zaman, H. & Torii, M., 1997. Rock magnetism of the mid-Cretaceous red beds from Kohistan and Karakoram blocks, northern Pakistan. In: Khadim, I.M., Zaman, H. & Yoshida, M. (eds.), *Paleomagnetism of Collision Belts*. Geoscience Laboratory, GSP, Islamabad, 13-33.

Rock magnetic studies were carried out in order to identify the remanence carrying minerals in the mid-Cretaceous red bed rocks from the Eastern Hindukush mountains, northern Pakistan. Rock magnetic properties indicate that remanence carrying minerals are variable from one formation to another. In the samples of the Purit Formation detrital specular hematite is the dominant carrier of characteristic remanent magnetization (ChRM), while low stability pigmentary hematite is responsible for the acquisition of secondary magnetization. Two kinds of magnetic minerals are present in the samples of the Bosh Formation, i.e., a dominant hematite and a subordinate magnetite. This hematite was probably formed by the in situ oxidation of pre-existing detrital magnetite, suggesting the ChRM origin as a chemical, while magnetite is the alteration product attributed to India-Asia collision. The magnetic mineralogy in the samples of the Northern Suture Zone (NSZ) is shared by hematite, magnetite and probably iron sulfides. Recently acquired ChRM in the samples of NSZ is probably due to the presence of ultrafine hematite grains. The ratio of magnetic minerals are changing in the samples of the Reshun Formation, where detrital hematite is dominant in the red mudstone and goethite in pebble sandstone. Here detrital and pigmentary hematite are responsible for the acquisition of ChRM and intermediate component of magnetization, respectively. In some samples, the presence of magnetite is also indicated by the isothermal remanent magnetization methods.

We report palaeomagnetic results obtained from Cretaceous red bed sample, collected from the eastern Hindukush mountains, northern Pakistan. Rock magnetic studies revealed specular haematite as the dominant remanence carrier, while pigmentary haematite, magnetic and goethite are responsible for the acquisition of secondary magnetizations. Thermal treatment generally revealed three components of magnetizations. The most unstable component (A) was removed between 200 °C and 500 °C, which corresponds to the local present field direction. The intermediate component (B) was generally separated between 200 °C and 600 °C. The omnipresence of this complex secondary component across the Northern Suture Zone suggests that movement of chemically active orogenic fluids at, or slightly before, the time of the India-Asia collision was probably responsible for the authigenic remagnetization processes. The characteristic component (C) was generally unblocked between 600 °C and 685 °C. The characteristic directions from 12 sites fall into two groups. The sites from the Purit Formation give a tilt-corrected mean direction of $D=311.20$, $I=4.40$, $K=12.4$, $\alpha_{95}=17.80$, indicating a counter-clockwise rotation of about 660 and 150 relative to Eurasia and India, respectively. The tilt-corrected mean direction for the Reshun and Drosh formation is $D=263.00$, $I=2.20$, $K=52.7$, $\alpha_{95}=10.60$ which indicates that the sampling area experienced a counter-clockwise rotation of about 1140 and 630 with respect to Eurasia and India, respectively. In both cases the palaeomagnetic rotation is consistent with the regional superstructure of the Hindukush-Pamir-Karakoram syntaxial bend. The difference in rotation between these two groups is probably due to local tectonic movement caused by the net rotation of thrust sheets along the Northern

Suture Zone. The palaeolatitudes calculated for Purit and Reshun+Drosh formations are 2.20S and 1.10N, respectively. This indicates that about 4000km of convergence has taken place since the mid-Cretaceous, of which about 90 per cent post-dates the India-Asia collision. The Late Cretaceous, inclination values across the Northern Suture Zone are almost identical, which indicates that suturing had been completed at the time of ChRM acquisition.

Geological and structural mapping of Kotli-Nikial-Khuiratta area of about 300 square km was carried on 1:50,000 scale of toposheet No's 43 K/2, 43 K/3, 43 G/11 and 43 G/15 of survey of Pakistan. The lithostratigraphic units described range in age from Pre-Cambrian to Pleistocene and consist mainly of sedimentary rocks. The Pre-Cambrian rock formation is Dogra Slate and Cambrian rock unit is Sirban Formation.

In this area apart from Lower Cambrian, all the formations of Paleozoic and Mesozoic are missing. Either they were not deposited or were weathered to form Bauxite/Fireclay representing an unconformity of a big gap. In the Tertiary period, Patala Formation, Margala Hill Limestone, Murree Formation and rocks of Siwalik Group were deposited. Section measurements were done to establish the stratigraphy. The rocks are folded and faulted comprising the major and minor structures of the area. The major folds of the area are khuiratta-Kohali anticline (11pp/325pp), Devigarh-Palana anticline (04pp/313p), Tattapani-Karela anticline (6pp/116pp) and Khad-Bahni syncline (6pp/228pp). The major fault is the Himalayan Frontal Thrust with minor thrust like Gala Thrust and Khad Thrust. Deformational events and stereographic projection of the area have been interpreted. The tectonic setup has been also discussed. About eighty five rock samples were taken from the field and carried back to the

laboratory for petrographic studies. In the field of economic geology, a number of deposits including Fireclay, Bauxite, Coal, Limestone, Chalk and Dolomite are of economic interest.

Z/36. Zanchi, A., 1992. Structural Evolution of the Karakoram Sedimentary cover: preliminary data. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 101.

Preliminary field structural analyses and reconnaissance mapping of the north Karakorum sedimentary cover has been carried out in the Chapursan and Shimshal valleys north of the axial batholith, on the basis of previous stratigraphic reconstructions (Gaetani et al., 1990).

In the Chapursan Valley the structure of the sedimentary cover consists of a complex and polyphasic stack of embricated and locally verticalized Permian to Jurassic thrust sheets, also including the discordant Tupop conglomerates, Cretaceous in age. The oldest deformational event is outlined by an E-W striking belt composed of verticalized and tectonized sediments belonging to the Permian-Jurassic sequences, overlain by the Cretaceous Tupop Formation with a sharp stratigraphical unconformity. Compressional events subsequent to Tupop deposition produced the main stack of thrust sheets, including strongly deformed and folded slices of Tupop. In the Chapursan Valley slip vectors along thrust planes and fold axes indicate a northward direction of transport, whereas NW-SE trending fold axes due to northeastward transport have been mainly observed in the Shimshal valley. The north vergent structure is widely crossed by successive breakback thrusting, evident along the northern side of the Chapursan valley (Northern fault of Gaetani et al., 1990), and along the contact between the sedimentary cover and the axial batholith outcropping in the Yaskuk Glacier area.

The last recognized tectonic phase is the activation of an important set of E-W sinistral strike-slip faults, causing further steepening of previously embricated thrust sheets. These faults may be interpreted as a consequence of a NW-SE directed simple-shear, probably due to deformation along major NW-SE dextral strike-slip faults, as the Misgar dextral strike-slip fault. The sedimentary cover of the north Karakoram is deformed under anchimetamorphic conditions in the Chapursan valley, while sericite to muscovite phyllites of low-grade outcrop in the Shimshal valley. Near the Shimshal Pass andalusite and biotite have been detected in phyllites at the contact aureole of large previously unknown granitic bodies. Cataclasis is mostly evident along thrust planes and strike-slip faults, thus showing brittle conditions of deformation.

The sedimentary cover of the north Karakorum terrain is composed of three main structural units: Gujhal, Sost and Misgar Units characterized by different stratigraphic and tectonic evolution. Fold and thrust surfaces

generally trend E-W in the Sost and Misgar Units, whereas they are clearly NW-SE in the Gujhal Unit. Several deformation events have been recognized. A mid-Cretaceous event is testified by the folded succession cropping out below the Cretaceous Tupop and Darband Formations in the Sost Unit. Mid-Cretaceous granodioritic intrusives, some of which have been dated at about 100 Ma, crossing previously formed schistosity, have been observed along the contact between the Gujhal Unit and the Karakorum Axial Batholith, in the Misgar Unit and the Karakorum Axial Batholith, and in the Misgar Unit, indicating a widespread orogenic event. Important post-Cretaceous thrusting is testified by the deformation of the Cretaceous sediments and also by stacking of Eocene intrusives in the Yashkuk area. North vergent tectonic transport seems to be followed in time by south vergent active, and are due to the prosecution of indentation phenomena between India and Eurasia.

The oldest deformational structures recognized in the Karakoram sedimentary cover north of the Karakoram Axial Batholith (KAB) consist of an E-W deformed belt composed of Permian-early Cretaceous sediments. This belt is overlain with a stratigraphical unconformity by the Cretaceous Tupop conglomerates and subsequent Late Cretaceous marine sediments. In the Chapursan Valley a complex and polyphase antiformal stack consisting of a Permian to Cretaceous succession was recognized. Post-Cretaceous northward and northeastward directions of transport are shown by slip vectors along thrust planes and by fold axes in the Chapursan Valley, whereas NW-SE-trending folds due to northeastward transport were observed in the Shimshal Valley. The north-vergent structure is crossed by successive north-dipping thrusts along the northern side of the Chapursan Valley and along the contact between the sedimentary cover and the northern continuation of the KAB.

The last tectonic phase recognized in the Chapursan Valley caused the activation of an important set of E-W-orientated sinistral strike-slip faults. In the Shimshal Valley, large E-W sinistral and NW-SE dextral faults are present as well, and may be interpreted as a consequence of a NW-SE-directed simple-shear due to deformation along major NW-SE dextral strike-slip faults.

The sedimentary cover of the Karakoram was deformed under anchimetamorphic conditions in the Chapursan Valley, whereas sericite to muscovite low-grade metapelites with occurrence of chloritoid, epidote and biotite are present in the lower Shimshal Valley. Near the Shimshal Pass, andalusite, garnet, muscovite and biotite were found in phyllites at the contact aureole of an important belt of large previously unknown granitic bodies.

Z/39. Zanchi, A., 1993b. Structural history of the sedimentary cover of the North Karakoram terrane in the upper Hunza valley (Pakistan). Abstract, Volume, 8th Himalaya-Karakoram-Tibet Workshop, Vienna, 82.

The Karakoram terrane belongs to the peri-Gondwanian blocks rifted from Gondwana during Permian and accreted along the southern Eurasian margin before collision with the Indian plate. The Karakoram block is located between two major suture zones: the Shyok Suture Zone to the South and the Rushan-Pshart suture to the North.

The Karakoram microplate includes a thick sedimentary cover, which is mainly Paleozoic in the western termination and Permian to Cretaceous in the central and eastern area. In the Hunza valley the cover consists of a thick pile of poorly metamorphic Permian-Cretaceous sediments cropping out north of the Karakoram Axial Batholith (KAB).

The sedimentary cover of the North Karakoram terrain is composed of three main structural units: the Gujhal, Sost and Misgar Units characterized by different stratigraphic and tectonic evolution. Folds and thrust surfaces generally trend E-W in the Sost and Misgar Units, whereas they are clearly NW-SE in the Gujhal Unit.

Several deformational events have been recognized on the basis of structural and geological analyses. A "mid-Cretaceous event" is testified by the folded succession cropping out below the Cretaceous Tupop and Darband Formations in the Sost Unit. Mid-Cretaceous granodioritic intrusives, some of which have been dated at about 100 Ma, crossing previously formed schistosity, have been observed in the region. Important post-Cretaceous thrusting is testified by the deformation of the Cretaceous sediments and also by stacking of Eocene intrusives in the Yashkuk area. North vergent tectonic transport seems to be followed in time by south vergent thrust motion. Complex strike-slip faults are successively active, and are due to the prosecution of indentation phenomena between India and Eurasia. Metamorphic conditions range between very low and low grade, which is reached in the deepest part of the Gujhal Unit. Andalusite is generally widespread around the intrusives, indicating low-

pressure conditions, Field work was carried out in during two field seasons (1991-1992), leading to the preparation of a preliminary geological map which is presented in the poster section. Three main geological transects from the KAB to the Misgar Unit have been reconstructed: 1) from Shimshal village to the Khunjerab pass through the Doesam and Chapchingal Pir, 2) along the Hunza and nearby valleys (Shikarjerab, Abgarch and Khudabad valleys) and along the Yaskuk glacier and the western part of the Chapursan Valley.

Z/41. Zanchi, A., Angiolini, L., De Amicis, M., Gaetani, M. & Le Fort, P., 1999. The new digital geological map of Central-Western Karakorum. Terra Nostra 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 187.

The new map of central-western Karakorum, presented in a preliminary version at the XII Himalayan Workshop held in Rome in 1997, has been completed and is now available in a digital format (ArcInfo covers). The mapped area (fig. 1) includes the sedimentary cover of the North Karakoram Terrain and the northern portion of the Karakorum central granitoid belt. The latter has been almost entirely mapped by P. Le Fort and represents the original base of the geological map recently published at 1:250,000 scale by Le Fort & Gaetani (1998). The new map summarizes the fieldwork carried out in Central Karakoram during the last years. Due to the lack of reliable topographic maps at the time of the fieldwork, mapping was directly performed using copies of three high resolution Spot images (panchromatic image with a pixel size of 10m) which have been printed at a 1:50,000 scale. The eastern part of the study area, from Lashkargaz to Babagundi Ziarat (Chapursan Valley) has been redrawn using the digital Spot image as a base after georeference and correction by a Geographic Information System (ILWIS 2.1). As far as concern the area located west of Lashkargaz, Spot images were available only in a photographic format and thus an automatic correction of the deformed images was not possible. The geological map has thus been redrawn on the 1:100,000 Russian map of the world, enlarged at a 1:50,000 scale, which represents a very precise and updated (1987) topographic base with contour intervals at 40 m. Due to the good quality of the topographic informations provided by this map together with the analysis of the panchromatic images, we have extended the map out of the boundaries of the area directly surveyed, over large part of the Afghan watershed region.

The database related to the map includes three topological levels of information:

- polygons, including about 8,000 geological units:

- lines, representing linear elements as faults, thrust lithological boundaries, etc. subdivided in about 30 layers. Topographical informations directly derived from the available cartography are also included within this database points, which represent the location of mesoscopic structural observations, sample locations, position of stratigraphic sections, etc. The new version of Fieldlog 3.1 (Geological Survey of Canada, 1998), a relational database which works in strict connection with Autocad 13-14 has been used for this purpose. Through Fieldlog, all kinds of structural data and informations related to the collected samples may be easily managed and represented in the digital map.

The final scale of publication will be 1:150,000, in order to fit the previous map of the Central Eastern Karakorum (Zanchi & Gaetani, 1994). The map represents an important step in the understanding of the geological structure of the region.

Z/43. Zanchi, A., Gaetani, M., Angiolini, L., De Amicis, M. & Poli, S., 1997. The 1:150,000 new digital geological map of the North Karakoram terrane from the Chapursan

valley to Morich Gol (Northern Pakistan). Abstract volume, 12th Himalaya-Karakorum-Tibet International Workshop, Rome, Italy, 239-240.

Between August and September 1996 we crossed the sedimentary cover of the North Karakorum Terrain, from the Hunza valley to Chitral passing through the Chillinji, Karambar and Shah Jinali passes. One of the main purpose of the expedition was to produce a geological map of the whole area, according to the stratigraphic and structural framework established during previous work and to the new observations performed in 1996.

Due to the lack of reliable topographic maps, field mapping was directly realized on pancromatic Spot images printed at a 1:50,000 scale. Correction and georeferencing of the images was obtained with current GIS software (ILWIS 1.4 ITC-Netherlands). Lithological boundaries, major tectonic structures and other topographic informations were digitized in a vector format on separate layers above the georeferenced images leading to a high level of precision. Data concerning mesoscopic structural observations and sampling were included using Fieldlog, a special multirelational database developed by the Geological Survey of Canada for mapping purposes. Finally, polygonization and map production was performed with standard ARC-INFO software.

Three preliminary sketches of our new map are presented in the poster. The first map includes the area between the upper Chapursan valley and the Chillinji (Karambar) region. From north to south we crossed the western prosecution of the Sost Unit (Zanchi & Gaetani, 1994) which is bounded to the south by the Upper Hunza Fault. South of this post-Cretaceous north-vergent thrust the Permian to Mesozoic Guhjal Unit of the Hunza Valley is tectonically associated with the Tas Kupruk Unit, and with a complete Ordovician to Permian section of the Paleozoic, (Gaetani et al., 1996). Complex superposed folding in part post-dating thrust stacking were recognized around Chillinji.

The second area is located north of the Karambar pass, where a poorly deformed Late Carboniferous succession was recognized on the basis of brachiopods assemblages (Angiolini et al., this vol.).

The third sector includes the area from the Shah Jinali pass to the Morich Gol in the Chitral region. From the Shah Jinali pass to the west we crossed from SW to NE the western prosecution of the Tas Kupruk Unit, the Paleozoic Lun Slates (Devonian), a narrow belt of metabasites (plagioclase-hornblende amphibolites) including small amounts of serpentinites with olivine and pyroxene relics, marbles with biotite-sillimanite metapelites, and finally the Late Paleozoic-Mesozoic carbonatic Atark Unit. Complex superposed folding and sinistral strike-slip shearing are characteristic of the structural framework of this area. The amphibolite-serpentinite belt represents the easternmost prosecution of similar complexes described by Buchroithner and Gamerith (1986) in the Arkari and Tirich Gols and may represent the remnant of a suture zone now coincident with the Tirich Mir Fault Zone, separating the Karakoram Block from the East Hindu Kush block. According to available data, the intrusion of the mid-Cretaceous Tirich Mir pluton post-dates the emplacement of the amphibolitic belt. Pre-Late Cretaceous suturing between Karakoram and Hindu Kush is also enhanced by the occurrence of Reshun-like conglomerates in the Atark unit, which suggest a common history for the two blocks since that period.

It is worth noting that, although mapped more than 10 years ago by the Austrian teams, and despite its structural importance, the presence of these basic and ultrabasic rocks was completely ignored in the new 1996 map of North Pakistan compiled by Searle and Khan (1996).

Z/45. Zanchi, A., Gaetani, M. & Poli, S., 1997. The Rich Gol metamorphic complex: evidence of separation between Hindu Kush and Karakoram (Pakistan). *Comptes Rendus del' Academie des Sciences Paris, Sciences de la terre et des planètes* 325, 877-882.

The westernmost part of the Karakorum belt and its prosecution along East Hindu Kush includes: 1) the southern portion of the Tash Kupruk Unit; 2) the Shah Jinali Phyllites; 3) the Rich Gol Metamorphic Complex (RGMC), a narrow belt of high-grade metabasites with serpentinites and metapelites, which forms a narrow strip along the Tirich Mir Fault, separating the Atark Unit (Hindu Kush?) from Karakorum metasediments. The RGMC may represent the easternmost part of similar complexes described around the Tirich Mir and may be linked to the boundary between Karakorum and East Hindu Kush.

Key words: Metamorphism, Hindu Kush, Karakoram.

Z/46. Zanchi, A. & Gritti, D., 1995. Multistage Structural Evolution of Northern Karakoram (Pakistan). Abstract Volume, 10th Himalaya-Karakoram-Tibet Workshop, (ETH Zurich) Switzerland.

The structural setting of the sedimentary cover of the Karakorum (fig. 1) is well exposed in the uppermost Hunza Valley, where several expeditions were carried out (Gaetani et al., 1990; Zanchi, 1993; Gaetani, 1994). General mapping and structural analysis were extensively performed in the Kundil, Borom, Shikarjerab and Abgarch side valleys located around Sost, where some of the most intriguing structures of the belt are exposed (fig.2). The mid-Cretaceous unconformity described by Gaetani et al. (1990) is exposed above Khudabad in the Borom and Kundil valleys in the southern part of the Sost Unit. Here the mid-Cretaceous deformed belt is covered by the Tupo Conglomerate and by the Late Cretaceous.

Below the unconformity folded limestones show E-W trending folds with subvertical axial planes; transposition and the slaty cleavage developed in the folded Jurassic marls and slates belonging to the deformed belt.

Along the top of the Borom and Kundil valleys thrust sheets of the Sost Unit override the Late Cretaceous sediments as well as the thrust sheet of the Guhjal Unit. E-W trending drag folds showing northward tectonic transport are present belt in the Darband Formation along thrust planes of the Sost Units. NW-SE folds and thrust planes developed in the the Guhjal Unit (fig.3), which also override the Cretaceous sediments along the Upper Hunza Fault, the major tectonic boundary between the Sost and Gubjal Units.

South-vergent thrust stacking was active along the northern part of Sost Unit and lead to the formation of a complex em. antiformal stack with strong lateral geometrical variations. Whereas in the Yashkuk Glacier area the western prosecution of the Sost Unit mostly records north-verging thrust stacking (Zanchi, 1993), around Sost south-vergent thrust sheets are dominant. In the Borom valley a large part of the Permian to Triassic successions show large be overturned concentric folds, indicating south vergent motion. Further east the same succession is tectonically reduced with intensive thickening of the Gircha Formation due to development of tight folds with subvertical axial planes and ring reverse faults.

The northern flank of the antiformal stack, which is overthrust by the Misgar Slates moving along the south-vergent Northern Fault, is crossed by the Misgar Fault Zone north of Sost, fonning a complex system of WNW-ESE trending tectonic flakes due to very intensive folding and at least partly successive strike-slip motion. The fault zone was identified by Gaetani et al., (1990) and located in the sedimentary thrust sheets of the Sost Unit; these authors indicated dextral motion on the basis of the displacement shown by the tectonic boundary between the Misgar and Sost Unit along the Northern Fault. Ogasawara (1992) also indicated dextral movements along a mylonitic shear zone developed around 60 Ma in the Misgar area near the Misgar Fault of Gaetani et al. (1990) and also including mylonitic metagranitoids intruded in the Misgar Unit. A few data collected along the Misgar Fault of Gaetani indicate complex and polyphasic fault motions along the structure. Complex reverse faulting, dextral and sinistral strike-slip movements were observed along the Karakorum Highway and in the Shikarjerab valley. Oblique dextral-reversal components indicated by calc-mylonites along thrust surfaces slightly south of the Misgar Fault Zone also indicate that transpression might be partly coeval with the embrication of the northern side of the stack.

The Misgar Fault Zone seems to be the westward prosecution of important dextral en echelon strike-slip faults observed in the upper part of the Skimshal. The steeply dipping E-W thrust surfaces of the central and southern part of the Sost stack are generally remobilized by sinistral strike-slip faults. During this phase microfolds with subvertical axes and conjugated kink bands developed in the slates of the unit, deforming previous foliations.

Dextral movements along major WNW-ESE to NW-SE fault zones (Misgar Fault) and possibly coeval pervasive sinistral movements along inherited E-W faults may be due to post-collisional dextral shearing active along the right corner of the Indian Indenter in extreme conditions of deformation. Coeval movements along mechanically unfavourable fault planes may be explained by strain accommodation in discrete domains bounded by E-W faults occurring along a mayor dextral fault zone. Activation of sinistral motions along E-W faults is probably due to the importance of inherited structures, represented by high-angle reverse faults formed during previous compressional phases.

Z/47. Zanchi, A. & Gritti, D., 1996. Multistage structural evolution of Northern Karakoram (Hunza region, Pakistan). *Tectonophysics*, 260, 145-165.

Detailed mapping and structural work in Upper Hunza Valley, Pakistan, have enlightened the tectonics and the structural evolution of the sedimentary cover of Northern Karakorum. This includes the Northern Sedimentary Belt (NSB) with the Guhjal and Sost Units (Permian-Cretaceous), cropping out north of the Karakorum Axial Batholith (KAB); the NSB is bounded to the north by the Misgar Unit, consisting of slates of unknown age. In the Sost Unit a mid-Cretaceous deformed belt is sealed with a strong angular unconformity by the Late

Cretaceous formations. Folds within the mid-Cretaceous belt possibly indicate north-vergent transport. Stacking of NE- to N-vergent thrust sheets postdates the deposition of Cretaceous sediments, which are largely included within tectonic slices developed along the southern flank of the Sost stack. The southern part of the stack is in turn intruded by the Palaeogene Kuk pluton belonging to the Batura Unit of the KAB.

S- to SSE-vergent thrusting was successively active, stacking steep north-dipping thrust sheets along the northern side of the Sost Unit, forming a complex antiformal stack, well exposed around Sost. High angle pure dip-slip reverse and oblique dextral motions are recorded by fault-slip data and calc-mylonites along major faults, forming a transpressive fault zone close to the contact between the Sost and Misgar Units. During this stage, the Misgar Unit was thrust southward above the Sost Unit along the Northern Fault. Prosecution of dextral motion was also active afterwards along the boundary between the two units. The importance of wrench tectonics is also indicated by widespread activation of E-W sinistral strike-slip faults in the whole study area, generally moving along pre-existent fault planes.

Z/48. Zanchi, A., Poli, S., Fumagalli, P. & Gaetani, M., 1999. Mantle peridotites along the Tirich Mir Fault (NW-Pakistan): Pre-mid Cretaceous accretion of the Karakorum terrane?. *Terra Nostra* 99 (Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany), 186.

Mesozoic progressive accretion of Perigondwanan terranes along the southern margin of Eurasia, before the collision of the Indian plate, has been so far recognized by several authors, even if the structural relationships, number, identity and evolution of these blocks are still poorly known. In Pakistan, the Main Mantle Thrust marks the boundary between India and the Mesozoic Kohistan arc, whilst the Northern Suture separates Kohistan from the Karakoram, which was located along the southern margin of the Mega Lhasa.

Ultramafic bodies, along with melanges or syntectonic sediments, have been so far largely used as a marker of sutures or major fault zones between the different terranes, although well documented mantle peridotites are rare. Our recent discovery of a narrow, but more than 150 km long, belt of deformed mafic and ultramafic sandwiched between East Hindu Kush and Karakoram (Zanchi et al., 1997) along the Tirich Mir Fault, Chitral, NW-Pakistan provides a strong argument for the location of the northwestern boundary of Karakoram, as previously suggested merely on the basis of paleogeographic reconstructions (Gaetani, 1997).

In 1996 and 1997 during two field expeditions, we have found a narrow belt of amphibolites, metagabbros, peridotites, gneisses, and quartzites, here named the Tirich Boundary Zone, (TBZ) extending from the Shah Jinali Pass to the Barum valley. North of the Shah Jinali Pass, the TBZ disappears along the Tirich Mir Fault, which prosecutes northward along the Yarkhun

Valley into Afghanistan, merging into a complex system of south-vergent thrusts which form the northern boundary of the Karakoram. West of the Tirich Mir, the same rocks still occur in the Sunitz, Arkari and Lutko valleys. From the Lutko valley the belt extends westward into the poorly known mountains of Nuristan, Afghanistan. Well-preserved spinel lherzolites and harzburgites (loss on ignition 1-3 wt0/o) have been found in the Tirich Gol, in the Barum valley, and in the Arkari Gol, whereas schistose serpentinites predominate in the Rich Gol. Whole-rock analyses show high MgO contents, coupled to low CaO, Al₂O₃, Na₂O and TiO concentrations that indicate the depleted signature of TBZ peridotites. The depleted character is further confirmed by the mineral chemistry of olivine, clinopyroxene, orthopyroxene and spinel. Microstructural and petrological features unequivocally indicate a mantle origin for these ultramafic bodies, equilibrated at temperatures ranging from 1000°C to 1100°C on the basis of currently available geothermometers. Peridotites are tectonically coupled to partially metamorphosed igneous bodies, which includes a whole range of rocks from hornblende gabbros, to cumulitic hornblendites to quartz-diorites. Metamorphic rocks lying south of the ultramafic-mafic complex mainly consist of quartzites, amphibolites and garnet-sillimanite (kyanite)-biotite gneisses and mica schists, locally displaying k-feldspar and migmatitic textures. Widespread greenschist facies reequilibration affect most units.

The high temperature attained by metasediments, by the mafic suite and by the peridotitic bodies, and the common reequilibration path through amphibolite to greenschist facies conditions suggest an early arrangement of the TBZ sequence, even though all current contacts are always of tectonic origin. Absence of an ophiolitic sequence s.s., relatively low temperatures of equilibration for lherzolites and harzburgites, along with coupling with a deep crustal sequence might suggest a sub-continental character of the TBZ peridotites. Therefore, this belt might represent a fragmented crust-mantle boundary developed either on a passive continental margin or along a zone of attenuated continental crust.

The mid-Cretaceous Tirich Mir Pluton intrudes this belt, clearly post-dating magmatism, metamorphism and deformation of the unit, which may be related to an early collision of the Karakoram terrane with the southern section of the Pamir belts (Pashkov and Budanov, 1990; Gaetani et al., 1993).

Key words: Tectonics, structural geology, peridotite, Tirich Mir fault, Chitral, Hindukush.

Z/49. Zanchi, A., Poli, S., Fumagalli, P. & Gaetani, M., 2000. Mantle exhumation along the Tirich Mir Fault Zone, NW Pakistan: pre-mid-Cretaceous accretion of the Karakoram terrane to the Asian margin. In: Khan, M.A[sif], Treloar, P.J., Searle, M.P. & Jan, M.Q. (eds.), *Tectonics of the Nanga Parbat Syntaxis and the Western Himalaya*. Geological Society, London, Special Publication 170, 237-252.

The left-lateral strike-slip Tirich Mir Fault, Chitral, NW Pakistan, is associated with a belt of peridotites, metagabbros and gneisses named the Tirich Boundary Zone (TBZ), separating the Late Paleozoic-Mesozoic units of the East Hindu Kush from the Paleozoic successions of the Karakoram block. These rocks were metamorphosed up to upper amphibolite facies conditions, followed by a greenschist facies overprinting, and then thrust on to very low-grade metasediments; they were finally intruded at shallow levels by the mid-Cretaceous Tirich Mir pluton. Ultramafic rocks along the fault zone include well-preserved spinel lherzolites and harzburgites (Tirich Gol, Barum valley, Arkari Gol), whereas schistose serpentinites occur in the Rich Gol. Whole-rock analyses and mineral chemistry of olivine, clinopyroxene, orthopyroxene and spinel from these peridotites show a depleted signature. Microstructural and petrological features suggest a mantle origin for these ultramafic bodies, which equilibrated at temperatures ranging from 100-1100°C, peridotites are faulted against partially metamorphosed igneous bodies including hornblende-gabbros, hornblende-gabbros, hornblende cumulates and quartz-diorites. Metamorphic rocks of the TPZ, which lay south of the ultramafic-mafic complex, include quartzites, amphibolites, garnet-sillimanite ($\pm$ kyanite $\pm$ K-feldspar)-biotite gneisses and mica schists, locally displaying migmatitic textures.

A sub-continental character of the peridotites indicated by low temperatures of equilibration and by the presence of a deep crustal sequence. These characters along with the absence of an ophiolitic sequence may suggest that the TBZ represent a fragmented crust-mantle boundary developed along a zone of attenuated continental crust. The TBZ is interpreted as a sheared lithospheric section of a Jurassic-Early Cretaceous orogenic complex, formed as a consequence of the accretion of the Karakoram terrane to the southern side of the Pamir belts, which were progressively accreted to the Asian margin.

Z/58. Zaninetti, L. & Bronnimann, P., 1975. Triassic Foraminifera from Pakistan. Rivista Italiana di Paleontologia e Stratigrafia, 81(3), 257-280.

The Landu Nala bed, Surghar Range, Pakistan, has 2 Triassic microfossiliferous intervals. The 1st, containing Endothyrales and Meandrosira pusilla, is attributed to the Lower Anisian. This calcarenitic unit is situated between the subadjacent Khatkiara sandstones and the dolomitic Kingriali formation. The latter formation, constituting the 2nd interval, contains Involutina comparable to those of Espahk formation (Iran). The probable age of the microfauna is Ladinian. At the base of the Samana Suk bed, Samana Range, Pakistan, an important association of Triassic Foraminifera, especially Involutinidae, was identified. Compared to the microfauna of the Espahk limestone, this association seems younger than that of the Kingriali formation in the Landu Nala bed. The age for the Samana Suk bed is estimated at Middle to Upper Triassic (Ladinian to Carnian).

Z/59. Zanin Buri, C., 1965. A new Permian epimastopora (calcareous alga) from Hunza valley (Western Karakorum). In: Desio, A. (ed.), Italian Expeditions to the Karakorum and Hindu Kush. Scientific Report 4(1), 79-88. Brill, Leiden.

While examining samples coming from a section made in the Permian of Hunza vally (right side of Chapursan river: on the way to Khudabad-raminj) during Prof. A. Desio's expedition, I recognized the presence of an algal form belonging to Epimastopora, unknown until now in this region. The specimens we examined have been taken from the samples of Girch formation with a thickness of 6000 m, whose upper part is formed by brown and black arenaceous layers with small interpositions of dolomitic limestone, while lower part is formed by light – coloured quartz – sandstones. Our specimens are coming from the calcareous layers in between the inferior and superior member of the formation.

Epimastopora forms are rather frequent and their presence has been noted by several authors in Upper Paleozoic of Asia, America and Europe. It has to be remembered by the way, that the nearest geographic finding is given by the species Epimastopora alpine Herak, coming from the Darvasian of Davas (central Tajikistan – NW Pamir). This species, in opposition to the one I have examined, has been found in association with some other species of calcareous Algae.

Notwithstanding the fact that it has frequently been noted, genus Epimastopora is still not very well known as we are not in a possession of sure data to recognize it exactly.

From stratigraphical point of view it has a great importance, having a limited vertical distribution: its oldest forms appear in Upper Carboniferous and most recent ones are not going over Permian; each species occurs even shortest intervals. For what concerns ecology, Epimastopora testifies warm marine environment such as littoral sea.

Analysis of fault-striations measured in the Kohistan part of the Indus Suture Zone (NW Himalayas, Pakistan) has been carried out to document dynamic evolution during the brittle stage of the collision of India and Asia. Processing of the data with a direct inversion method identified four stress fields, which were chronologically ordered from field evidence as SSE-NNW compression, E-W compression, radial extension and SSW-NNE compression. The last corresponds to the present-day stress field defined from seismic activity. The earlier stress fields are related to times during the Miocene, when convergence-related stresses were disturbed by the formation of the nearby Nanga Parbat and Indus syntaxis.

Z/65. Zeilinger, G., Burg, J.P., Schaltegger, U. & Seward, D., 2001. New U/Pb and fission track ages and their implication for the tectonic history of the Lower Kohistan arc complex, Northern Pakistan. Journal of Asian Earth Sciences 19, 16th HKTI workshop special abstract issue, p.79.

The Kohistan arc complex separates the Indian and Asian plates in NW Pakistan. It was formed as an Island arc during Mesozoic times. Accretion to Asia and subsequent thrusting onto the northern margin of the Indian plate along the northward dipping Indus suture zone (ISZ) constitute the collisional history. The early tectonic evolution of the arc can be subdivided into 2 stages: (1) a juvenile stage (estimated at ca. 110±95 Ma): lithospheric growth through partial melting of a fertile mantle in an intraoceanic subduction environment and SW-thrusting expressed by anastomosing shear zones in the southern, i.e. lower part of the arc imposed by

subduction of the Tethys oceanic crust; and (2) an intra-arc rifting stage (around 80 Ma) with the emplacement of large bodies of gabbro and of felsic dykes. We will present two groups of new ages obtained in the lower Kohistan arc complex: (1) crystallization ages of gabbro to granodioritic intrusions reflecting the early arc related history and (2) zircon and apatite fission track (FT) cooling ages related to the younger continent/arc±continent collision and post-collisional uplift.

Z/66. Zeilinger, G., Schaltegger, U., Burg, J.P., Chaudhry, M.N., Dawood, H. & Hussain, S.S., 2001. Precise U-Pb ages from the Kohistan complex (Northern Pakistan) illustrate rapid formation of arc-type crust. 11th EUG Meeting, Strasbourg, J. Conference Abstract 6, p.388.

The Kohistan Arc Complex in northern Pakistan was formed in the Tethys ocean in Mesozoic times and subsequently obducted onto the Indian plate along the Indus Suture in the Late Cretaceous - Paleocene times. The tectonic evolution of the arc can be subdivided into (1) a juvenile stage (estimated at ca.110-95 Ma) involving lithospheric growth through partial melting of a fertile mantle in an intra-oceanic subduction environment; (2) intra-arc rifting (around 85 Ma) marked by the emplacement of large volumes of volcanoclastic rocks in the intra-arc extensional basin and underplating of the arc crust by gabbroites; (3) a mature stage with Andean-type granitoid magmatism, which ceased with the India-Asia collision 60 to 40 Ma ago.

The structurally lowest levels of the Kohistan Arc Complex comprise the Jijal complex, which consists of ultramafic rocks overlain by granulite-facies gabbros. The complex is covered by a pile of metamorphic gabbro to tonalitic dykes and sills overlain by metabasalts and metasediments. This association was intruded by partial melts of mantle origin (gabbros, tonalites, granitoids) representing the first stages of crustal growth (stage 1) in an intraoceanic arc. Precise age determinations yielded for a sub-granulitic gabbro and a granitoid sheet-like intrusion significantly discrete ages of 99 and 97 Ma, respectively; a tonalite body was emplaced into the same environment at 92 Ma. The whole complex was again penetrated by mantle melts (gabbroites to granitoid dykes) during rifting (stage 2). A gabbroite from the so-called Chilas Complex and a granitoid kyanite-bearing dyke yielded ages of 85 Ma and 83 Ma, respectively.

The time period for the initial arc buildup with intrusion of gabbro to granitoid melts is constrained to a short time period between 99 and 92 Ma. Intra-arc rifting characterized by the intrusion of gabbroites and granitoid dykes is dated between 82 and 85 Ma. The ages represent the first protolith ages from the sub-arc mantle-crust transition. Initial arc magmatism may therefore be constrained to at least three magmatic pulses of <5 m.y. duration with each magmatic cycle most likely comprising gabbro to granitoid lithologies, pointing to rapid differentiation processes. The granitoid stocks, sheets and dykes were emplaced prior to obduction onto the Indian plate.

Z/67. Zeitler, P.K., 1980. The tectonic interpretation of Fission-Track ages from the Himalayan Ranges of Northern Pakistan. M.A. Thesis, Dartmouth College, 92p.

Fission track ages of sphene, zircon and apatite from rocks collected along the Swat valley and from Hunza (north Pakistan) date the recent uplift history of this region. A major E-W fault, the Main Mantle Thrust (MMT) or Patan Fault crosses the Swat valley and separates regions of markedly different uplift history. Ages ranging from 50 to 55my for apatite were obtained from the region north of this fault. To the south the ages range are 20 to 25my for sphene, 17 to 26my for zircon and 16 to 23my for apatite. This distribution of ages indicates either that differential uplift occurred across the MMT prior to about 15 my, or that this fault has brought together terrains of differing uplift history. Should the latter have been the case, the fission track data indicate that the faulting took place between 15 and 20my at depths of between 3.5 and 6 km. As the MMT may represent the traces of collision between India and an Island arc at 53 my, the offset along this fault at 15 my determined in this study may indicate that the process of complete.

Z/68. Zeitler, P.K., 1983. Uplift and Cooling History of the NW Himalaya, Northern Pakistan. Evidence from Fission-Track and ⁴⁰Ar/³⁹Ar Cooling Ages. Unpublished Ph.D dissertation, Dartmouth College Hanover, New Hampshire 03755, 266p.

This study reports 145 fission-track and 21 ⁴⁰Ar/³⁹Ar cooling ages from the Himalaya of northern Pakistan. Studies of the Himalaya are important because they provide geologists with an opportunity to test models of

orogenesis in an active tectonic setting. As the Himalaya become better known and models become more quantitative, information about thermal histories and rates of uplift and erosion will be needed. This provides the motivation for this dissertation.

The cooling ages suggest, and thermal modeling confirms, that throughout the Tertiary, the cooling history of northern Pakistan was controlled by the effects of accelerating uplift and erosion. On average, from 30 Ma to the present, uplift rates increased from less than 0.1 mm/yr to 0.4 mm/yr. This uplift and erosion, however, has been variable in space as well as time. For example, over the past 10 Ma, western and southern portions of northern Pakistan have been uplifted less than 3.5 km at rates as high as 1.0 mm/yr, and the Nanga Parbat-Haramosh Massif and Hunza regions have been uplifted on the order of 10 to 15 km at rates (over the past 0.7 Ma) nearly 5 mm/yr.

The association of the Nanga Parbat-Haramosh Massif and Hunza with very young cooling ages and with rapid uplift maintained for a period of several million years is the most striking discovery made by this study. The location of these two areas at the heart of the Pamir-Himalaya Arc suggest that their anomalous behavior is linked in some way to a locally vigorous collision of India and Eurasia, possibly due to a promontory of India crust. Several of the cooling ages reported here helps constrain the emplacement ages of intrusives located in northern Pakistan. In addition, cooling ages from the southern Swat-Hazara region can be interpreted to give the time of (final?) southward thrusting of the Kohistan Arc along the Main Mantle Thrust, at about 30 Ma.

Z/69. Zeitler, P.K., 1985. Cooling history of the NW Himalaya Pakistan. *Tectonics* 4, 127-135.

Fission-track and $^{40}\text{Ar}/^{39}\text{Ar}$ cooling ages indicate that the late-Tertiary cooling history of the Himalayan ranges of northern Pakistan is largely a function of uplift and erosion. Interpretation of cooling ages which range from under 0.5 Ma to over 80 Ma suggests that during the late Tertiary, long-term uplift rates at least doubled, from under 0.2 mm/yr to in some cases well over 0.5 mm/yr. Uplift rates show strong and systematic regional variations as well which reflect the greater uplift of eastern and northern regions. The association of very rapid uplift and erosion with the Nanga Parbat-Haramosh Massif can be explained by a locally vigorous collision of India with Eurasia near a promontory of Indian crust. The resultant rapid uplift of the Nanga Parbat-Haramosh Massif reactivated the Main Mantle Thrust melange zone with a reversed sense of motion. Discontinuities in the cooling age distribution along the Main Mantle Thrust in the southern Swat-Hazara region may be the result of the thermal effects of overthrusting.

Very young leucogranites, some only a few million years, occur in NW Himalaya in the Nanga Parbat area. The tectonic significance of these is discussed. For additional information, consult the following account.

Key words: Petrogenesis, tectonics, leucogranites, ion microprobe, NW Himalaya.

Z/73. Zeitler, P.K. & Chamberlain, C.P., 1991. Petrogenetic and tectonic significance of young leucogranites from the northwestern Himalaya, Pakistan. *Tectonics* 10(4), 729-741.

In the Himalaya of northwestern Pakistan, small discordant bodies of leucogranite intrude metamorphosed basement of the Indian crust. As the first step in assessing the tectonic significance of these granites, we have used the SHRIMP ion microprobe to obtain U-Pb dates on zircon. Zircons of igneous appearance are scarce in the leucogranites, and with one exception are associated with xenocrystic components, which occur as discrete grains and as cores rimmed by young zircon. Zircons of igneous appearance are high in U [5000 to 40,000 ppm], low in Th/U [0.01 to 0.05], and frequently colored a distinct blue. Xenocrystic components give a range of Proterozoic ages consistent with ages previously reported for Indian crust. In sharp contrast, zircons of igneous appearance yield clusters of concordant Tertiary ages. Two leucogranite dikes from southern localities yield rather old emplacement ages of about 35 Ma (Swat) and about 50 Ma (Naran). Together with previously determined $^{40}\text{Ar}/^{39}\text{Ar}$ and fission track cooling ages, these ages document immediate and rapid metamorphism and denudation following Eocene collision. Three leucogranite dikes from northern localities within the Nanga Parbat-Haramosh Massif are very young, having emplacement ages of about 2.3 Ma, 5 Ma, and 7 Ma. The formation and emplacement of these leucogranites during the rapid late Tertiary denudation of the Nanga Parbat region suggests to us that decompression melting may be a viable mechanism for leucogranite genesis.

Z/76. Zeitler, P.K., Chamberlain, C.P. & Smith, H., 1992. Quaternary anatexis and Neogene metamorphism at Nanga Parbat, Pakistan. Abstract Volume, 7th Himalaya-Karakoram Workshop, Department of Earth Sciences, Oxford University, England, 102.

Our recent geochronological work has shown that the Nanga Parbat massif (NW Himalaya, Pakistan) has experienced extensive metamorphic and igneous activity within the past 10 Ma. We summarize here our geochronological and petrological observations, which include U/Pb analyses on zircons and monazites from a variety of igneous and metamorphic units.

Tourmaline-bearing pegmatite dikes, which occur along the western and northern flank of the Nanga Parbat massif yield ages of between 2.2 and 8 Ma, based on monazite and zircon analyses. Monazite from samples of metamorphic basement yield ages ranging from 4 to 11 Ma. Finally, use of the SHRIMP ion microprobe in drilling mode reveals that zircons from two samples of schists are overgrown by thin, high-U rims which are less than 5 Ma in age, a result similar to that obtained from drilling analysis of zircons sampled along the Indus River section some 80 km to the north.

In the core of the Nanga Parbat massif, between Tato village and the northern face of Nanga Parbat, extensive migmatites are present in which pelitic units commonly show the assemblage alkali feldspar-cordierite-sillimanite-garnet. A variety of granites intrude these migmatites and associated biotite gneisses and calc-silicates, including a 1-km stock of fine-grained, equigranular two-mica granite, dikes similar in composition to this granite, coarse tourmaline-bearing pegmatites, and several-meter-thick granite sheets containing clots of biotite. Ion-probe analyses of zircon from all these units yield well-defined ages of ~1 Ma. Zircons extracted from a sample of migmatite yield scattered ages which average about 3.5 Ma, two monazite fractions from the same sample yield concordant ages of 3.3 Ma, and $^{40}\text{Ar}/^{39}\text{Ar}$ ages of hornblende are between 1 and 2 Ma.

Migmatization within the core of the Nanga Parbat massif occurred at about 650°C and 4.5 kbar. Together with the age of 3.3 Ma determined on migmatites, the petrological data confirm previous cooling-age estimates for the rapid Quaternary denudation of the Nanga Parbat massif. Our new data suggest a mean denudation rate of .5 mm/yr for the past 3 my, indicating that unroofing of Nanga Parbat has been both extensive and rapid.

Z/77. Zeitler, P.K., Chamberlain, C.P. & Smith, H.A., 1993. Synchronous anatexis metamorphism and rapid denudation at Nanga Parbat (Pakistan Himalaya). *Geology* 21, 347-350.

The Nanga Parbat-Haramosh massif of the western Himalaya is a north-trending half-window of Indian crust that provides spectacular exposures of Precambrian basement gneisses that have been overprinted by Himalayan metamorphism. We report here petrologic data and U/Pb dates on zircon and monazite which document that Nanga Parbat gneisses underwent a Pliocene-Pleistocene episode of high-grade metamorphism and anatexis during an interval in which the Nanga Parbat massif was undergoing rapid denudation at mean rates of ~ 5 mm/yr. We speculate that by initiating decompression melting, this denudation may be at least partly responsible for the anatexis and high-grade metamorphism.

Key words: Denudation, anatexis, metamorphism, Nanga Parbat, NW Himalaya.

Z/78. Zeitler, P.K., Johnson, N.M., Naeser, C.W. & Tahirkheli, R.A.K., 1982. Fission-track evidence for the Quaternary uplift of the Nanga Parbat region, Pakistan. *Nature* 298, 255-257.

The north-striking Nanga Parbat-Haramosh Massif protrudes into the northwestern Himalaya along the axis of a great syntaxis^{1,2} (Fig. 1), where the Hindu Kush, Karakorum, and Himalayan ranges converge. As the Indus Suture Zone³ enters this region from the east it bifurcates into two branches, encircling what may be a docked island-arc terrane⁴. The southern branch (the Main Mantle Thrust) crops out on both flanks of the Nanga Parbat massif, forming a tight structural loop⁵. This massif and the adjacent terrane contain some of the highest peaks in the Himalaya; Nanga Parbat and the Indus River (located just 20km away) define the world's greatest continental relief (6,930 m). We report here the discovery of unexpectedly young sphene, zircon and apatite fission-track dates from the Nanga Parbat-Haramosh Massif. These dates (as low as 1.3 Myr for zircon and 0.4 Myr for apatite) imply that during the Pleistocene the Nanga Parbat region was uplifted and eroded at nearly 1 cm yr⁻¹.

Fig. 1 Structural trends of northern Pakistan. Heavy barbed lines show suture zones and major thrust faults. Dashed lines show trends of folds in molasse sediments. NP, Nanga Parbat (8,126 m), located on Nanga Parbat-Haramosh Massif. A-A' is line of profile

Geodynamics of the Nanga Parbat Massif, Pakistan Himalaya. *Terra Nostra* 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 189-190.

Within the great syntaxial bends of the India-Asia collision, the Himalaya terminate abruptly in a pair of active metamorphic massifs. Nanga Parbat in the west and Namche Barwa in the east are antiformal domes, which expose Quaternary metamorphic rocks and granites, and are loci of ferocious denudation where they are transected by major Himalayan rivers (Indus and Tsangpo). Comprehensive geophysical and geological data we have collected at Nanga Parbat support a model in which these metamorphic massifs owe their origin to erosionally induced deformation of the crust near deep gorges cut by the Indus and Tsangpo as these rivers turn sharply towards the foreland and exit their syntaxes. Primarily, the intense metamorphic and structural reworking of crustal lithosphere seen at the terminations of the Himalayan arc owes its origin to mesoscale feedbacks between erosion and tectonics.

Widely taken as the type example of a collisional mountain belt, the Himalaya have seen increasing use as a natural laboratory in which to examine a variety of collisional processes. Over the past four years, an approximately 5,000-km² area of the central Nanga Parbat massif of the northwestern Himalaya has been the focus of our Nanga Parbat Continental Dynamics Project, a multidisciplinary study aimed at understanding how the continental lithosphere comes to be pervasively reworked during continental collision. Nanga Parbat exposes extremely young metamorphic and igneous rocks and is an ideal place to examine the specific processes involved in crustal reworking, particularly erosion, which has come to be recognized of late as a critical control on the mechanical and petrological evolution of mountain belts. The Nanga Parbat project involved the coordinated effort of numerous investigators, working in a broad range of disciplines, including the areas of geochronology, structural geology, geomorphology, seismology, remote sensing geomorphology, dynamical modeling, geochemistry, magnetotellurics and neotectonics. Together with petrologic and geomorphic studies carried out by other groups, we now have an excellent understanding of the evolution and state of the crustal lithosphere at Nanga Parbat.

The Nanga Parbat-Haramosh Massif exposes polymetamorphic Indian-plate gneisses which have been undergoing an episode of pronounced crustal reworking; this has involved pervasive deformation, young metamorphism and melting, widespread fluid flow, rapid and pronounced exhumation, and sculpting of the crust into spectacular, steep topography. Within the core of the Nanga Parbat massif, there is a bull's-eye coincidence between the massifs most extreme topography and high-temperature granulite-grade migmatites, a young and active anti formal pop-up structure, young 1-2 Ma granitoids, abundant seismicity with sharp bottom and lateral cut-offs, pronounced hydrothermal activity, steep new-surface thermal gradients, and rapid denudation documented across a wide range of timescales. These coincident features beg a simple, shared explanation.

Erosionally concentrated strain attributable to large magnitude incision by the Indus River focuses Indian Plate material from the south into the developing Nanga Parbat massif. Advection elevates isotherms beneath the massif, creating a relatively high-temperature/low-pressure region where sillimanite and dry melt are stable that coincides with a zone of anomalously low electrical conductivity. At approximately 12 km depth these relatively dry rocks interact with highly-exchanged meteoric or metamorphic water and generate vapor-present, cordierite-bearing granitic veins. The hot rock packet then passes toward the northwest, advecting isotherms, elevating the position of the brittle-ductile transition, and generating a vigorous hydrothermal system. The base of the predicted rheological transition coincides with a cutoff in observed microseismicity.

Work by J. Burg and colleagues and mapping by Chinese geologists suggests that the Namche Barwa massif in the eastern Himalayan syntaxis shares a very similar geological and tectonic setting with Nanga Parbat. We suggest that such hyperactive metamorphic massifs may be signature features of syntaxial regions, where large orogen-scale rivers such as the Indus and Tsangpo are diverted towards the foreland, rapidly cutting deep gorges as they make their steep exit from the hinterland.

Local, sub-orogen scale erosional exhumation at Nanga Parbat (and, we suspect, at Namche Barwa), far from being overrated, is in fact of first-order importance in controlling the metamorphic, topographic, and structural

evolution of the cores of the Himalayan syntaxes. Such pervasive structural and metamorphic overprinting of old basement rocks is a fundamental geodynamic process in its own right. Ultimately, the dynamics of syntaxial metamorphic massifs may be reconciled with broader orogen-scale collision processes through the feedbacks between deformation, topographic evolution, and erosion that lead to the channeling of major river systems through the syntaxes. Our results contribute to the growing appreciation of the importance those surficial processes and crustal rheological variations have on controlling the shape, dynamics, and evolution of mountain belts, at many scales.

Z/81. Zeitler, P.K., Koons, P.O., Bishop, M. L., Chamberlain, C.P., Craw, D., Edwards, M.A., Hamidullah, S., Jan, M.Q., Khan, M.A., Khattak, M.U.K., Kidd, W.S.F., Mackie, R.L., Meltzer, A.S., Park, S.K., Pecher, A., Poage, M.A., Sarker, G., Schneider, D.A., Seeber, L., and Shroder, J., 2001. Crustal Reworking at Nanga Parbat, Pakistan: Evidence for erosional focusing of crustal strain. *Tectonics*, 20, 712-728.

Within the syntaxial bends of the India-Asia collision the Himalaya terminate abruptly in a pair of metamorphic massifs. Nanga Parbat in the west and Namche Banwa in the east are actively deforming antiformal domes which expose Quaternary metamorphic rocks and granites. The massifs are transected by major Himalayan rivers (Indus and Tsangpo) and are loci of deep and rapid exhumation. On the basis of velocity and attenuation tomography and micro-seismic, magnetotelluric, geochronological, petrological, structural, and geomorphic data we have collected at Nanga Parbat we propose a model in which this intense metamorphic and structural reworking of crustal lithosphere is a consequence of strain focusing caused by significant erosion within deep gorges cut by the Indus and Tsangpo as these rivers turn sharply toward the foreland and exit their host syntaxes. The localization of this phenomenon at the terminations of the Himalayan arc owes its origin to both regional and local feedbacks between erosion and tectonics.

Key words: Orogeny, tectonics, Nanga Parbat.

Z/82. Zeitler, P.K. & the Nanga Parbat Working Group, 1998. Crustal reworking at Nanga Parbat: The Nanga Parbat continental dynamics project. *Geological Bulletin, University of Peshawar* 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 227-228.

A considerable amount is now known about the Nanga Parbat massif, which has been the focus of intense study over the past several years by several teams. Our ongoing Nanga Parbat Continental Dynamics Project has been using Nanga Parbat as a natural laboratory to examine processes of pervasive synorogenic crustal reworking, on the basis that the Precambrian rocks of the massif have been deeply overprinted by a recent and intense metamorphic, magmatic, and deformational episode that remains active today. We are currently synthesizing results from investigations in the areas of magnetotellurics, seismology, structural geology, tectonics and neotectonics, geochronology, geomorphology, petrology, geochemistry, and dynamical modelling in order to test hypotheses about mesoscale linking between petrologic, tectonic, and surficial processes.

The Precambrian rocks of the Nanga Parbat massif occur within a northward projection of Indian-plate basement flanked to the west and east by rocks of the Mesozoic Kohistan-Ladakh arc terrane and to the north by rocks of the Asian plate. Originally overthrust from the north (in the early Tertiary) by mafic and intermediate volcanic and plutonic rocks of the Kohistan terrane, Nanga Parbat basement has recently been exhumed by NW-directed thrusting and development of a large north-south oriented antiform. Ferocious exhumation has occurred by mass wasting and glacial erosion, with the nearby Indus River providing efficient removal of debris from the region: fluvial incision rates along the Indus are among the highest in the world, reaching 12 mm/yr (Burbank et al. 1996). The summit massif in the central portion of the antiform is ringed by concentric isograds, which culminate in cordierite-K-feldspar grade, and in this region a moderate number of undeformed granitoid dikes and pegmatites as well as a few small bodies of undeformed granite occur. To the south of Nanga Parbat, towards Babusar Pass and the relatively low-grade rocks which occur there, there is a major telescoping of isograds across what is most likely a thrust system of some sort.

Much of the exposed geology at Nanga Parbat is young or the result of ongoing rapid processes. The 7000 meters of relief defined by Nanga Parbat and the Indus River reflect unroofing rates as high as 5 mm per year, as documented at several time scales by geomorphic, petrologic, and fluid-inclusion studies. These rapid unroofing rates are also reflected in the very young cooling ages seen within the Nanga Parbat massif, with mica Ar-Ar ages of as young as 1 Ma and metamorphic monazite ages on migmatites of known P-T conditions of as young as 3 Ma; these data suggest cooling rates for exposed surface rocks of well over 200 C/m.y., and unroofing in

the past 3 Ma of some 15-20 km. Granite ages from 1 to 8 Ma indicate that emplacement in at least some places took place during exhumation, leading to the suggestion that some of the Nanga Parbat granites owe their origin to decompression melting. There is abundant evidence for fluid flow within the Nanga Parbat massif involving circulation of metamorphic and magmatic waters as well as penetration of meteoric water to depths having temperatures of some 600°C. This fluid flow and the high thermal gradients under the massif are attested to by the presence of numerous hot springs, and fluid-inclusion studies suggesting gradients over the top 3 km being some 100 C/km. Active faulting is common within the Nanga Parbat massif, and includes the substantial NW-directed Raikot/Liachar thrust, which places basement over gravels, as well as faults further outboard to the west of Nanga Parbat which have displaced rocks of the Kohistan terrane. The massif is quite active microseismically, but only to depths of some 7 km, presumably reflecting the high thermal gradients and a shallow brittle-to-ductile transition. To date we have found no evidence for significant extensional exhumation and it appears that the extreme exhumation at Nanga Parbat stems from erosion of rocks exposed by reverse faulting.

The relationship between the spatially rather limited metamorphic anomaly at Nanga Parbat and its broad geodynamic setting is an important question to which we are ultimately directing our efforts. Recent reports by J.-P. Burg and coworkers suggest that the geology and active tectonics of Namche Barwa, located at the far eastern end of the Himalayan chain, is remarkably similar to that seen at Nanga Parbat. The location of the Himalayas' two hyperactive metamorphic massifs precisely within the orogen's two great syntaxes is surely no coincidence, and raises interesting questions about the nature and evolution of indentor corners.

Z/84. Zeitler, P., Sutter, J., Williams, I.S., Zartman, R.E. & Tahirkheli, R.A.K., 1989. Geochronology and temperature history of NPHM, Pakistan. In: Malinconico, Lillie, R.J. (eds.), Tectonics of the Western Himalayas. Geological Society of America, Special Paper 232, 1-22.

The gneisses of the Nanga Parbat Haramosh Massif (NPHM), Pakistan, experienced peak metamorphic temperature in the interval from 25 to 30 Ma, as revealed by $^{40}\text{Ar}/^{39}\text{Ar}$ cooling ages of hornblende and the ages of the youngest intrusions of the Kohistan batholith located immediately adjacent to the NPHM. $^{40}\text{Ar}/^{39}\text{Ar}$ and fission-track mineral ages indicate that the postmetamorphic cooling history of the NPHM has been controlled over the past 5 – 10 M.Y. by active tectonism associated with the Raikhot Fault, although passive uplift and erosion in response to over thrusting of the NPHM by the Kohistan Arc has been underway as well. Net cooling rate for the NPHM gneisses exposed today along the Indus River at low elevations have accelerated from 200C / m.y. at ~20Ma to 3000C /m.y. at 0 to 0.4 Ma. following emplacement of aplite dikes at about 30 to 35 Ma, portions of the Kohistan batholith adjacent to the NPHM experienced cooling rates similar to the NPHM of about 20 C/m.y. over the period of 25 to 10 Ma, but the net cooling rates for the batholith of ~30C/m.y. over the past 10 m.y. have been much lower than those experienced within the NPHM. Ion microprobe and conventional U/Pb analyses of Zircon show that the protoliths for the Iskere gneiss and the structurally lower Shensgus gneiss of the NPHM are, respectively, ~1850 Ma and 400 to 500 m.y. in age.

Z/85. Zeitler, P.K., Tahirkheli, R.A.K., Naeser, C.W. & Johnson, N.M., 1982. Unroofing history of a suture zone in the Himalaya of Pakistan by means of Fission-Track annealing age. Earth and Planetary Science Letter 57, 227-240.

The uplift history of the Swat Valley and Hazara region of northwestern Pakistan has been established using 22 fission-track dates on apatite, zircon and sphene. A major fault, the Main Mantle Thrust (MMT) strikes east-west across the Swat Valley, separates regions of markedly differing fission-track age regimes, and may be a suture zone separating an extinct island arc terrane on the north from the Indian plate to the south. Fission-track ages ranging from about 55 to 58 m.y. for sphene, 18 to 53 m.y. for zircon, and 9 to 17 m.y. for apatite were

obtained from the region north of the MMT. To the south the fission-track age ranges are 20 to 25 m.y. for sphene, 17 to 26 m.y. for zircon, and 16 to 23 m.y. for apatite. Disparate zircon and sphene ages on each side of the MMT imply different cooling histories for each side of the fault prior to 15 m.y. Similar apatite ages on both sides of the fault imply similar cooling histories during the past 15 m.y. This may indicate that faulting ceased by 15 m.y. Mean uplift rates have been derived from the fission-track data using mainly the mineral-pair method. Uplift rates in the region north of the MMT increased from 0.07 to 0.20 mm/yr during the period 55 to 15 m.y. south of the fault, uplift rates averaged in excess of 0.70 mm/yr for the period 25 to 15 m.y. During the past 15 m.y. uplift across the MMT in the Swat Valley shows no discontinuities, ranging from 0.16 mm/yr in the south to 0.39 mm/yr in the north. A plausible interpretation for the fission-track uplift data has the MMT verging to the south with overthrusting taking place at a depth between 3.5 and 6.0 km, juxtaposing two terranes that were originally separated by a substantial, but unknown distance. In this model, regional uplift followed cessation of faulting just prior to 15 m.y.

Z/86. Zeitler, P.K., Tahirkheli, R.A.K., Naeser, C., Johnson, N. & Lyons, J., 1980. Preliminary fission track ages from the Swat valley, Northern Pakistan. *Geological Bulletin, University of Peshawar* 13, 63-65.

A number of the lithologies found in the Swat Valley have been dated by the fission track method to assess and to describe the area's uplift history. Pb/U determinations made on three zircon splits obtained from the pyroxene granulite located to the north of the MMT fall nearly on Concordia at about 84 m.y. Zircon obtained from a metasediment located south of the fault give a fission track age of about 22 m.y., the same as zircons obtained from associated granites and gneisses. Thus it can be shown that the fission track ages of rocks located north of the MMT are not intrusive ages, and similarly that ages of rocks located south of the MMT must be yielding uplift ages.

Granitic rocks occurring in Kunlun and northern Karakorum belts, and Taxkorgan alkaline complex are described. The Khunjerab granitic belt in northern Karakorum extends along the border of Pakistan and China. It is composed of tonalite, monzolithic granite, K-feldspar granite and two-mica alkali feldspar granite, with isotopic ages around 100 ma. they contain 59-75 % SiO₂ and classify as calc-alkaline. Trace elements and REE data are given for the rocks; they contain high REE and LREE/ HREE = 10.3. The analyses plot in the field of volcanic arc /post collision granites and in active plate margin fields.

Z/95. Zimmermann, J.L., Debon, F. & Bertrand, J.M., 1986. The upper Miocene Baltoro granite (Karakorum axial batholith, northern Pakistan): K-Ar dates and cooling history. Terra Cognita 6, p.193.

The Baltoro granite, an intrusion more than 100 km long and ca. 4 to 20 km wide, probably represents the youngest acidic plutonic unit of the composite Karakorum axial batholith. Proposed for a long time from a comparative study of pleochroic haloes in biotite, its Upper Miocene age of emplacement has only quite recently been revealed by isotope dating methods, viz. three internal Rb-Sr isochrons (8.8 ± 0.3 Ma) and ten K-Ar dates (8.5 ± 0.8 Ma). The K-Ar dates have yielded the following results : (1) for three whole rocks : 8.85 / 9.35 / 9.25 Ma, average 9.2 Ma; (2) for three biotites and one muscovite: 7.45 / 8.0 / 8.85 / 8.85, average 8.3 Ma; (3) for three K-feldspars : 7.2 / 7.85 / 8.95, average 8.0 Ma. It is suggested that the three average ages (9.2, 8.3, 8.0 Ma) reflect the Cooling - crystallization timing of the Baltoro magma, from its emplacement (c a. 9.2 Ma) down to the K-feldspar isotope closure. Much detailed work is needed to be done to transform this rough speculative estimate into tested and accurate hypotheses. The Baltoro granite offers a rare possibility: a concrete and full-size approach of the cooling history of a plutonic body.

Add/1 Alizai, A.H.K., 2000. Geochemistry of Water and Soil from Dera Ismail Khan NWFP, Pakistan. M.Phil. Thesis, University of Peshawar.

The aim and motive to start 'work on the waters and soils of D.I. Khan division was to establish a brief chemical and environmental report on the quality of water, because various types of diseases have been reported from the area. For this purpose water of the area was divided into four categories i.e. deep water (tube-wells); shallow water (dug-well, settling ponds/nalas and hand-pumps), surface water (streams and rivers). A total of thirty-four water samples were selected for study of twenty-two parameters. In order to see any contribution made by soils and rocks to the water. Twenty-two soil samples adjacent to water samples and five rock samples were also analyzed for major and trace elements.

The results obtained for the water samples from different places of D.I. Khan division are compared with that US-EPA (1989) and WHO (1981) standards for safe drinking water. On the basis of these standards the water quality of many areas are found not suitable for drinking. For example water sample from Gomul Rivers suggest that it is not safe for drinking water, however, major portion of population of the D.I. Khan division use it for drinking. The chemical radicals exceeding the permissible limit of US-EPA (1989) and WHO (1981) are: Bicarbonate (225 mg/l), sulphate (400 mg/l). Iron (43.3 mg/l), Magnesium (47 mg/l). Manganese (0.21 mg/l). Na (102 mg/l) and copper (10 mg/l). In Porra the following constituents are out of permissible limit i.e. Sulphate (1600 mg/l); Bicarbonate (250 mg/l); Chloride (244 mg/l); Na (175 mg/l), Magnesium (73.7 mg/l). Apart from these two areas, the water quality of other areas, which is not safe for drinking purpose are Mullazai, Tank, Umer Ada. Potah. Chudhwan. Ramak. Kulachi and Gomul university. Sulphate is high in the middle and lower part of the D.I. Khan division. High sulphate concentration in water causes diarrhea and dehydration (Zunae, 1990). Nitrate is found high at shallow water (Dug well, hand pumps, settling ponds Nala). It is reported alarmingly high at Mullazai (17mg/l) and at Chudhwan spring (90 mg/l), as compared to the maximum limit (10 mg/L) of WHO (1984) for safe drinking water. High nitrate cause infection to gastrointestinal tract and large concentration of nitrate in water may result in the potential formation of carcinogenic nitro amines (Zunae, 1990). Chloride concentration is maximum i.e. 618 mg/l at Ramak area of D.I. Khan division, which considerably exceeds the permissible limit (200 mg/L) of WHO (1984). It crosses the permissible limit at eight other places of D.I. Khan division. Except two samples, iron is out of limit in all the water samples. Magnesium is also high at six places.

Manganese is crossing the limit at sixteen places. Potassium is high at five places. In trace elements copper is considerably out of range in the water of Gomul River. Pb is high (0.3 mg/L) in the water sample taken from Gomul University tube well where by the safe limit of lead in the drinking water is 0.05 mg/l. Fluoride is also high at six places. The generalized trend for many constituents increase from north to south. The results show the concentration of many elements are high towards south.

Collection of soil and rock samples was made from the same areas where water samples were collected. The objective of this detail geo-chemical results of the rock and soil samples were to see the influence of these rock and soil samples on the water samples of the same area. The results are discussed in the concerned chapter. For the treatment or removal of these constituents can be done by the method established by US-EPA. (1988). Filtration, ion exchange and lime softening can remove copper and iron. Nitrate can be removed by biological denitrification. sulphate by ion exchange and fluoride by reverse osmosis. All these methods are effective but practically non-economical.

Add/2 Anczkiewicz, R., Burg, J.P., Villa, I.M., & Meier, M. 2000. Late Cretaceous blueschist metamorphism in the Indus Suture Zone, Shangla region, Pakistan Himalaya. *Tectonophysics* 324, 111–134

Rb–Sr and ³⁹Ar–⁴⁰Ar phengitic muscovite dating of the transitional blueschist–greenschist facies rocks from the Shangla region of Pakistan Himalaya resulted in a concordant ca. 80 Ma age interpreted as a time of metamorphic peak. ³⁹Ar–⁴⁰Ar age spectra of sodic amphiboles were unsuitable for precise age determination. Mass-balance calculations show that the K concentration in glaucophane/crossite is ca. 25 ppm, and the K–Ar budget is dominated by inclusions of phengitic muscovite.

E–W-oriented (parallel to Kohistan arc) stretching lineation defined by preferred orientation of amphiboles was accompanied by synkinematic growth of riebeckite rims on the edges of microboudins. Evolution of the pressure conditions based on the Al₂O₃ content in sodic amphibole shows that this deformational stage was accompanied by a decrease in pressure from ca. 700 to ca. 400 MPa. This, together with our dating results, strongly suggests μ 10 km late Cretaceous exhumation of the Shangla blueschists. The exhumation may have been associated with the increase

of arc parallel displacement rate due to changes of arc obliquity. This led to thinning caused by arc parallel extension and to exhumation of the Shangla blueschists. A lack of strong Eocene metamorphic overprint implies that after the peak metamorphism, blueschists were accreted to the Kohistan arc, which helped to prevent burial and metamorphism during continental collision. The final emplacement of the Shangla blueschists most likely occurred during the India-Kohistan arc collision and was accompanied by the weak, locally developed greenschist facies overprint.

Keywords: $^{39}\text{Ar}/^{40}\text{Ar}$ dating, Rb–Sr dating, blueschists, collision tectonics, exhumation, Himalaya, Indus Suture.

Add/3 Anczkiewicz, R., Oberli, F., Burg, J.P., Villa, I.M., Gunther, D. & Meier, M. 2001. Timing of normal faulting along the Indus Suture in Pakistan Himalaya and a case of major $^{231}\text{Pa}/^{235}\text{U}$ initial disequilibrium in zircon. *Earth and Planetary Science Letters*, 191, 101 – 114. We report age data by TIMS $\text{U}^\wedge\text{Pb}$, LA-ICP-MS and $^{39}\text{Ar}/^{40}\text{Ar}$ techniques for main magmatic events in the Lower Swat region of Pakistan, in order to constrain the tectonic evolution of the northwestern Himalaya. The pre-Himalayan history of the Indian continent is documented by single-zircon $\text{U}^\wedge\text{Pb}$ results from the peraluminous Choga granite gneiss, which yielded a 468 ± 5 Ma lower concordia intercept interpreted to approximate the time of magmatic emplacement. The presence of a well-defined 870 ± 7 Ma inherited component (upper intercept) suggests a plutonic or volcanic protolith residing at unexposed levels of the Indian crust. Zircon data for the Swat granite gneiss from the northern part of the Loe Sar dome give an emplacement age of $267 \pm 6/33$ Ma, which is at variance with earlier correlations favoring an early Paleozoic origin. Subsequent to metamorphic overprint by the Himalayan orogeny, the Swat granite was intruded by late kinematic alkali-granite dykes. Single zircons from one of these dykes show reproducible $^{206}\text{Pb}/^{238}\text{U}$ data giving a precise mean age of 29.26 ± 0.12 Ma, whereas the $^{207}\text{Pb}/^{235}\text{U}$ ages scatter between 34 and 81 Ma, pointing to huge and variable enrichment in ^{207}Pb . The unsupported ^{207}Pb can be explained by incorporation of ^{231}Pa , an intermediate long-lived daughter nuclide in the ^{235}U decay chain, in excess of the secular equilibrium ratio. LA-ICP-MS measurements confirm the presence of unsupported ^{207}Pb , but do not show any correlation between the latter and other selected trace element concentrations in these zircons. A concordant $\text{Ar}^\wedge\text{Ar}$ muscovite age of 28.4 ± 1.1 Ma obtained for the same dyke postdates regional mica 'cooling' ages and indicates a lack of younger regional events capable of resetting the $\text{K}^\wedge\text{Ar}$ system in muscovite. Because the dyke is pre- to synkinematic relative to normal faulting and related north-vergent folds, its emplacement age provides a maximum age for this event or reflects already ongoing local extension. A lower limit of 15 Ma has previously been established by apatite fission track analysis. The 29 ± 15 Ma age bracket for normal faulting is coeval with extension along the South Tibetan Detachment System (STDS) on the north side of the High Himalaya. This suggests that the Indus Suture in Pakistan has acted as a western continuation of the STDS and that related faulting was roughly contemporaneous over most of the Himalaya. **Keywords:** Himalayas; Indus-Yarlung Zangbo suture zone; extension; geochronology; uranium disequilibrium; $\text{U}^\wedge\text{Pb}$; $\text{Ar}-^{39}\text{Ar}/^{40}\text{Ar}$; Pakistan.

Add/4 Butler, R.W.H., Casey, M., Loyd, G.E., Bond, C.E., McDade, P., Shipton, Z. & Jones, R., 2002. Vertical stretching and crustal thickening at Nanga Parbat, Pakistan Himalaya. a model for distributed continental deformation during mountain building. *Tectonics*, 21(4), 9-17. The localization of strain in the continental crust during compressional tectonics is examined using the active structures at the Nanga Parbat massif, an exhumed tract of Indian continental crust in the Pakistan Himalaya. This large-scale (~40 km wavelength) structure is considered to involve the whole crust. Thrusting at the modern surface places gneisses of the Indian continental crust onto Holocene deposits. At the Raikhot transect, the thrust zone carries a relatively narrow (2 km wide) shear zone within which minor structures are asymmetric and the deformation apparently noncoaxial. However, modeling of foliation and augen preferred orientation/ellipticity suggests that the bulk deformation is a combination of relatively small simple shear strains ($\gamma = 1$) with larger stretching strains. Heterogeneous stretching within the shear zone was accommodated by localized shearing on metabasic layers so that strain is partitioned. Outside this shear zone on the transect there is penetrative deformation throughout the Nanga Parbat massif. This broadly distributed deformation shows no asymmetry or evidence of rotation. Rather this deformation is better described as near pure-shear subvertical stretching. Augen ellipticities suggest subvertical stretches of greater than 200%. Consideration of plausible changes in crustal thickness during the amplification of the Nanga Parbat structure suggests the magnitude of vertical stretch decays with depth. Presumably these strains in the deep crust are more distributed but weaker than in the exposed middle crustal sections, assuming conservation of horizontal shortening displacement with depth. These studies suggest that penetrative vertical stretching through dominantly pure shear deformation is an effective mechanism for thickening the continental crust and that models which assume that simple shear zones penetrate the whole crust need not be of ubiquitous applicability.

Key words: Crustal thickening, deformation, Nanga Parbat.

Add/5 Clift, P.D., Hannigan, R., Blusztajn, J. & Draut, A.E. 2002. Geochemical evolution of the Dras–Kohistan Arc during collision with Eurasia: Evidence from the Ladakh Himalaya, India. *The Island Arc*, 11, 255–273

The Dras Volcanic Formation of the Ladakh Himalaya, India, represents the eastern, upper crustal equivalent of the lower crustal gabbros and mantle peridotites of the Kohistan Arc exposed in Pakistan. Together these form a Cretaceous intraoceanic arc now located within the Indus Suture zone between India and Eurasia. During the Late Cretaceous, the Dras–Kohistan Arc, which was located above a north-dipping subduction zone, collided with the south-facing active margin of Eurasia, resulting in a switch from oceanic to continental arc volcanism. In the present study we analyzed samples from the pre-collisional Dras 1 Volcanic Formation and the postcollisional Kardung Volcanic Formation for a suite of trace elements and Nd isotopes. The Kardung Volcanic Formation shows more pronounced light rare earth element enrichment, higher Th/La and lower end values compared with the Dras Volcanic Formation. These differences are consistent with an increase in the reworking of the continental crust by sediment subduction through the arc after collision. As little as 20% of the Nd in the Dras 1 Volcanic Formation might be provided by sources such as the Karakoram, while approximately 45% of the Nd in the Kardung Volcanic Formation is from this source. However, even before collision, the Dras–Kohistan Arc shows geochemical evidence for more continental sediment contamination than is seen in modern western Pacific arcs, implying its relative proximity to the Eurasian landmass. Comparison of the lava chemistry in the Dras–Kohistan Arc with that in the forearc turbidites suggests that these sediments are partially postcollisional, Jurutze Formation and not all pre-collisional Nindam Formation. Thus, the Dras–Eurasia collision can be dated as Turonian–Santonian (83.5–93.5 Ma), older than it was previously considered to be, but consistent with radiometric ages from Kohistan.

Key words: collision, Himalaya, isotopes, Kohistan.

Add/6 Fraser, J.E., Searle, M.P., Parrish, R.R. & Noble, S.R., 2001. Chronology of deformation, metamorphism and magmatism in southern Karakoram Mountains. *Geological Society of America Bulletin*, 113, 1443–1455.

U–Pb dating of metamorphic and igneous rocks from the Hunza Valley and Baltoro regions of the Karakoram Mountains in northern Pakistan addresses the thermal and magmatic evolution of the thickened Asian plate crust before, during, and after the collision of the Kohistan arc and the Indian plate. Crustal thickening and high-temperature, sillimanite-grade metamorphism in the southern Karakoram Mountains followed the collision and accretion of the Kohistan arc during the Late Cretaceous. U–Pb ages of metamorphic monazites from sillimanite gneisses in the Hunza Valley are 63.3 ± 0.4 Ma, ca. 50–52 Ma, and 44.0 ± 2.0 Ma, and monazites from a kyanite-grade schist from the Baltoro region are 28.0 ± 0.5 Ma. Metamorphic monazites from a highly graphitic garnet + staurolite schist from the Hunza Valley yield a crystallization age of 16.0 ± 1.0 Ma. Sillimanite gneisses from the Dassu dome have magmatic zircons of 1855 ± 11 Ma, reflecting a Proterozoic continental crustal source, and metamorphic monazites of 5.4 ± 0.2 Ma. Magmatism was also sporadic; early granodiorite, monzogranite, and leucogranite dikes yield zircon, monazite, and uraninite ages of 50–52 Ma and 35.0 ± 1.0 Ma. Widespread lower crustal melting during the latest Oligocene–early Miocene culminated with emplacement of the Baltoro Plutonic Unit in the Karakoram batholith that cuts deformation fabrics in the high-grade gneisses to the south. The youngest magmatic phase dated is the 9.3 ± 0.2 Ma Sumayar leucogranite pluton. On the basis of detailed structural field studies combined with U–Pb geochronology, sillimanite-grade metamorphism was either a protracted event lasting as long as 20 m.y. (64–44 Ma) or peaked at different times within the lower crust following collision of first, the Kohistan arc, and later, the Indian plate. We also present evidence for southward propagation of peak metamorphism and postmetamorphic thrusting and folding of isograds within the past 5 m.y. Detailed geochronology shows that deformation, metamorphism, and magmatism in the middle and lower crust of the south Asian margin has been occurring within the Karakoram metamorphic complex for more than 60 m.y. Similar processes may also have affected the unplumbed depths of the south Tibetan crust.

Add/7 Heuberger, S., Burg, J.P., Dawood, H. & Hussain, S. 2001. Mapping on the North-Kohistan Suture Upper Shishi Valley, Chitral, NW Pakistan. 16th HKT in Austria. *J. Asian Earth Sciences*, 19 (3A).

The North-Kohistan Suture separates the Kohistan Paleo-Island Arc Complex from the Karakoram Plate. We report results from field work carried out in 1999 and 2000 in Chitral (Northwest Pakistan), more precisely in the Shishi Valley and in the region around Drosh. Several sections across the suture in the uppermost Shishi Valley show that the so-called *mélange* is an imbricate zone in which slices with well-defined lithologies can be recognised.

The Karakoram Plate consists of gabbros and diorites (Karakoram or Transhimalaya Batholith), of shelf type sediments like fossiliferous limestones (Aptian-Cenomanian age), shales, volcano-lithic conglomerates and metavolcanics, and of serpentinites and talcschists derived mostly from harzburgites.

The Kohistan Paleo-Island Arc Complex consists of sheared gabbros and diorites (Kohistan Pluton), of volcanosedimentary greenstones, calc-alkaline andesites succeeding to andesite lavas, tuffs and agglomerates, and of red shales and sandstones (deep water turbidites). The imbricate lithologies of the so-called *mélange* mostly belong to the Karakoram Plate. The present-day imbrication is due to a series of brittle sinistral faults that have faulted away the original, thrust-dominated imbrication of the suture zone.

Add/8 Hildebrand, P.R., Noble, S.R., Searle, M.P., Waters, D.J. & Parrish, R.R. 2001. Old origin for an active mountain range: Geology and geochronology of the eastern Hindu Kush, Pakistan. *GSA Bulletin*, 113(5), 625–639, 10 figures; 1 table.

Prior to accretion of the Kohistan island arc during the Late Cretaceous and final suturing of India with Asia at ca. 50 Ma, the Hindu Kush mountains along the border of Afghanistan and northwest Pakistan were situated on the active southern margin of Asia. Geology and geochronology of the eastern Hindu Kush range in Pakistan demonstrate that localized crustal melting and leucogranite intrusion took place in the Gharam Chasma area at ca. 24 Ma. More regionally developed and widespread deformation, metamorphism, and magmatism took place before collision between both India and the Kohistan island arc with Asia. Ca. 195 Ma U-Pb monazite ages on a deformed leucogranite dike from the upper Lutkho valley indicate an Early Jurassic phase of crustal melting. U-Pb monazite ages of 135–126 Ma on a staurolite schist from near Gharam Chasma are interpreted as a minimum age for staurolite-grade metamorphism. Within the Tirich Mir fault zone, pegmatite dikes crosscut the staurolite schists. U-Pb dating of uraninites from one of these pegmatite dikes reveals an age of 114 ± 62 Ma. Monazites from the same rock give ages of 125–121 Ma, possibly due to inheritance of older cores. These Jurassic– Early Cretaceous constraints on metamorphism and magmatism relate to subduction and accretion processes, perhaps including the suturing of the Karakoram and Hindu Kush terranes along the Tirich Mir fault. In general, high-temperature, low-pressure metamorphism and subduction- related granitoid magmatism in the eastern Hindu Kush suggest a high thermal gradient in an active-margin setting from Early Jurassic to Cretaceous time. Keywords: active margin, collision, geochronology, Hindu Kush, metamorphism, monazite.

Add/9 Houston, C.S., 1939. The American Karakoram Expedition To K2, 1938. *The alpine Journal*, 51, 54-68.

The author describes his visit to the Karakoram during an American expedition to the area. This travelogue does not have an abstract. The first few pages are reproduced here for ready reference.

For a hundred miles parallel to the great Himalayan backbone along its north-western end runs a minor range, the Karakoram. This small satellite of the main watershed boasts some of the world's most beautiful and least known peaks. Mt. Godwin Austen, called K2, 28,250 ft. high, is the highest of these and is now established as second only to Everest in altitude.

All about it cluster great peaks such as Broad Peak, Gasherbrum, Masherbrum, Bride Peak, Mustagh Tower. Truly the little travelled Karakoram is a climbers' paradise. In the 1860's Colonel Godwin Austen of the Survey of India entered the Karakoram and explored the Baltoro Glacier among others, and was probably the first to see K2 from nearby. In his honour the peak now bears his name. Sir Francis Younghusband, at the end of his great trek across Asia, crossed into India not thirty miles from K2 • Martin Conway and Dr. and Mrs. Bullock Workman also made extensive studies of the glaciers of the Karakoram and its peaks. In 1902 Wessely, Guillaumod, Eckenstein and Pfannl made an abortive attempt to climb K2 via the N.E. ridge, the first attempt ever made on the mountain, but their gallant effort was cut short by illness. In 1909 the Duke of the Abruzzi, one of the great expedition leaders of all time, led a huge party up the Baltoro Glacier to camp beneath K2. In the course of a forty-day campaign he reached 22,800 ft. on Savoia Pass where begins the steep and rocky W. ridge. He then went 20 miles eastward to Windy Gap from which he examined the E. and N.E. aspects of the mountain.

Finally he made a brief but determined attempt on the S. ridge which is now called Abruzzi Ridge. On this he reached about 21,000 ft., where he was forced to turn back owing to limited time and continuous difficulties. In his opinion the W. ridge seemed to be the route of choice. The map of the Baltoro Glacier, and the famous photographs taken by Vittorio Sella and not yet surpassed, form a great contribution to the records of exploration.

Twenty years later the Duke of Spoleto with another large expedition continued the geographical and geological survey of the district, but did not touch K2. Half a dozen other parties have seen the mountain from various angles but there have been no other assaults on its summit. It has come to be recognized as an outstanding problem for the mountaineer and a challenge to the explorer. After two years of effort the American Alpine Club obtained permission from the Government of Kashmir to enter Baltistan and accept this challenge. In October 1937 plans for the first American Alpine Club expedition were begun. Owing to the formidable nature of the mountain, to the obstacles encountered by our illustrious predecessors, and to our own convictions it was definitely planned that the first expedition should be one of reconnaissance primarily. We were to make careful study of the three great routes on the mountain and decide which of these was the most favourable for an attack. Once this survey was completed we were to try to go as high as possible on the route chosen. Only in our secret thoughts did we expect to do much more than a thorough preliminary study. The nucleus of the party was soon formed and about it gathered other climbers. From many candidates a small team at last emerged: Robert H. Bates of Philadelphia, veteran of many Alaskan climbs; Richard L. Burdsall of Port Chester, New York, who was one of the conquerors of Minya Konka; William P. House of Concord, New Hampshire, one of the two who reached the summit of Mt. Waddington; Paul K. Petzoldt of Jackson Hole, Wyoming, with many fine climbs in the Tetons to his credit; and myself. To our great good fortune the Government of India gave permission for Captain N. R. Streatfeild, M.C., of the Bengal Mountain Artillery, to accompany us as liaison officer.

Even after consulting all available literature and many authorities we could find no unanimous opinion about weather in the Karakoram. Some said that the monsoon began in June, others said July, while still others said that the monsoon did not reach K2 May and June, June and July, September and October, all were advocated as the best two months for climbing in the Karakoram. In despair we decided to take the two months most convenient for us: June and July.

Add/10 Karim, A. & Veizer, J., 1999. Weathering processes in the Indus River Basin: implications from riverine carbon, sulfur, oxygen, and strontium isotopes. *Chemical Geology*, 170(1–4), 153–177.

This study deals with the major ions and isotope systematics for C, O, S, and Sr in the Indus River Basin (IRB). Major ion chemistry of the Indus, and most of its headwater tributaries, follow the order $\text{Ca}^{2+} > \text{Mg}^{2+} > (\text{Na}^+ + \text{K}^+)$ and $\text{HCO}_3^- > (\text{SO}_4^{2-} + \text{Cl}^-) > \text{Si}$. In the lowland tributaries and in some of the Punjab rivers, however, $(\text{Na}^+ + \text{K}^+)$ and $(\text{SO}_4^{2-} + \text{Cl}^-)$ predominate. Cyclic salts, important locally for Na^+ in dilute headwater tributaries, constitute about 5% of the annual solutes transported by the Indus. Weathering of two lithologies, sedimentary carbonates and crystalline rocks, controls the dissolved inorganic carbon (DIC) concentrations and its carbon isotope systematics throughout the Indus, but turbulent flow and lower temperatures in the headwaters, and storage in reservoirs in the middle and lower Indus promote some equilibration with atmospheric carbon dioxide. Combined evidence from sulfur and oxygen isotopic composition of sulfates refutes the proposition that dissolution of these minerals plays a significant role in the IRB hydrochemistry and suggests that any dissolved sulfates were derived by oxidation of sulfide minerals.

In the upper Indus, silicate weathering contributes as much as 75% (or even higher in some tributaries) of the total Na^+ and K^+ , declining to less than 40% as the Indus exits the orogen. In contrast, about two-thirds of Ca^{2+} and Mg^{2+} in the upper Indus (over 70% in some tributaries) and three-fourth in the lower Indus, are derived from sedimentary carbonates. The $^{87}\text{Sr}/^{86}\text{Sr}$ ratios tend to rise with increasing proportions of silicate derived cations in the headwater tributaries and in the upper and middle Indus, but are out of phase or reversed in the lower Indus. Finally, close to the river mouth, the discharge weighted average contribution of silicate derived $\text{Ca}^{2+} + \text{Mg}^{2+}$ and silicate derived $\text{Na}^+ + \text{K}^+$ are, respectively, about one-fourth and two-thirds of their total concentrations.

Is erosion important to the structural and petrological evolution of mountain belts? The nature of active metamorphic massifs co-located with deep gorges in the syntaxes at each end of the Himalayan range, together with the magnitude of erosional fluxes that occur in these regions, leads us to concur with suggestions that erosion plays an integral role in collisional dynamics. At multiple scales, erosion exerts an influence on a par with such fundamental phenomena as crustal thickening and extensional collapse. Erosion can mediate the development and distribution of both deformation and metamorphic facies, accommodate crustal convergence, and locally instigate high-grade metamorphism and melting.

Add/20 Zielinger, G, Arbaret, L., Burg, J.P., Chaudhry, N. Dawood, H. & Hussain, S., 1998. Structures in the lower units of the Kohistan arc (NW Pakistan): preliminary results. Geological Bulletin, University of Peshawar 31, Abstract Volume, 13th Himalayan-Karakoram-Tibet International Workshop, 224-227.

In NW Pakistan, the Kohistan paleo-arc, which was developed as plate an island arc above the northward subduction zone of the Tethyan Ocean during the Mesozoic, separates the Indian from the Asian plates. The southern boundary of the Kohistan arc is the so called Main Mantle Thrust (MMT), a crustal scale, northward dipping thrust on which the southern parts of the Kohistan are have been thrust over India.

Preliminary results of detailed mapping carried out in the uppermost Indian Plate (at Duber Bazar,) and the low levels of the Kohistan paleo-arc (from Jijal to Kiru) has covered the following lithologies:

Indian units: Granodiorite and strongly foliated gneisses. SW of MMT the gneisses are folded parallel to the SW trending stretching lineation. Kinematic determination shows a dominant southwestward sense of shear.

Kohistan units: The lowest levels of the Kohistan paleo-arc are dominated by dunites, pyroxenites and peridotites. Dikes of greenish chromite-clinopyroxenites cut this ultramafic sequence. Upwards, meta-gabbros (age 101 ± 5 Ma., R. Anczkiewicz, oral com.) with high magmatic garnet content complement the so called Jijal Complex. Ca. 700 m SW of Patan, anastomosing shear zones appear in these garnet rich rocks. The density of the anastomosing shear deformation increases northward in this ca. 3 km wide zone, up to 2 km NE of Patan. This shear zone is described in more details in a companion poster. To the NE of this anastomosing shear zones, rocks are variable in composition, but mainly comprise of gabbros, hornblendite gabbros, diorites, norites, amphibolites and smaller bodies of nearly pure hornblendite (Kamila Belt). Pegmatites intruded this sequence during and after ductile deformation and correspond to a late magmatic event.

In this poster we present structural data on the anastomosed shear zone. The anastomosed shear zone, developed during finite magmatic stage, shows all deformation facies from undeformed protolith to ultra-mylonite (for details: The sense of shear on the dispersed, but in average flat to NE dipping shear zones shows dominantly SW directed relative movement of the hanging wall and minor NE directed shear. To the NE of these zone of anastomosing pattern, other shear zones form parallel W-E striking units of amphibolite facies (age 83 ± 1 Ma.). These regular shear zones, containing porphyroclastic garnet, reach a thickness of up to 20m. Lineations strike NE-SW. The foliation of the shear zones dips more regularly to the NNE and the relation between normal and reverse shearing is balanced. The difference in the features and age (ca. 18 Ma.) between the anastomosed shear zone and the amphibolitic shear zone let us to separate the Kamila shear zone s.s., to the NE, from the Patan ductile shear zone, which is the anastomosed system described here and in the companion poster.

The region underwent late, pervasive faulting. Striations record essentially strike-slip and normal faulting. Results of principal stress calculation show three different stress fields: a poorly recorded one has a SW-NE maximum compressive principal stress (σ_1), a second one has a NW-SE σ_1 , dominantly identified by strike-slip movements. Preliminary analysis of superimposed striations indicates the SW-NE (σ_1) as the older one. The youngest, best represented stress field shows a SW-NE minimum principal stress and steep cycle, responsible for normal faulting. The NE dipping Patan-fault is a prominent fault-structure which cuts the anastomosed shear zones. Minor offsets in lithology, recent seismic activity, rotated blocks (indicated by the change of foliation attitude from mainly W-E to NNE-SSW, south of Patan-fault) and the smooth topography in the widened Indus valley at Patan indicate a still active Patan-fault, but it seems to be a recent and regionally minor fault-contact. The Patan ductile shear zone must be separated from the Kamila shear zones. Further work on these structures will give more details about the evolution of the "Patan shear zone" and the relationship with the Kamila shear zone.

Key words: Collision, Subduction, Structure, Southern Kohistan arc.

Add/21 Zielinger, G., Arbaret, L., Burg, J.P., Chaudhry, N., Dawood, H. & Hussain, S., 1999. How is the petrography affected by shear zones in the Kohistan complex, N Pakistan? Terra Nostra 99, Abstract Volume, 14th Himalaya-Karakoram-Tibet Workshop, Kloster Ettal, Germany, 187-188.

In NW Pakistan the Kohistan complex separates the Indian and Asian plates. It was formed as an Island Arc during Mesozoic times (Bard, 1983; Coward et al., 1986). Accretion to Asia and subsequent thrusting over the northern margin of the Indian plate along the northward dipping Indus Suture (also called Main Mantle Thrust = MMT) (Tahirkheli et al., 1979) constitute the collisional history (Coward et al., 1987). Earlier history involves arc related deformation like splitting the arc in a volcanic and remnant arc (Burg et al., 1998) and SW-thrusting expressed by

anastomosing shear zones in the southern, i.e. lower part of the arc probably imposed by subduction of the Tethys oceanic crust.

Our area of interest is comprised of two lithologies: The granulitic gabbro forms the upper part of the Jijal complex and is described as a calc-alkaline magma emplaced during the arc activity (Jan and Howie, 1981). The granulitic gabbro is intrusive in, and intruded by Hornblendites. P-T conditions point to granulite facies metamorphism ($T > 750^{\circ}\text{C}$ and $P > 1.8$ GPa, Ringuelet et al., 1998) and Sm-Nd cooling ages are 91 Ma and 96 Ma (Yamamoto and Nakamura, 1996; Anczkiewicz and Vance, 1997).

The Sarangar gabbro (NE of Patan) crystallised at 800°C and 0.8-1.1 GPa as deduced from preserved plagioclase-clinopyroxene assemblages (Yoshino et al., 1998). Ages are not available but structural relationship indicates that the Sarangar gabbro is younger and intrusive into the granulitic gabbro (see companion abstract Arbaret et al., this conference). Regional amphibolite facies metamorphism affected these rocks and ended probably 83 Ma ago (Ar-Ar age of amphibole, Treloar et al., 1990). All these sites show remarkable strain localisation and provide sections from undeformed, weakly deformed with well preserved magmatic fabric, to mylonitic high shear strain zones within tens of centimetres. Bard (1983) and Treloar et al. (1990) estimate the metamorphic conditions for the shear zones in the Sarangar gabbro at $550\text{--}650^{\circ}\text{C}$ and 0.9-1.0 GPa.

Many petrographical and geochemical studies on these rocks have been published and are partly cited above. Unfortunately they do not describe in details the relationship between petrography and deformation. Our particular aim is to obtain a better understanding of the interaction of petrography and ductile deformation. Therefore petrographic analysis across anastomosing shear zones was carried out at these distinct sites, in both the granulitic and Sarangar gabbros.

The composition in the undeformed rock of the granulitic gabbro is plagioclase, pyroxene, garnet, amphibole, quartz and rutile. The mid to fine-grained heteroblastic rock shows a granoblastic texture. The pyroxene is hypidioblastic with lobate to symplectitic contacts to plagioclase. The intensity of the symplectitic feature is getting stronger closer to the shear zone. The garnets are poikiloblastic intergrown with plagioclase, quartz and amphibole. At the scale of hand-specimen a magmatic foliation is visible but there is no evidence, even under the microscope, for deformation structures. The magmatic foliation is bent close to the shear zone into the well-defined mylonitic foliation within the shear zone. Beside a strong decrease in grain size, the decrease in amount of pyroxene and the increase of amphibole and quartz are the most striking phenomenon. The garnet is porphyroclastic in the very fine-grained matrix ($\sim 0.3\text{ mm}$), partly rotated and fractured with new grown amphibole inside these fractures. Recrystallised quartz in the pressure shadows of garnets as well as the amphibole crystals oriented parallel to the foliation point to a higher shear strain. The change in the mineral assemblage points to a sharp increase of hydration from the undeformed to the mylonitic part of the garnet granulite.

Dominant composition in the Sarangar gabbro is amphibole (mainly hornblende), pyroxene, plagioclase, epidote and quartz. In a 13 cm long section from the undeformed gabbro to the centre of one reference shear zone the main changes are as follow:

The hypidioblastic magmatic pyroxene is successively replaced by metamorphic pyroxene, amphibole and quartz. Close to the shear zone the metamorphic pyroxene is idioblastic whereas further away it rims the magmatic pyroxene. This first rim shows symplectitic intergrowth with the second rim comprised of greenish amphibole. In the shear zone, no magmatic pyroxene was observed. The plagioclase shows also symplectitic structures within the vicinity of the shear zone. The amphiboles underline the fabric in the shear zone and are cut by small quartz veins. Poikiloblastic garnet occurs infrequently. The macroscopic porphyroclasts ($\sim 2\text{ mm}$) are plagioclase, quartz and pyroxene. Hydration towards the shear zone is remarkable.

Amphibolitic facies developed new minerals preferably in the shear zones and progressively (in the range of a few centimetres) into the undeformed gabbro. The hydration in the shear zone is strong and is propagating successively from the high shear strain zones to the nearly undeformed parts.

Our observation points to a high fluid flux in developing shear zones that were weak features (reduced grain size) with the hydration being concentrated in these thin zones. This process further reduced the hydrated rock strength in which in turn could be the site of increased fluid flow and subsequent amphibolitisation in the shear zone and their vicinity. The biggest amount of amphibolitised gabbro is therefore limited to the shear zones protecting the granulitic undeformed parts by channelling the fluid flux. The quantity of amphibolitised gabbro is small relatively to the undeformed gabbro.

SUBJECT INDEX

Aggregate /Alkali aggregates

Aggregate resources, R/79

Aggregate, S/76

Alkali aggregates, A/313, 408, C/78, 81, 82, 85, 98, 133, 134, 160, S/171, Z/12, 13

Indus aggregates, C/159, 161

Light weight aggregates, H/207, 208, 223, K/519, P/18

Alkaline rocks

Alkaline complex, B/69, 70, 72, 73, C/152, J/78, K/294, M/35

Alkaline granites, K/83, 88, 91

Alkaline Magmatism, L/87, M/36, M/119

Alkaline rocks, A/91-94, 599, 621, B/55, 60-62, 64, 67, 68, K/89, R/24, S/424, 425, 432

Alluvium/Alluvial

Alluvial deposits, A/348, D/126, 268, 269, N/51, R/146

Alluvial Fan, S/17

Alluvial sand, S/416

Alluvial, S/223

Gravel, C/85, 133, 134, H/223, Z/12, 13

Indus alluvium, G/154, T/6, 10

Building material/ Dimension stones/Cement/Concrete

Building material, A/639, C/78, D/241, 242, G/96, H/64, 90, 177, K/143, 236, M/210

Cement/Concrete, A/305, 317, 554, G/160, H/201, 203, 204, K/369, S/197, Z/12, 13

Export potential, H/177

Cement Raw material, H/201, 203, 204, S/231

Carbonates/ Carbonatite

Carbonates B/61, J/120, K/377, L/59, M/205-208, 292, 308, Q/63, R/7, 63, S/464

Carbonatite, A/166, 586, 599, B/342, 354, D/85, F/72, H/70, J/1, 2, 42, 72, 89, K/88, 89, 431, 432, 452, 468, 481, 482
M/7, 31, 114, 117-120, 122-124, 211, P/134, Q/37, 38, 41, 44, 45, 47, R/53, 132, S/272, S/424, T/145

Fenites, J/1, 72, M/211, 216-218

Chronology/Geochronology/Thermochronology

Ar/Ar dates, H/28, L/88

Chronology, B/276, 277, 286, 291, D/225, 238, 256, 257, F/152, E/22, 23, F/150, 164, 165, J/168, L/59, 84, 88, 112, M/69, 70, 158, P/34, 54, 59, 123, 129, S/14, 16, 303, 398, W/118, 119, 121

Dating, C/28, 29, G/94, K/482, 541, 543, M/225-227, 229, 231, N/12, O/12, P/ P/23, 24, S/93, 123, 125, 445-447, 513, T/179, V/29, Y/5, 6, W/93, 117, Z/65, 66, 68, 70, 86, 89

Fission-track ages, C/28, 29, 46, 47, F/152, J/164, P/129, Q/37, W/53, Z/67-69, 78, 85, 86

Geochronology, A/221, 456, 462, 465, B/25, 26, 34, 35, 133, 250, 261, C/54, 238, 239, D/86, 196, 212, G/89, 90, 91, 209, H/28, 92, J/61, L/75, N/12, O/12, 13, 14, 29, P/23, 24, S/93, 101, 102, 127, 133, 320, 445-449, T/127, 178, 182, 183, 184, 192, 193, V/31, Y/5, 6, 7, W/53, 70, 93, 117, Z/3, 65, 66, 68, 70, 80, 82-84, 86

Provenance, C/109, 110, 250, D/245, 246, F/19, K/56, Q/14

Thermochronology, G/92, K/541, 543

Clay/Clay Mineralogy

China clay, F/47, I/9, M/284, 295

Clay mineralogy, A/16, D/130, K/312, T/109, 111, 112

Clay, A/117, 180, 207, 242, 340, 345, 357, 604, B/59, F/36, 37, 174, H/51, 283, 289, I/1, J/29, 146, K/72, 289, 519, N/27-30, 40, P/18, Q/7, 10, 11, 26, 53, R/177, S/34-36, 312

Climatology

Atmospheric aerosol, T/129

Biodiversity, S/39

Channel pattern, A/19

Climate, A/646, B/129, 191, 256, C/9, D/122, F/138, H/75, 79, 137, J/142, K/239, L/102, M/224, O/39, T/133, Y/47, W/37, 83, 100

Environment, H/79, 122, 168, I/32, S/534-536, T/113, 115

Monsoon, F/117, M/145, Q/28

Paleoclimate, I/39, K/95, 96

Economic geology/mineral deposits/mineral exploration

Acid leaching, K/204

Alkali syenite, B/65, 66, S/427

Alum, D/38

Apatite, H/70

Barite, A/60, B/63, H/178, 182-185, 286, 288, K/163, S/10, Z/62

Base metal, A/208, H/52, K/155, 392, R/153, S/186, 193-195, 212-214, 221, 222, W/88

Bauxite, A/342, 578, 588, F/155, H/292, M/68

Beneficiation, B/180, H/237, I/9, K/136, 154, 326, 465

Bentonite, A/411, 416, B/212, C/86, F/34, P/5, S/253

Ceramic colors, F/31

Ceramic, F/32, 36, 37, H/51, S/247

Chromite, A/637, 638, B/211, C/164, J/73-75, 102, 117, 129, 130, 131, K/29, 41, 136, 416, M/172, 234, N/47, Q/70, R/200, S/26, 42, 43, 163, S/224, U/9

Chromite/Chrome spinel, A/4, 6, 167, 168, 171, 265, 266, 267, 271, 272, 280, 284, 294-296, 426, 482, 519, 522, 524, 520, 529, 531, 535, 609, 636-638, F/59

Copper, A/64, 121, 123, 142, 192, 250, 251, B/12, 13, 270, F/136, H/190, K/15, 16, 326, M/141, S/187, 189, 191, 192, 201, 217, 219, 348, T/69, 71, 72, 73, 74, 75, 75, 76, 77

Decorative stones, S/269, T/3

Economic geology, A/5, 106, 121, 141, 145, 357, 363, 410, 417, 420, 422, 481, 482, 492, 575, 578, 579, 588, 591, 598, 607, 608, 614, 617, 626, 644, 645, 663, 676, 678, B/10-13, 16, 17, 59, 63, 67, 68, 163, 170, 183, 348, 370, C/12, 206, 262, E/34-38, F/147, G/69, 98, 99, 139, 163, H/6, 70, 181, 254, J/133, K/22, 52, 72, 73, 124, 129, 381, 536, 236, M/21, 68, N/36, 38, 56-58, Q/45, R/34, 70, 76, 119, 177, S/47, 48, 159, 225, 357, T/7, 198, V/4, 6, W/88, Z/8, 62

Economic minerals, B/254, 255, D/78, H/115, K/22, 521-523, L/36, R/74, 136

Exploitation, H/151, S/159

Exploration, B/189, L/1, Z/31

Fireclay, A/342, F/40, H/276

Fluorspar, B/52

Galena, A/273

Geochemical exploration, K/29, 116, S/213, 557-560

Geochemical prospecting, A/173, H/243, K/114, 115

Glass industry, A/369, 409, 630, Glass sand, R/30

Glass raw material, R/28, 29

Glass, B/65, D/239, 240, F/29, 33, R/26, 27

Gold exploration, C/185, D/80, K/78, 108

Gold mineralization, K/187, 336, 418

Gold potential, K/116

Gold prospects, K/107, M/51

Gold, A/660, F/14, C/210, D/80, H/187, 188, K/111, 113, 362, 392, 417, N/26, R/42, S/212-214, 222, T/6, 7, 26

Graphite schist, R/56, 70

Graphite, A/299, 424, 591, E/37, 38, 44, 45, G/131, H/237, K/208, 307, 349, M/55, N/42, T/56, 57

Industrial mineralogy, B/65

Industrial Minerals, A/143, B/16, C/180, G/100, 194, H/284, 285, K/367, 466, R/138, T/3
 Industrial rocks, M/112, 113, P/5, Q/72, T/20
 Industries, A/553
 Iron Ore, A/412, 644, 645, 648, B/183, 201, 273, D/26, E/40, F/39, 42, 43, 48, 51, 54, 70, H/6, 8, 53, 54, K/193, 194, 328, 351, 521-523, M/99, 139, N/52, Q/22, R/58, S/159, 226, Y/30, 36, 37
 Kaolinite, A/578, F/30, 35, S/227
 Laterite, A/160, 427, F/155, L/32, S/516, 526, Y/29
 Lead/ Lead-Zinc, A/111, 192, 327, 397, 488, B/180, C/72, 95, 96, H/191, K/154, 155, 204, 381, 325, M/141, R/34, S/230, 415, T/4, 70
 Lead-antimony, B/368
 Lithium mineralization, B/351
 Lithochemical, S/560
 Magnesite, A/522, 532, 538, 539, 607, H/180, 195, 265, K/23, 24, 192, M/277, 294, V/6
 Manganese, G/55, H/260, 261, 266, K/120, N/52, Q/33, 35, S/365
 Marbles, A/106, 231, 299, 424, 639, 640, 649, C/97, 206, 208, B/86, 135, K/223, 277, 279, 539, L/111, M/24, 264, 265, O/19, P/61, R/63, S/27, 465
 Metallic mineralization, A/5, 600, 615, H/191, K/16
 Metallic minerals, R/56, S/190, S/335, 429, 526
 Metallogeny, A/261, G/56, 60, J/41, 133, K/56, 62, 390, S/388, 435-437, T/31
 Mine development, A/662
 Mineral deposits, A/60, 63, 202, 205, 210, 414, 415, 416, 418, 419, 429, 485, 505, 595, 604, 616, 618, 648, 663, B/8, 17, 51, 52, 155, 171, 182, 189, 190, E/34, 35, 37, F/160, H/53, 112, 179, 263, G/53, 55, 131, 133, 165, H/182, I/11, 13, J/145, 146, K/62, L/1, M/278, N/52, R/78, 104, 133, S/7, 256, 415
 Mineral development, F/25, W/41
 Mineral exploration, A/629, 661, 662, B/359, K/349, 368
 Mineral industry, H/23, 175, 270
 Mineral potential, J/41, M/32, O/18
 Mineral Resources, A/141, 142, 256, 257, 268, 269, 281, 413, 488, 553, 592, 597, 599, 643, B/156, 188, C/13-15, 212, D/43, 273, H/102, 151, 291, 292, F/69, 76, 80, 158, 159, G/52, 54, 57, 72, 73, 178, J/33, 169, K/52, 61, 148, 159, 160, 189, 267, 390, M/246, O/25, R/117, S/327, 340, 466, T/15, 29, 154
 Mineral survey, E/31, 32
 Minerals (Industrial), A/145, 630, 214-216, T/198
 Mining, R/170, 171, S/47-49, T/15, 146, 198
 Mn-deposits, S/203, 204
 Molybdenite, K/203
 Molybdenum mineralization, C/92
 Molybdenum, A/597, S/345
 Natural resources, R/82
 Ore minerals, A/82
 Ore processing, A/488, R/132
 Ore, A/121, 273, 362, H/195
 Phosphate beneficiation, M/114, N/31
 Phosphate deposits, G/135
 Phosphate, A/151, 166, 616, B/173-175, 177, 178, D/43, 280, H/71, 72, 150, 152, 179, 294, I/33, K/137, 138, 156, 240, 345, 453, 465, L/23, 26, M/114, 180,318, S/45-49, 371, 517, T/19, 24
 Phosphorite, A/190, 575, 594, 626, B/80, 171, 194, 195, G/133, 134, H/67, 68, 73, 181, 186, 243, 287, K/158, N/15, S/190
 Placer Minerals, A/209
 Platinum-group elements/PGE, A/535, 608, 613, H/91, K/38, 41, 44, 188, 413, L/116, M/234, P/4, 62
 Potash, A/356, 367, B/170, 182
 Precious metals, F/67, 68, K/108, 111, R/153, S/52, 206
 Pyrite, A/253, C/172, 207, F/49, K/113, S/426
 Refractories, A/618, C/180, T/21, 22
 Rock Salt, A/641, 642, D/50, S/540
 Salt deposits, D/63, 64, F/60, 73

Salt efflorescence, G/172
Salt Mines, A/356
Salt, B/316, W/22
Salt-tectonics, D/277, P/111
Sand, A/317, 369, C/81, 82, 133, 134, D/239, 240, F/29, 33, 41, 62, H/223, P/18, Z/12, 13
Scheelite, D/42, K/187, M/51, S/560, Z/8-10
Siderite, K/99
Silica sand, A/369, B/8, H/192, 193, N/58, R/26, S/419
Soapstone, A/420, 481
Soapstone, B/10, 11, C/12, I/13
Sphalerite, S/185, 187
Steel, F/52, 53, K/521, 522, Q/22, S/226
Syenite, B/72, E/40, J/1, 2, K/88, 431, 432, M/118, 211
Tungsten, S/345
Zinc, A/192

Energy/fuel resources

Basin analyses, A/150, W/52
Black shale, B/359, R/59
Coal, A/262, 601, 602, B/120, D/27, F/61, 79, 134, G/132, H/214, J/43, K/73, 129, 365, 366, 391, L/4, 5, M/164, 165, 220, P/133, Q/69, 71, 73, R/170, S/170, 180-182, 264, W/58, 59

Expedition, A/655, 656, D/1, 13, 100, 107, 108, 110, F/122, 123, 124, 128, 129, 130, G/23, H/110, L/42, M/85, 89, 105, 151, 219, 289, W/25, 148
Exploration, F/174, M/81, 219, W/25, 129
Hindukush expedition, D/231
Italian Expedition, A/46, 443, D/9, 10, 133-135, 146, 156, 195, B/126, C/5, 183, 263, D/3, 18, 101-106, 109, 131, 132, 144, 145, 151, 165, 192, 193, 194, 204, 207, 209, F/116, L/105, M/73, 82, 83, 88, 203, N/66, 67, O/28, P/48, S/78, 79, 438-440, 530-532, V/5
Italian Scientific Exploration, D/175, 186
K2 ascent, D/148
Mountaineering, C/196, V/7
Netherlads 1922 Expedition to Karakoram, R/160, W/149

Foreland basin/Siwaliks/Siwalik molasse

Fold belt, B/87, S/144
Foredeep, B/280, 288
Foreland basin, A/11, 12, 14, 559, K/174, 176, 176, 177, 178, 184, 185, L/91, 92, N/13, 14
Foreland basin, B/226, 283, 284
Foreland fold-and-thrust belt, D/274, 275
Genesis, A/527, F/58, S/193, 194, 195
Himalayan Foredeep, B/303
Himalayan foreland basin, B/281
Himalayan Red beds, Z/18, 19, 20, 25, 26, 27
Jalipur Mollase, C/79
Neogene molasse, S/250
Neogene metamorphism, W/116
Siwaliks, A/7, 11, 13, 14, 17, 18, 20, 22-29, 48, 50, 54, 200, 201, 337, 486, 545, 546, 590, 686, 687, 689, B/3-7, 19, 44-47, 100, 101, 105-112, 114-116, 132, 139-143, 184, 215, 234, 235, 243, 257, 258, 281, 283, 284, 288, 307, 308,

360, C/47, 49, 88, 132, 166-168, 186, 201, 203, 249, D/115, 116, 118, F/24, 143, 166, 167, G/50, J/20, 23, 24, 28, K/19, 79-81, 144, 168-173, 175, 179, 181-184, 186, 308, 320-322, 534, 537, L/94-101, M/41, 166, 191, 285, 293, N/12-14, 19, Q/53, R/77, 94, 110-112, 114, 185, R/93, 94, S/50, 54-56, 58, 60, 61, 63, 64, 66, 68, 70-73, 84, 87, 89, 228, 262, 265, 268, 361, 362, 363, W/7, 76, 77, 103, 104, 105, 106, 107
Tredian Formation, M/43

Gemstones,

Aquamarine, V/53

Corundum, A/501, J/100, 101, O/19, P/35

Emerald, A/493, 494, 527, 532, 534, B/231, 364, D/67, 238, F/15, G/200, 202, 203, 205, H/39, 46, 112, 255, 256, 257, 258, 262, J/44, 88, K/63, 65, 74-76, K/123, 190, 462, L/38, 49, P/142, Q/46, R/11-13, S/113, 118, 451, 452

Gems Exploration, H/259

Gemology, F/15, G/58, 205, 206, H/40, 46, 112, 116, J/3, K/74-76, 528-531, L/49, M/232, S/95, 113, 451, 452, 514

Gemstones, A/463, 479, 502, B/C/30, B/83-85, 91, 179, 214, 231, 353, 362, 364, F/55, 56, 57, 58, 63, 75, G/165, 200, 201, 202, 203, 204, H/62, 116, 255, 256, 257, 258, 259, J/44, 48, 56, 105, 106, 118, K/57-59, 63, 65, 67, 68, 148, 150, 462, 536, L/37, M/56, 57, 187, 209, 258, P/49, 61, 141, Q/46, R/11-13, S/256, 296, T/157, V/53, W/64, 67, 69, 108

Jewellery, B/214

Lazulith, H/40

Lepidolite, B/363

Pearls, A/479

Peridot, J/105, 106, K/40, K/40, 433-436, M/232

Precious stones, G/58, K/57-59, 67, 68

Ruby, A/355, 501, B/86, 91, 353, D/279, F/55, 56, 57, 58, 63, 75, G/200, 201, 203, J/100, 104, L/111, M/56, 57, P/35, 61

Topaz, A/495, 502, B/83-85, G/165, 204, 206, J/48, 56, K/150, P/49, S/514

Tourmaline, A/534, Z/10

Beryl, A/252, B/364, D/67, H/258, J/88, 98, 99, K/387, 528, R/12, 13, S/186, 296, V/4,

Jade, B/307, 308

Sapphire, F/75

Zircon, K/528

Geochemistry/chemistry,

Atomic Absorption, A/387

Chemistry, F/81, 137, H/11, 12, 27, 36, 53, J/73-75, 102, 116, 117, 130, 149, 151, K/191, M/35, Q/43, 47, R/27, S/188, 193-195, 344, 346, 423, 451, 452, W/29, 30, 83

Geochemistry, A/43, 44, 50, 57, 84, 151, 157, 167, 168, 171, 177-179, 184, 199, 219, 259, 260, 275, 288, 289, 370, 385, 386, 445, 521, 527, 536, 537, 539, 540, 564, 565, 570, 571, 579, 582, 584, 623-625, 628, 667, B/37, 45, 47, 71, 72, 80, 81, 91, 102, 140, 185, 218, 354, C/17, 88, 90, 91, 94, 102, 154, 157, 158, 195, 231, 243, D/32, 35, 36, 86, 238, 245, E/26, G/48, 87, 213, H/13, 19, 21, 37, 173, 186, 259, 266, I/7, 30, J/1, 29, 42, 50, 51, 58, 65, 67, 77, 81, 83, K/10, 20, 44, 94, 107, 108, 120, 163, 233, 283, 290, 291, 292, 293, 339-342, 353, 400, 403, 406, 407, 417, 422, 426, 434-437, 443, 513, L/2, 3, 75, 84, 111, M/18, 34, 36, 38, 99, 115, 117, 123, 124, 211, 218, 233, 290, N/26-28, P/11, 51, 52, 53, 54, 55, 57, 59, 118, Q/13, 48, 73, R/5, 9, 16, 24, 39, 40, 41, 44, 162, S/12, 26, 44, 52, 74, 81, 96, 97, 118, 126, 127, 133, 163, 165, 168, 183-185, 191, 192, 198, 199, 201, 203-205, 207-209, 211-213, 217-219, 222, 33, 240, 310, 316, 337, 338, 340, 341, 471, 478, 482, 498, 501, 545, 551, 557-559, T/65, 66, 67, 68, 69, 70, 71, 72, 73, 76, 77, 80, 86, 110, 113, 114, 115, 176, U/2, V/20, 46, W/55, 56, 57, 112, Z/1, 2, 4, 57, 61

Gravimetry, C/25, M/82, 84, 86, 87

Heavy metals, H/26, 29-31, N/28-30, S/28, 554

Hornblende, H/12, J/69, K/82, 86, W/55

Hydrothermal alteration, K/39

Hydrothermal Process, B/241, 345

Hydrothermal system, C/53, 232

Hydrothermal, C/57, 231, G/63, S/191, 192, 317, T/72

Isotopes, A/458, 461, 650, B/80, 127, 129, 209, D/85, 238, 257, E/13, G/63, 64, 94, H/173, I/34, 35, K/39, 291, 292, 293, 476, 478, M/115, 117, 229, 231, 285, P/10, 52, 53, 54, 123, 134, Q/26, 27, 29, 73, S/221, S/464, 465, 501, 512, 537, T/70, 72, 73, 76, 114, W/55, 56, 57, 91, 98, 99

Mineral chemistry, H/14, 32, L/72, R/54, S/341, Y/40, 41
Oxygen Isotopes, B/102, C/231, S/217
Trace elements, A/177, 180, 387, D/85, S/554, W/98

Geography

Remote sensing, A/433-435, 496, B/197- 200, 358, N/65, O/11, R/179, S/385, 428, T/107

Satellite imagery, H/107

Glaciers/ Glaciology

Ablation, H/132, K/304, S/91, Y/44, Z/90

Cambrian, B/30, 89

Fluctuation, G/174,

Glacial basins, C/188

Glacial deposits, D/119, 121, 122, M/128, T/118

Glacial history, D/123, 127, 268, R/154

Glacial landform, S/116

Glacial till, D/120, L/89

Glaciation, C/19, 209, D/120, 154, 222, 270, G/156, 193, H/74, 77, 89, 128, I/39, K/55, 101, L/27, 121, M/223, N/44, 62, 65, O/41, 46, 47, 48, 51, P/136, S/131, 397-399, T/119, 120

Glacier exploration, R/6

Glacier surge, F/95, P/91

Glaciers, A/105,657, A/9, 10, 652, 653, B/127, 147, 157, 236, 270, 299, C/1, 2, 4, 7, 8, 18, 25, 26, 62, 63, 187, 190, D/4- 6, 9, 11, 12, 14, 15, 17, 24, 94, 124, 136, 139, 155, 171, 199, 202, 205, 206, 215, 221, 222, 280, F/5, 77, 95, G/46, 140, 173, 174, 186, 197, H/76, 98, 119, 125, 127, 140, 141, 142, 155, 162, J/157, 159, 160, K/304, 305, 495-509, 511, 520, 549, 551, L/104, M/2, 104, 106-108, 137, 138, 144, 145, 179, 198-200, 286, 287, N/49, O/35, 36, P/89, 92, 93, P/127, R/6, 123, 161, 182, 201, S/90, 91, 108, 109, 115, 372-377, 380, 385, 386, 515, 545, T/195, U/6, 7, V/39, 41, 42, 44, W/17, 24, 28-31, 33, 61, 74, 122, 124-142, Y/1, 2, Z/90, 91, 92, 94

Glaciology, B/15, 198, 200, C/27, D/141, 204, 264, F/108, 113, 123, 125, 162, G/47, 49, 140, H/75, L/102, M/1, 101, 102, P/90, R/180, V/43, 45, Y/42, 43, 44, W/61

Ice age, D/221, H/89, K/510, 551

Ice dam, H/120

Ice front, H/121

Ice, H/129-131, H/129-131, P/93

Indus floods, M/103, 280

Meltwater runoff, C/187, F/113

Moraines, W/17

Precambrian glaciation, B/174
Snow accumulation, W/28, 29, 30
Snow line, G/197, K/550, W/122

Hazards/Natural Hazards

Asbestos deposits, J/148, 149
Asbestosis, H/23, J/149-151
Avalanches, F/100, S/90, 372, Y/2
Cracks, F/99, K/213
Debris accumulation, I/39
Debris flow, B/147, 263, W/62
Debris slide, K/215
Debris slopes deposits, B/262
Debris transport, S/115
Debris deposits, W/62
Disaster, D/46, H/168
Feasibility, I/16
Fibrosis, J/150
Flood, A/40, B/278, 320, C/198, F/4, H/127, 128, 168, S/428
Hazards, A/30, 31-33, 37, 40, 66, 430, C/60, G/137, H/47, 135, 136, J/70, K/213, 286, M/44, 266, S/382, Y/18, Z/11
Health hazard, D/33, H/25, S/28
Landslide hazard, C/176, D/247, L/31, R/35, 45, S/454
Landslides, A/30-34, 37, 172, 331, 555, B/121, F/101, 102, 103, 105, F/21, 22, H/84, 128, 140, I/10, J/70, K/149, 206, 207, 209, 212, 213, 244, 245, 255, 286, 459, M/2, 14, 44, 171, N/33, O/46, S/19-23, 162, 286-288, U/4, Z/11
Mass movement, A/30, 31, L/60, O/43, S/391
Mudflows, F/100
Natural Hazards, A/406, B/320, H/111, 126, K/151, O/45, S/19-24, 336
Silica industry, H/24
Silicosis, H/23
Slope failure, A/34, S/389
Snowfall, H/47
Asbestos, H/10, 25, J/151-154, Q/9, 10, 12
Slope Stability, A/406, C/176, F/97, 98, 106, H/252, I/10, 16, K/21, K/149, 161, 244, 245, M/39, 46, 47, 266, W/45

Igneous rocks/complexes

Acidic rocks, A/91, 583
Amphiboles, B/274, J/85, L/109, M/214, 215, T/178, W/56
Amphibolite belt, B/343, C/153, J/92, 115, K/353
Amphibolites, A/58, 59, 556, 563, 576, 577, B/43, 81, 355, C/97, 99, 144-146, H/15-17, 36, 37, 171, 238, 239, J/47, 50, 53, 57, 58, 66, 67, 101, K/17, 246, 265, 295, 324, 470, 486, L/38, 113, M/11, 12, R/31, 89, 143, S/75, 164, 199, 202, 210, 211, T/167, U/5, V/25, Y/3, 41
Andesite, H/32
Aplite, A/565, 567, 676-678
Basic dykes, D/31, M/34, 35, P/57, R/17
Basic rocks, A/91, J/83, 85, 97
Biotite, J/86, M/216
Calcalkaline magmatism, S/220
Chemical-mineralogical classification, D/91
Chloritoid-ilmenite rock, J/121
Chromian andradite, J/132
Cordierite, F/114
Cumulates, A/613
Deccan Traps, J/18
Diorite, A/610, 665, C/46, H/28, 86, 239, J/47, 50, K/199, R/5, 89, 139, 143, S/27, 199, 242, 310, 338, 563, U/5
Dolerite, A/278, K/20, 379, R/188, S/248, 339, S/293

Dunite, A/608, C/164, J/131, 132, S/43, 292, U/9
 Eclogites, G/176, L/72, 106, 108-110, O/1, 2, P/117, S/472, 475-477, 484, 490, 494, 496, 500-502, 509-511, 513, T/155, 174, V/28
 Epidotes, J/86
 Fluid inclusions, B/173, C/232, S/118, 500, T/73, 77, W/117, 118, 119
 Gabbro-norites, J/50, 54, K/472, M/228, 230
 Gabbros, J/92, R/89
 Garnet granulite, J/52, 68, 126, 127, 128
 Gneisses, B/251, 268, C/31, D/137, G/63, S/132, 133, 135, 138, 308, 314, 332, 359, W/12, 91
 Granite gneisses, A/221, G/64, H/20, J/39, K/343, 482, M/115, 156-158, 305, R/39, 41, 61, S/283, 284, Y/13
 Granite magmatism, H/146, K/2, L/65
 Granite, A/44, 94, 97, 100, 102-104, 132, 184, 372, 385, 386, 444, 542, 574, 598, 651, , B/55, 119, 202, 341, 345, 352, 364, C/31, 37, 39, 72, 97, 142, C/205, D/81, 93, 94, 95, 196, 199, 200, 203, 212, 224, 225, 243, F/23, 76, 80, 114, G/92, H/20, 86, 169, 198, I/4, 6, J/79, 147, K/10, 27, 132, 157, 223, 276, 287, 306, 412, 422, 431, 432, 456, L/37, 38, 39, 64, 67, 68, M/17, 70, 95, 98, 156, 157, 263, N/63, O/3, 13, 14, P/17, 23, 46, 94, R/1, 14, 25, 33, 38, 40, 55, 74, 144, 161, S/27, 32, 126, 135, 137, 138, 242, 293, 295, 304-308, 318-320, 322, 328, 331, 332, 337, 344, 346, 359, T/66, 67, 127, 156, U/2, V/2, Z/2, 3, 4, 70, 93, 95
 Granitic batholith, S/354
 Granitic complex, S/33
 Granitic plutons, D/86, 153, L/66, 80, U/2, Z/61
 Granitoid magmatism, C/242, 243
 Granitoids, A/570, C/40, 146, D/89, I/34, 35, K/98, 100, 532, S/350, V/46, Z/55, 56, 60
 Granodiorite, M/11, 33, Q/75, S/164
 Granulite, J/58, L/106, Q/40, R/ 190, T/172, W/109, Y/5-8, 41
 High pressure rocks, S/500, 502, 509-511
 Hornblende group, D/71
 Hornblende, A/610, K/470
 Hornblendites, B/78
 Igneous rocks, A/127, 128, 129, 130, 401, 597, C/92, H/95, I/36, K/372, S/27, 546, V/47, W/12, Y/3
 Igneous-sedimentary-metamorphic rocks, C/140, K/378, 379, Y/13
 Leucogranites, B/102, C/241, 245, H/144, S/93, 498, T/190, W/90, 91, 97, 98, Z/72, 73
 Mafic and intermediate rocks, C/99
 Mafic dykes, K/438
 Mafic granulites, C/195
 Mafic rocks. A/43
 Mafic sheets, T/172
 Mafic-ultramafic, A/613
 Magma, N/48, S/81, W/111
 Mansehra Granite, B/348
 Mantle, A/439, B/293, 294, K/5
 MCT, C/105, 117, 124, 126, 129, 137, 138, 155, H/172, S/355, 479, 481, 493
 Metagabbros, J/93
 Nepheline syenites, A/592, 596, C/94, K/191, 225, N/56, 57, R/28, 29
 Norite, A/610, J/47, S/242, 310, 338, 563
 Oceanic crust, K/545, 548, M/233
 Oceanic rocks, B/356, 357, H/172
 Oceanic tholeiites, C/153
 Ophiolite Melange, G/32, H/268
 Ophiolite, A/266, 270-272, 280, 282-287, 289, 519-521, 524, 525, 529, 530, 533-535, 537, 538, 540, 541, 598, 623-625, 647, 666, 667, 669, B/12, 94, 128, 130, 134, 239, 249, 355, C/35, G/111, 112, 139, H/260, 261, 268, J/73-75, 102, 117, 122, 130, K/65, 66, 126, 393, 395, 397, 400, 402, 403, 406, L/49, M/213, P/63, R/18, S/42, 204, 209, 246, Y/26
 Panjal Formation, B/172
 Panjal ophiolites, C/102
 Panjal volcanic, B/356, 357, C/130, 157, 158, D/66
 Pegmatoid, B/341, 345, D/71

Peraluminous granites, C/150
 Plutonic rocks, C/17, D/91, K/379, Q/75, S/460, Z/57
 Plutonism, D/87, 92
 Plutons, J/63, 64, L/80, S/99
 Pyroxene granulite, J/54, 59, 82
 Quartz diorites, J/55, J/77
 Serpentine-marble, C/246
 Serpentinite, A/170,523, G/96
 Serpentinite, D/250
 Serpentinization, C/91
 Sheeted dykes, K/403, 430
 Synkinematic intrusions, E/16
 Synkinematic plutonism, S/96
 Tonalite, J/77
 Ultrabasics, A/232, J/83
 Ultramafic complex, A/612, J/80, 87,
 Ultramafic rocks, A/4, 6, J/52, 57, 60, 63, 65, 84, 103, L/114, 116, R/143, 200, S/209, 310, 338,
 Ultramafics, A/227, 267, 292, 294, 295, 296, 520, 531, 533, 536, 540, 541, 615, 620, 666, 668, B/78, 211, 372, C/69,

Mapping

Atlas, G/61
Geological Map, A/62, 185, 341, 499, 503, 632, B/54, 166, 167, 338, D/161, H/5, 109, 209, 213, 224, 229, K/9, 25, 31, 121, 122, 128, 303, 348, 411, 414, L/19, M/131, R/116, 143, 179, S/5, 242, 308, 352
Mapping, A/39, 53, 71, 75, 108, 164, 195, 246, 324, 331, 343, 356, 370, 374, 408, 417, 453, 504, 505, 552, 664, 672, 675, 679, 685, B/265, 267, C/16, 68, 129, 140, 144, 146, 151, 176, 201, 203, D/77, 81, 82, 177, 218,232, 247, F/27, E/18, 149, G/3, 62, 75, 77, 85, 86, 115, 124139, 164, 162, H/90, 118, 197, 199, 202, 234, 240, 242, 248, 252, 253, 293, I/2, 8, 22, J/37, 96, 100, 119, 124, 139, 141, 152, K/21, 26, 54, 70, 71, 139, 230, 235, 259, 284, 300, 346, 350, 352, 357, 361, 374-376, 383, 384, 404, 408, 415, 485, 487, 514, L/12, 69, 73, 74, 77-79, 117-124, M/22, 25, 26, 30, 174, 184, 244, 247, 250, 260, 266, 271, 311, N/6, 7, 25, 37, P/46, 104, Q/34, 50, 55, 57, 61, R/4, 10, 32, 35, 36, 46, 86, 136, 137, 141, 142, S/234, 269, 280, 281, 357, 366, 418, 424, 432, 434, 518, 519, T/23, 53, 58, 105, 126, Y/11, 26, W/3, 6-10, 34, 35, 63, Z/42, 44
Maps, H/198, 206, 212, 225, 228, 267, 282, K/420, M/165, 167, 168, Q/60, S/283, 289, 293, 379, 527, V/10, W/15, Z/41, 43

Metamorphism/ Metamorphic rocks

Barrovian metamorphism, C/121
Blueschists, A/462, 551, B/24, 27, 98, D/176, 179, 210, 211, J/62, 68, K/447, M/37, S/313, 324, 341, 484
Calcite, M/18
Dolomite, A/213, 347, 564, 617, C/208, F/38, 74, K/192, M/18, R/27
Gneiss domes, A/439
Greenschists, J/68, W/57
Greenstones, E/25, K/447, P/63
High-P metamorphism, B/98, D/176, J/68, 94, 120, L/72, P/117, S/309

Isograds, B/252, 253
 Kyanite, S/300
 Low-grade metasediments, C/37, 39
 Metamorphic belts, V/34, 36
 Metamorphic evolution, F/163, L/108, W/86
 Metamorphic history, F/153
 Metamorphic rocks, A/86, 89, 90, 95, 97, 149, 182, 196, 279, 288, 392, 401, 458, 461, 462, 480, 512, 549, 597, 622, 667, B/347, C/57, 118, 239, D/259, H/81, J/66, K/8, 238, 256, 257, 454, S/27, 546
 Metamorphism, B/2, 27, 28, 96, 97, 104, 161, 242, 309, C/53, 92, 115, 145, 191, D/148, 249, 258, 260-262, F/137, 147, 148, 150, 164, G/6, 7, 110, 127, 175, 176, 181-183, 209, 165, H/143, 240, 250, J/46, 104, K/66, 95, 96, 231, 246, 259, 271, 273, 274, 424, 474, 475, 477, 478, 480, 482, 532, L/54, 66, 71, 84, 86, 88, 112, 113, M/8, 69, 177, 190, 254, 255, 257, N/3, O/1, P/8, P/11, 60, 132, 63, 114, 115, 116, Q/39, 42, 43, R/59, 163, 187-194, S/94, 111, 123, 134, 135, 137, 138, 185, 198, 202, 244, 290, 293, 295, 298-300, 305, 308, 324, 343, 357, 443-449, 460, 478, 490, T/47, 52, 56, 57, 145, 155, 158, 159, 160, 162, 163, 165-168, 171-173, 177, 178, 180, 181, 182, 183, 184, 188, 189, 190, 191, 194, V/26, 27, 28, W/55, 56, 94, 97, 101, 110, 111, 115, 121, Z/8, 45, 46, 75, 76, 77, 79
 Metasedimentary rocks, P/123, 139, R/65, T/18, 37
 Metasediments, B/252, 253, G/20, H/220, J/39, K/27, 105, 106, 197, 198, 377, 467, 486, 532, Q/5, R/25, 192, S/185, 313, Z/60
 Metasomatism, D/279, L/38, Q/5, 6, R/38, S/347, Z/10
 Metavolcanics, G/20, S/198, 200, 201, 215, 217, 219, 243
 Misri Banda Quartzite, B/138, S/273-275
 Mylonite, H/170, O/12
 P/T boundary, G/22
 Phase chemistry, J/62
 P-T estimates, B/252, 253, K/257
 P-T-t paths, C/55, 56, G/209, P/114
 Quartz-Ilmenite/Kyanite Veins, A/581, T/5
 Quartzite, A/618, S/417
 Retrograde metamorphism, J/132
 Rodingite, Q/5, 6
 Schists, A/299, C/191, K/86, 90, M/305, S/251, 299
 Geothermometry, A/666, K/256, 478, 480, R/176, S/185, W/93, 120
 Geothermobarometry, G/176, 210, K/271, O/19, Z/9

Mineralogy

Chalcopyrite, S/187, 189, 426
 Classification, A/583, P/85
 Microprobe, H/266, R/54, S/101
 Mineralogy, A/82, 93, 94, 170, 272, 275, 278, 279, 282, 283, 285, 286, 290, 348, 358, 371, 445, 523, 530, 537, 540, 621, 624, 625, 666, B/59, 64, 70, 202, 274, 342, C/69, 86, 98, 246, D/35, 93, 263, E/26, F/30, 32, 35, 81, 137, G/216, H/11, 36, J/1, 50, 72, 83, 145, J/106, 123, K/14, 15, 20, 82, 120, 150, 163, 191-194, 426, 449, L/32, 33, 110, M/31, 37, 114, 116, 139, 211, 214-217, 272, 284, N/20, 21, P/1, 47, Q/9, 11, 12, 13, R/27, 56, 184, S/184, 191-195, 202, 219, 294, 416, 423, 431, T/65, 69, 70, 73-77, 79-84, 109, W/55
 Ore microscopy, S/426
 Peimontite, J/123
 Plagioclase, T/79, 80, 83, 84, 87
 Pseudomorphs, S/298, 300
 Twinning, R/173, T/79, 80, 83, 84, 87

Palaeomagnetism/ Paleomagnetism

Magnetic minerals, K/97
 Palaeomagnetism/ Paleomagnetism, A/55, 126, 127, 128, 132, 133, 134, 135, 136, 137, 140, 350, 351, 401, 490, B/7, 142, 227, 228, J/166, 168, K/14, 175, 309, 310, 524, O/29, 30, 31, 32, R/156, S/361, Y/27, 29-31, 33, 34, 36, 38, 39, Z/17-28

Paleomagnetic data, K/525
Paleoposition, Z/21, 22, 23

Palaeontology/ Paleontology

Albian Echinodea, C/264
Algae, F/14
Ammonites, D/75, F/83, 84, 92
Ammonoidea, S/461, 462
Belemnite, K/562, N/60, S/462, 463
Biochemical, A/349
Biogeography, B/258, R/185, S/178
Bivalves, I/26
Brachiopods, A/467-472, 474, D/44, 45, M/297, 298, S/13, 533
Cambrian, A/52, 97
Cephalopods, C/247, 248, F/93, S/461, 463
Conodont, A/337, M/267, 268, 269, S/561, T/94, 95, 99
Corals, E/25, 141, G/95, 187, V/30
Early hominids, K/81, D/118
Early Proterozoic, D/256, 257
Elephant, S/57, 60, 61
Elephantoide, T/116
Eocene, B/226, 269, C/80, 189, /229, D/55, 56, 60, 246, M/16, 26, 28
Eocimmerian, B/230
Fauna, B/5, F/146, H/105, K/399, 401, L/100, M/153-155, N/19, 60, P/19, 20, S/110, 461
Foraminifera, A/334, C/183, B/333, D/65, H/58, 60, 251, K/485, 556-562, 566, M/312, S/40, Z/58
Fossil collection, B/108
Fossil plants, F/109
Fossiliferous limestone, D/197
Fossils, B/260, C/230, D/52, 53, 73, 97, 98, 162, 226, 230, F/168, G/157, 158, 168, 170, 171, 195, J/8, 12, K/516, M/160, 161, 201-203, 282, 296, O/20, P/21, 22, 67, 68, 120, Q/27, R/185, V/48, W/5, 76
Fusulinids, G/19
Gastropods, C/226, 228, E/4, I/26, V/61
Hercynian, B/230
Hominoids, B/139, K/534, P/73, 74, 75, 78, 79, 80, 82, R/114, S/266
Human Origin, D/116, 117
Hydroids, V/30
Indraloris, G/153
Invertebrates, C/230
Lamellibranchia, C/226, 228, E/3
Mamalia, T/135, 136, 137, 140
Mammal, A/526, B/166-168, 186, 257, 258, G/147-150, H/274, 279, J/15, L/101, M/282, P/64, 67, 68, 86, 88, S/50, 68, 71, 433, W/72, 78
Marine limestones, E/13
Marine sediments, R/93, P/87
Micropaleontology, A/225, 366, C/165, H/246, 251, K/101, 419, L/18, 20, 28, M/238, S/8
Mollusca, C/227, 229
Morphology, S/59, 62
Nerineids, R/197, 198
Orbitoids, V/60
Orthonautiloids, D/72
Ostracode, S/456-458
Ostrocode, L/6
Palaeogeography, C/219
Palaeontology, A/54, 69, 163, 394, 467, 477, 486, 545, 546, B/4, 103, 105, 107, 108, 111-113, 115, 116, 118, 141, 169, 184, 233, 248, 257, 259, 269, 300, C/42, 49, 84, 118, 166-168, 186, 226-229, 247, 248, 264, D/39, 48, 49, 54-56,

70, 72, 75, 96, 98, 99, 111, 115, 118, 166, 208, 265, 267, 272, E/4, 5, 42, F/6, 7, 82,84, 92, 131, 140, 141, 142, 143, 144, 145, 173, G/2, 145-151, 157, 167, 169-171, 187, 189, 195, H/58, 60, 103, 104, 106, 154, 158, 159, 160, 167, 272, 274, 277, 278, 279, I/3, 19, 23-27, J/11-18, 38, K/133, 134, 195, 516, 556-561, 564-566, 568, 485, L/16, 22, 83, 94-101, 124, M/109, 136, 160, 161, 267-269, 285, 288, N/8-10, 18, 60, P/64, 65, 68-75, 77-81, 83, 84, 86, 121, 137, 148, O/20, 33, Q/30, R/50, 88, 107-109, 112, 114, 127-131, 160, 185, 195-199, 205, 206, S/13, 38, 65, 433, 456-458, 521, 522, 530, 533, 561, T/88-95, 98, 99, 116, 132, 135-142, V/5, 11, 45, 48, 49, 50, 59, 60, 61, 62, 63, Y/12, 26, W/2, 26, 72, 75, 77, 78, 80, Z/58, 59

Palaeozoic/ Paleozoic, A/94, B/29, 356, 357, C/43, D/147, 197, 230, M/76

Paleoanthropology, S/268

Paleobotany, B/191

Paleocurrent, B/132, 215, S/363

Paleodrainage, B/244

Paleoecology, B/5, Q/28

Paleogene, B/331, D/129, W/73, 106

Paleogeography, B/156, G/50, K/158, 292, S/549, 552

Paleosols, A/627, B/234, Q/27, Y/35

Paleotectonic, G/50

Palynology, A/404, 448, B/58, M/238, T/156

Permian, B/58, 127, 233, 300, 365, D/265, 272, M/74, 204, 206, 207

Pholidote, P/65

Ranikot beds, D/51

Ranikothalia, B/332

Rodentia, D/96

Rodents, D/97, 98, F/144, H/275, J/11, 13, 16, 17, L/94-97, 99, W/76

Rudistids, R/197, 198

Scaphopoda, E/4

Sivaladapis, G/153

Taxonomy, S/55

Unionidae, V/51

Vertebrate paleontology, A/517, 518, 526, 528, 627, K/81, S/54-64, 66-73, W/79

Vertebrate, B/4, 105, 107, C/167, G/146, 147, 151, 152, 153, H/277-279, K/183, O/33, P/70-78, R/109, W/80

Petrography

Petrochemistry, A/91, B/72, H/184, M/228, 230, S/215

Petrogenesis, A/565, 571, 582, 584, 675, B/62, 73, C/163, F/94, H/27, I/36, K/36, 44, 166, 431, 432, 438, 481, L/39, O/19, P/53, 57, Q/43, R/21, 22, S/285, 316, T/68, Z/53, 72, 73

Petrography, A/48, 49, 50, 67, 80, 87, 83, 100, 104, 111, 126, 149, 197, 199, 201, 217, 322, 225, 284, 304, 358, 366, 394, 436, 542, 548, 549, 556, 673, 674, 675, 687, 689, B/9, 50, 72, 77, 78, 118, 119,343, 349, 353, 354, 359, C/77, 79, 88, 89, 97, 99, 102, 133, 134, 140, 142, 144, 150, 154, 160, 161, 164, 165, 174, 179, 192, 194, D/31, 66, 71, 83, 93, 215, 245, F/17, 23, 24, 132, G/132, 164, 180, 211, H/1, 22, 32, 44, 52, 56, 86, 181, 186, 198, 238, 241, 281, I/18, 41, J/38, 42, 44, 47, 49, 51-55, 78, 89, 144, K/8, 10, 17, 83, 101, 105, 106, 118, 144, 164, 229, 262, 313, 324, 355, 409, 410, 416, 419, 445, 446, 452, 454, 469, 470, 472, 493, 494, 526, 554, L/75, 109, M/7, 10, 12, 17, 23, 34, 42, 170, 261, 262, 272, 292, 309, N/39, P/46, 140, Q/17, 18, R/1, 5, 9, 15-17, 19, 20, 31, 59-67, 73, 81, 89, 122, 139, 143, 176, 186, 187, S/12, 33, 75, 165, 183, 202, 210, 211, 229, 248, 276, 285, 294, 295, 310, 337, 338, 343, 344, 356, 359, 402, 427, 465, 553, 555, 562, U/8, V/45, 46, Y/12, Z/50, 51, 52, 54, 55

Texture, B/202, K/101, S/189, 191, 192, W/2

Petrology

Orbicular rocks, S/563

Paragenesis, A/538, O/19

Pegmatite, A/277, 346, 368, 424, 436, 497, 498, 565, 567, 574, 580, 596, 634, 676-678, B/351, 362, C/94, H/92, J/115, 118, K/278, 282, 387, 421, L/37, 38, M/53, 121, N/1, 35, S/235, 276

Petrology, A/43, 71, 72, 76, 81, 82, 91, 92, 103, 125, 148, 184, 196, 203, 227, 232, 236, 246, 264, 276, 290, 296-300, 310, 322, 323, 328, 440, 441, 450, 523, 544, 548, 549, 551, 552, 566, 577, 590, 594, 596, 612, 614, 621, 665, 668, 669, 671, 673, 689, , B/2, 43, 44, 60, 81, 94, 96, 97, 99, 163, 164, 168, 194, 195, 218, 293, 294, 309, 355, 366, 372,

C/31, 50, 54, 65, 66, 69, 86, 90, 91, 94, 113, 115, 116, 132, 142, 152, 158, 249, G/102, 139, 163, 211, 216, F/20, 23, 94, H/16-21, 37, 43, 45, 81, 86, 171, 176, 189, 236, 239, 267, 288, I/4, 6, 12, 17, 31, 38, J/31, 35, 39, 50, 51, 57, 67, 84, 97, 103, 105, 115, 116, 126, 127, 145, K/17, 20, 30, 35, 38, 44, 83, 85, 87, 90, 94, 120, 163, 168, 199, 233, 234, 238, 243, 294, 295, 306, 327, 343, 352, 353, 371, 372, 380, 400, 426, 473, 517, 546, 547, L/32, 110, M/12, 21, 23, 31, 33, 123, 262, 290, 291, 307, N/21, 36, 39, P/51, 55, 59, 104, Q/1, 15, 16, 20, 39, 40, 42, R/9, 24, 25, 31, 38, 40, 70, 72, 74, 144, 149, S/82, 85, 184, 209, 216, 251, 272, 282, 285, 339, 340, 422, 427, 551, T/65, 66, 67, 78, 81, 82, 85, 126, U/3, 5, 9, Y/3, 15, 51, 52, 53, W/63, 64, 118, 119, Z/5, 36, 49, 53, 54, 62
Zoned pegmatite, A/572, L/39

Sedimentology/ Sedimentary rocks

Aggradation, B/280
Basin configuration, C/189
Basin evolution, B/244, P/109, 113
Break-out flood sediments, C/197
Calcareous Quartz, H/238
Calcareous schists, C/146
Calcareous, C/97
Deposition, A/300, 301, 309-312, 316, 404, C/84, 114, 182, D/278, J/165
Depositional environments, M/192, 208, P/108, 109, S/273-275, 366
Detrital sediments, C/89
Dhok Pathan Formation, A/23, S/89
Diamictation, D/128, K/322, O/44, 47, R/77
Diaspore, A/604
Evaporites, J/169, L/24, R/172
Facies change, G/44, 45
Facies, C/143, L/30, S/482, 513
Fluviatile deposits, K/173
Giumal sandstone, M/75
Greywacke, M/41
Gypsum, H/271, M/113, R/119, S/225, 466, W/21
Heavy minerals, A/29, 358, B/144, 176, C/45, 210, D/239, 240, J/34, K/338, R/83, S/166, 167, 223, 403, 416, 524, 529
Intermontane basin, B/276, 277, 285, O/49, 50
Jurassic, A/191, C/80, 84, 114, 219, 228, D/44, 45
Kawagarh Formation, A/306, 309, 315, 316, 318, B/329, C/73, 108, 147, M/26, S/40
Kuldana Formation, C/189, D/245, 246, R/72, W/72
Lacustrine basin, B/220
Lacustrine deposits, C/197, D/35, 268
Lake Sediments, H/42
Langrial limestone, B/48
Limestone, A/163, 213, 303, 304, 317, 357, 383, 431, 554, B/103, C/83, 200, D/72, 243, E/26, 38, 50, 81, G/160, H/176, 194, 201, 203, 204, I/30, J/140, K/223, 369, 378, L/9, 13, 15, 18, M/112, N/23, P/44, 98, R/79, S/76, 197, 402, 420, T/121, 122, W/1, 2, 21
Lithification, M/111
Lithofacies, A/247, 303, 404, Q/52, R/110, S/177, 179-181
Lithology, A/228, 443, 484, 569, C/179, D/233, 236, E/18, F/18, 135, G/51, 157, H/290, J/34, K/131, 226, 228, 322, L/33, M/15, 100, 128, 186, R/134, 181, 183, 184, S/37, 358, 559, T/1, 8, 12-14
Lithostratigraphy, A/188, 453, 478, F/85, 87, M/312, 313, S/178, W/95
Lithostructure, A/319, 675, 685, C/151, G/162, 164, K/13, 166, 230, 237, M/16, 28, Q/34, R/86, 120, 134, S/455
Lockhart Limestone, A/311, M/16, 28, R/71
Loess deposits, K/464, N/53-55, R/157, 158, 159, S/431, Y/28, Z/1
Lumshiwal Formation, A/307, 310, 404, C/76, 77, 141, 143, M/192, N/2, R/62, 73
Microfacies, A/301, 306, 309, 314, 315, 334, 404, 431, B/48, C/73, 84, 143, 147, 182, 184, D/278, J/140, M/13, 195-197, 292, Q/63, R/62, 81, 152, 204, S/278, 279, 368, 369
Miranjani limestone, C/171

Murree Formation, B/45, 47, 226, D/97, 98, C/90, 109, 110, 156, M/48, 49, R/120
 Murree red beds, C/189, 250
 Permeability, A/116
 Porosity, A/116, M/308
 Potash, J/169
 Reef Complex, A/390, 391, B/103, 138, G/43, K/227, 229, 490, M/315, P/120, S/522, 555, T/121, 122
 Samana Suk Formation, M/110, 111, R/88, S/369
 Sandstone, A/49, 50, B/89, 360, C/47, 88, 132, 249, F/19, 166, G/50, J/45, K/168, 289, M/253, P/105, Q/53, R/75, 79, 92, S/402, W/1
 Sediment transport, B/147, C/188
 Sedimentary basin, R/97
 Sedimentary cover, Z/36, 38, 39
 Sedimentary dykes, H/42
 Sedimentary Facies, A/12, 306, 311, 312, 314, 318
 Sedimentary petrography, B/138, K/166, M/191
 Sedimentary petrology, D/263, 270, N/50, Q/54, R/151, S/280
 Sedimentary rocks, D/259, G/9, H/6, 183, 240, J/30, M/309, W/21
 Sedimentary sequence, M/204
 Sedimentary zones, R/103
 Sedimentary, B/127, C/43, 59
 Sedimentation, B/290, C/108, G/6, 7, 17, 118, G/12, 17, 24, J/162, K/179-181, 195, 196, 308-311, L/83, N/46, O/18, 27, 39, 40, 49, P/110, 143, R/93, 157-159, S/362, W/71, 107
 Sedimentology A/11, 18, 20, 22, 25, 26, 36, 152, 154, 153, 198, 200, 302, 307, 379, 431, 448, 594, 674, B/19, 21, 143, 204, 243, 245, C/67, 75, 76, 80, 83, 100, 114, 141, 148, 149, 156, 171, D/119, F/19, G/4, 47, H/235, 290, I/2, J/165, K/144, 169, 172, 183, 227, 229, 237, 335, 464, M/16, 28, N/2, 13, 51, O/46, 50, P/105, 107, Q/51, 56, 64, R/120, S/280, 549, 552, 555, V/40, W/49, 50
 Sediments, B/5, 144, 279, 281, 299, C/163, F/24, F/112, G/36, H/8, 121, 273, 280, I/40, J/160, K/285, M/45, P/15, 45, 76, 148, R/145, S/18, S/115, 394, T/104, 106, 111, 117, W/38, 39
 Skarns, A/600, K/32, 34, 37, 94, M/55, S/294
 Stream sediments, K/114, 115, S/52, 166, 206, 212, 214, 524
 Tilloid, K/84, 85, T/102, 103
 Turbidites, K/444, 448

Seismology/Earthquakes/Neotectonics

Decollement, S/145
 Earthquake, A/47, 68, 107, 238, 321, 446, 447, B/39-41, 93, 193, 320, C/175, 60, 61, 64, D/46, E/24, 133, G/177, H/168, J/5, 7-9, K/48, 49, 205, 488, P/41, 128, S/157, 401, T/101, Y/18, 24
 Neotectonics, B/93, 192, 323, K/50, 51, 383, M/3, 4, O/41, S/83, 84, T/188, 189, Y/17
